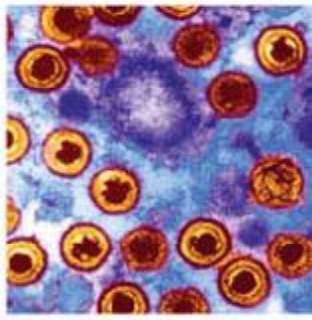
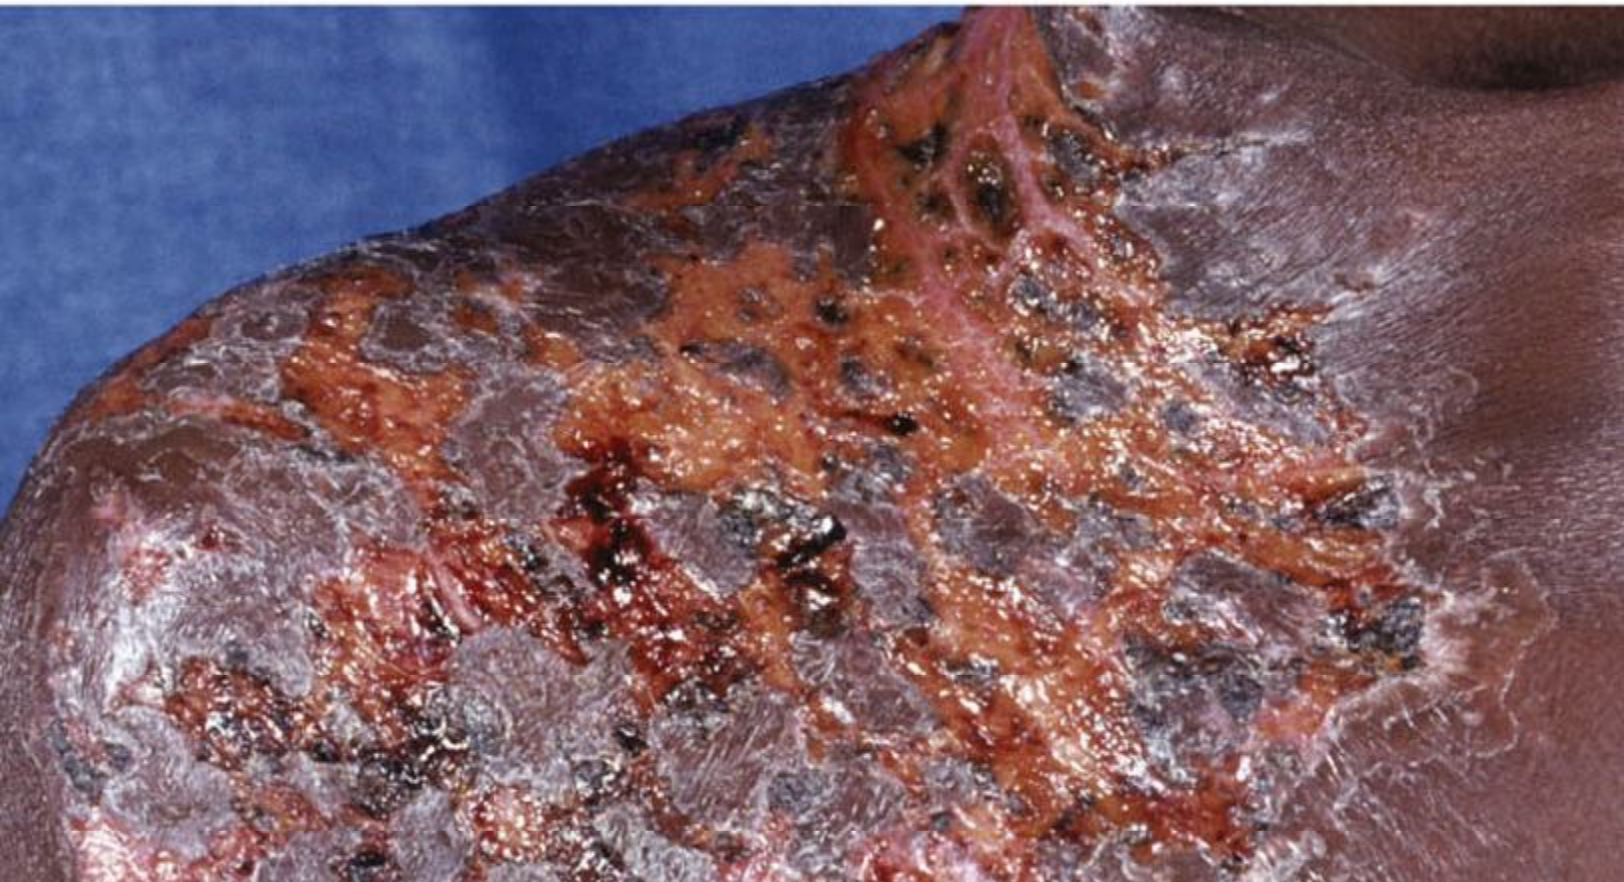
Seventh Edition
Volumes 1 & 2

Fitzpatrick's DERMATOLOGY IN GENERAL MEDICINE



KLAUS WOLFF • LOWELL A. GOLDSMITH
STEPHEN I. KATZ • BARBARA A. GILCHREST
AMY S. PALLER • DAVID J. LEFFELL



Fitzpatrick's Dermatology in General Medicine

SEVENTH EDITION

KLAUS WOLFF, MD, FRCP
Professor of Dermatology
Chairman Emeritus
Department of Dermatology
Medical University of Vienna
Vienna, Austria

LOWELL A. GOLDSMITH, MD
Professor of Dermatology
University of North Carolina School of Medicine
Chapel Hill, North Carolina
Dean Emeritus
University of Rochester School of Medicine and Dentistry
Rochester, New York

STEPHEN I. KATZ, MD, PHD
Director, National Institute of Arthritis and Musculoskeletal and Skin Diseases
National Institutes of Health
Bethesda, Maryland

BARBARA A. GILCHREST, MD
Professor and Chair of Dermatology
Department of Dermatology
Boston University School of Medicine
Boston, Massachusetts

AMY S. PALLER, MD
Walter J. Hamlin Professor and Chair of Dermatology
Professor of Pediatrics
Feinberg School of Medicine
Northwestern University
Chicago, Illinois

DAVID J. LEFFELL, MD
Professor of Dermatology and Surgery
Chief, Section of Dermatologic Surgery and Cutaneous Oncology
Department of Dermatology
Yale University School of Medicine
New Haven, Connecticut

DEDICATION

This Seventh Edition of *Fitzpatrick's Dermatology in General Medicine* is dedicated to the memory of two innovators in the field, whose visionary approach to dermatology is reflected throughout:

Thomas B. Fitzpatrick, MD, PhD
and
Irwin M. Freedberg, MD

Dr. Fitzpatrick (d. 2003) was Wigglesworth Professor of Dermatology Emeritus at Harvard Medical School, and the Founder of DIGM as well as its Editor-in-Chief for the first four editions.

Dr. Freedberg (d. 2006) was the George Miller MacKee Professor of Dermatology, New York University Medical Center, and the Editor-in-Chief for the fifth and sixth editions and led the book to new heights.

CONTENTS

Contributors xvii
Preface xxxiii
Acknowledgments xxxv

Volume One

PART 1 1

INTRODUCTION

SECTION 1. General Considerations 3

1 The Epidemiology and Burden of Skin Disease 3
Martin A. Weinstock, MD, PhD, and Mary-Margaret Chren, MD

2 Evidence-Based Dermatology 8
Michael Bigby, MD, Rosamaria Corona, DSc, MD, and Moyses Szklo, MD, MPH, DrPH

3 Public Health in Dermatology 18
Hywel C. Williams, MSc, PhD, FRCP, Sinéad Langan, MRCP, and Carsten Flohr, MRCPCH

SECTION 2: Approach to Dermatologic Diagnosis 23

4 Structure of Skin Lesions and Fundamentals of Clinical Diagnosis 23
Amit Garg, MD, Nikki A. Levin, MD, PhD, and Jeffrey D. Bernhard, MD

5 Diagnostic Procedures and Devices 40
Alon Scope, MD, and Allan C. Halpern, MD

6 Basic Pathologic Reactions of the Skin 43
Martin C. Mihm, Jr., MD, Abdul-Ghani Kibbi, MD, FACP, and Klaus Wolff, MD, FRCP

SECTION 3: Overview of Biology, Development, and Structure of Skin 57

7 Development and Structure of Skin 57
David H. Chu, MD, PhD

8 Genetics in Relation to the Skin 73
John A. McGrath, MD, and W. H. Irwin McLean, MD

9 Basic Science Approaches to the Pathophysiology of Skin Disease 87
Paul R. Bergstresser, MD

PART 2 93

DISORDERS PRESENTING IN SKIN AND MUCOUS MEMBRANES

SECTION 4. Inflammatory Disorders Based on T-Cell Reactivity and Dysregulation 95

10 Innate and Adaptive Immunity in the Skin 95
Robert L. Modlin, MD, Jenny Kim, MD, PhD, Dieter Maurer, MD, Christine Bangert, MD, and Georg Stingl, MD

11 Cytokines 115
Ifor R. Williams, MD, PhD, Benjamin E. Rich, PhD, and Thomas S. Kupper, MD

12 Chemokines 127
Sam T. Hwang, MD, PhD

13 Allergic Contact Dermatitis 135
David E. Cohen, MD, MPH, and Sharon E. Jacob, MD

14 Atopic Dermatitis (Atopic Eczema) 146
Donald Y. M. Leung, MD, PhD, Lawrence F. Eichenfield, MD, and Mark Boguniewicz, MD

15 Nummular Eczema and Lichen Simplex Chronicus/Prurigo Nodularis 158
Susan Burgin, MD

16 Vesicular Palmoplantar Eczema 162
Daven N. Doshi, MD, and Alexa B. Kimball, MD, MPH

17 Autosensitization Dermatitis 167
Donald V. Belsito, MD

18 Psoriasis 169
Johann E. Gudjonsson, MD, PhD, and James T. Elder, MD

19 Psoriatic Arthritis 194
Robert Winchester, MD

20 Reactive Arthritis 207
Andrew Keat, MD

21 Pustular Eruptions of Palms and Soles 215
Ulrich Mrowietz, MD

22 Seborrheic Dermatitis 219
Gerd Plewig, MD, and Thomas Jansen, MD

23 Exfoliative Dermatitis 225
Jane Margaret Grant-Kels, MD, Megan L. Bernstein, MD, and Marti J. Rothe, MD

24 Pityriasis Rubra Pilaris 232
Daniela Bruch-Gerharz, MD, and Thomas Ruzicka, MD

25 Parapsoriasis and Pityriasis Lichenoides 236
Gary S. Wood, MD, Chung-Hong Hu, MD, and Andrea L. Garrett, MD

26 Lichen Planus 244
Mark R. Pittelkow, MD, and Mazen S. Daoud, MD

27 Lichen Nitidus 255
Mark R. Pittelkow, MD, and Mazen S. Daoud, MD

28 Graft-Versus-Host Disease 258
Misty T. Sharp, MD, and Thomas D. Horn, MD

29 Skin Disease in Acute and Chronic Immunosuppression 267
Lynda Kauls, MD, and Andrew Blauvelt, MD

SECTION 5. Inflammatory Diseases Based on Neutrophils and Eosinophils 279

30 Regulation of the Production and Activation of Neutrophils and Eosinophils 279
Steven M. Holland, MD, James Loveless, MD, and Lisa A. Beck, MD

31 Acute Febrile Neutrophilic Dermatosis (Sweet Syndrome) 289
Philip R. Cohen, MD, Herbert Hönigsmann, MD, and Razelle Kurzrock, MD, FACP

32 Pyoderma Gangrenosum 296
Frank C. Powell, MD, and Bridget C. Hackett, MRCPI

33 Granuloma Faciale 302
Darius R. Mehregan, MD, and David A. Mehregan, MD

34 Sub-Corneal Pustular Dermatosis (Sneddon-Wilkinson Disease) 305
Franz Trautinger, MD, and Herbert Hönigsmann, MD

35 Eosinophils in Cutaneous Diseases 307
Kristin M. Leiferman, MD, and Margot S. Peters, MD

SECTION 6. Inflammatory Diseases Based on Abnormal Humoral Reactivity and Other Inflammatory Diseases 319

36 Humoral Immunity and Complement 319
Lela A. Lee, MD

37 Urticaria and Angioedema 330
Allen P. Kaplan, MD

38 Erythema Multiforme 343
Jean-Claude Roujeau, MD

39 Epidermal Necrolysis (Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis) 349
L. Valeyrie-Allanore, MD, and Jean-Claude Roujeau, MD

40 Cutaneous Reactions to Drugs 355
Neil H. Shear, MD, Sandra R. Knowles, BScPhm, and Lori Shapiro, MD

41 Pityriasis Rosea 362
Andrew Blauvelt, MD

42 Erythema Annulare Centrifugum and Other Figurate Erythemas 366
Walter H. C. Burgdorf, MD

43 Granuloma Annulare 369
Julie S. Prendiville, MD, MRCPI, FRCPC

SECTION 7. Disorders of Epidermal Differentiation and Keratinization 375

44 Epidermal Growth and Differentiation 375
Stanley J. Miller, MD, Tung-Tien Sun, MD, and Pierre A. Coulombe, PhD

45 Skin as an Organ of Protection 383
Ehrhardt Proksch, MD, PhD, and Jens-Michael Jensen, MD

46 Irritant Contact Dermatitis 395
Antoine Amado, MD, James S. Taylor, MD, and Apra Sood, MD

47 The Ichthyoses 401
Philip Fleckman, MD, and John J. DiGiovanna, MD

48 Inherited Keratodermas of Palms and Soles 424
David P. Kelsell, MD, and Irene M. Leigh, MD

49 Acantholytic Disorders of the Skin: Darier-White Disease, Acrokeratosis Verruciformis, Grover Disease, and Hailey-Hailey Disease 432
Alain Hovnanian, MD, PhD

50 Porokeratosis 442
Grainne M. O'Regan, MRCPI, and Alan D. Irvine, MD, FRCPI, MRCP

SECTION 8. Disorders of Epidermal and Dermal-Epidermal Cohesion and Vesicular and Bullous Disorders 447

51 Epidermal and Epidermal-Dermal Cohesion 447
Leena Bruckner-Tuderman, MD, and John R. Stanley, MD

52 Pemphigus 459
John R. Stanley, MD

53 Paraneoplastic Pemphigus 468
Grant J. Anhalt, MD, and Carlos H. Nousari, MD

54 Bullous Pemphigoid 475
John R. Stanley, MD

55 Cicatricial Pemphigoid 481
Kim B. Yancey, MD

56 Linear Immunoglobulin A Dermatosis and Chronic Bullous Disease of Childhood 485
Caroline L. Rao, MD, and Russell P. Hall III, MD

57 Pemphigoid Gestationis (Herpes Gestationis) 490
Jeff K. Shornick, MD, MHA

58 Epidermolysis Bullosa Acquisita 494
David T. Woodley, MD, and Mei Chen, PhD

59 Dermatitis Herpetiformis 500
Russell P. Hall III, MD, and Stephen I. Katz, MD, PhD

60 Inherited Epidermolysis Bullosa 505
M. Peter Marinkovich, MD, and Eugene A. Bauer, MD

SECTION 9. Disorders of the Dermal Connective Tissue 517

61 Collagen, Elastic Fibers, and Extracellular Matrix of the Dermis 517
Jouni Uitto, MD, PhD, Mon-Li Chu, PhD, Richard Gallo, MD, PhD, and Arthur Z. Eisen, MD

62 Morphea 543
Vincent Falanga, MD, FACP, and Christina E. Killoran, MD

63 Lichen Sclerosus 546
Ulrich R. Hengge, MD

64 Dermal Hypertrophies 550
Mandy Harting, MD, M. John Hicks, MD, DDS, PhD, and Moise L. Levy, MD

65 Anetoderma and Other Atrophic Disorders of the Skin 557
Catherine Maari, MD, and Julie Powell, MD

66 Constricting Bands (Ainhum and Pseudoainhum) 562
Robert T. Brodell, MD, and Stephen E. Helms, MD

67 Acquired Perforating Disorders 564
Mark Lebwohl, MD

SECTION 10. Disorders of Subcutaneous Tissue 569

68 Panniculitis 569
Luis Requena, MD, Evaristo Sánchez Yus, MD, and Heinz Kutzner, MD

69 Lipodystrophy 585
Meredith P. Sheedy, MD, and Sarah A. Myers, MD

SECTION 11. Disorders of Melanocytes 591

70 Biology of Melanocytes 591
Hee-Young Park, PhD, Marinya Pongpudpunth, MD, Jin Lee, MD, MBA, and Mina Yaar, MD

71 Albinism and Other Genetic Disorders of Pigmentation 608
Thomas J. Hornyak, MD, PhD

72 Vitiligo 616
Rebat M. Halder, MD, and Sumayah J. Taliaferro, MD

73 Hypomelanoses and Hypermelanoses 622
Hilde Lapeere, MD, Barbara Boone, MD, Sofie De Schepper, MD, Evelien Verhaeghe, MD, Katia Ongenae, MD, PhD, Nanja Van Geel, MD, PhD, Jo Lambert, MD, PhD, Lieve Brochez, MD, PhD, and Jean-Marie Naeyaert, MD, PhD

SECTION 12. Disorders of the Oral and Genital Integument 641

74 Biology and Pathology of the Oral Cavity 641
Ginat Wintermeyer Mirowski, DMD, MD, and Eva Rawlings Parker, MD

75 Diseases and Disorders of the Male Genitalia 654
Christopher Barry Bunker, MA, MD, FRCP

76 Diseases and Disorders of the Female Genitalia 675
Rochelle R. Torgerson, MD, PhD, and Libby Edwards, MD

PART 3 685

DISORDERS OF THE SKIN APPENDAGES

SECTION 13. Disorders of the Sebaceous Glands 687

77 Biology of Sebaceous Glands 687
Amanda M. Nelson, PhD, and Diane M. Thiboutot, MD

78 Acne Vulgaris and Acneiform Eruptions 690
Andrea L. Zaenglein, MD, Emmy M. Graber, MD, Diane M. Thiboutot, MD, and John S. Strauss, MD

79 Rosacea 703
Michelle T. Pelle, MD

80 Perioral Dermatitis 709
Sarah L. Chamlin, MD, and Leslie P. Lawley, MD

SECTION 14. Disorders of the Eccrine and Apocrine Glands 713

81 Biology of Eccrine, Apocrine, and Apoeccrine Sweat Glands 713
Theodora M. Mauro, MD, and Lowell A. Goldsmith, MD

82 Disorders of the Eccrine Sweat Glands and Sweating 720
Robert D. Fealey, MD, and Kenzo Sato, MD, PhD

83 Disorders of the Apocrine Sweat Glands 731
Marni C. Wiseman, MD, FRCPC

SECTION 15. Disorders of the Hair and Nails 739

84 Biology of Hair Follicles 739
George Cotsarelis, MD, and Vladimir Botchkarev, MD, PhD

85 Keratosis Pilaris and Other Inflammatory Follicular Keratotic Syndromes 749
Maureen Rogers, MD

86 Hair Growth Disorders 753
Ralf Paus, MD, Elise A. Olsen, MD, and Andrew G. Messenger, MD

87 Biology of Nails and Nail Disorders 778
Antonella Tosti, MD, and Bianca Maria Piraccini, MD

PART 4 795

DISORDERS DUE TO THE ENVIRONMENT

SECTION 16: Disorders Due to Ultraviolet Radiation 797

88 Fundamentals of Cutaneous Photobiology and Photoimmunology 797
Irene E. Kochevar, PhD, Charles R. Taylor, MD, and Jean Krutmann, MD

89 Acute and Chronic Effects of Ultraviolet Radiation on the Skin 809
Antony R. Young, PhD, and Susan L. Walker, PhD

90 Abnormal Responses to Ultraviolet Radiation: Idiopathic, Probably Immunologic, and Photo-Exacerbated 816
John L. M. Hawk, MD, and James Ferguson, MD

91 Abnormal Responses to Ultraviolet Radiation: Photosensitivity Induced by Exogenous Agents 828
Henry W. Lim, MD

SECTION 17. Skin Changes Due to Other Physical and Chemical Factors 835

92 Thermoregulation 835
Dean L. Kellogg, Jr., MD, PhD

93 Cold Injuries 844
Gérald E. Piérard, MD, PhD, Frédérique Henry, MD, and Claudine Piérard-Franchimont, MD, PhD

94 Thermal Injuries 852
Robert L. Sheridan, MD

95 Radiobiology and Radiation Effects 858
Frederick D. Malkinson, MD, and Renato G. Panizzon, MD

96 Skin Problems in Amputees and Ostomates . . . 862
Calum C. Lyon, FRCP, MB BChir, and Michael H. Beck, FCRP, MB ChB

97 Corns and Calluses 871
Thomas M. DeLauro, DPM, and Nicole M. DeLauro, DPM

98 Sports Dermatology 873
Dirk M. Elston, MD

99 Decubitus (Pressure) Ulcers 878
Tania J. Phillips, MD, and Lilian M. Odo, MD

100 Body Art 886
Anne Laumann, MB ChB, MRCP

PART 5 893

NEUROCUTANEOUS AND PSYCHOCUTANEOUS ASPECTS OF SKIN DISEASE

SECTION 18. Neurocutaneous and Psychocutaneous Skin Disease 895

101 Neurobiology of the Skin 895
Martin Steinhoff, MD, PhD, and Thomas A. Luger, MD

102 Pathophysiology and Clinical Aspects of Pruritus 902
Gil Yosipovitch, MD, Aerlyn G. Dawn, MD, MBA, and Malcolm W. Greaves, MD, PhD, FRCP

103 Psychocutaneous Diseases 912
Andrea Sandoz, MD, Thomas Koenig, MD, Daniel Kusnir, MD, and Francisco A. Tausk, MD

104 Cutaneous Manifestations of Drug Abuse 921
Miguel R. Sanchez, MD

105 Skin Signs of Physical Abuse 927
Howard Pride, MD

PART 6 933

SKIN CHANGES ACROSS THE SPAN OF LIFE

SECTION 19. From Birth to Old Age 935

106 Neonatal, Pediatric, and Adolescent Dermatology 935
Mary Wu Chang, MD, and Seth J. Orlow, MD, PhD

107 Skin Changes and Diseases in Pregnancy 955
Julie K. Karen, MD, and Miriam Keltz Pomeranz, MD

108 Aging of Skin 963
Mina Yaar, MD, and Barbara A. Gilchrest, MD

PART 7 975

NEOPLASIA

SECTION 20. Carcinogenesis 977

109 Genome Instability, DNA Repair, and Cancer 977
Kenneth H. Kraemer, MD, and Thomas M. Rünger, MD

110 Carcinogenesis: Chemical 986
Andrzej A. Dlugosz, MD, and Stuart H. Yuspa, MD

111 Oncogenes, Tumor Suppressor Genes, and Viral Carcinogenesis 995
Nicole Basset-Séguin, MD, Celeste Lebbé, MD, Charlotte Proby, MD, and Alan Storey, MD

112 Carcinogenesis: Ultraviolet Radiation 999
Douglas E. Brash, PhD, Timothy Heffernan, PhD, and Paul Nghiem, MD, PhD

SECTION 21. Epidermal and Appendageal Tumors 1007

113 Epithelial Precancerous Lesions 1007
Karynne O. Duncan, MD, John K. Geisse, MD, and David J. Leffell, MD

114 Squamous Cell Carcinoma 1028
Douglas Grossman, MD, PhD, and David J. Leffell, MD

115 Basal Cell Carcinoma 1036
John A. Carucci, MD, and David J. Leffell, MD

116 Basal Cell Nevus Syndrome 1042
Anthony E. Oro, MD, PhD

117 Keratoacanthoma 1049
Lorenzo Cerroni, MD, and Helmut Kerl, MD

118 Benign Epithelial Tumors, Hamartomas, and Hyperplasias 1054
Valencia D. Thomas, MD, Neil A. Swanson, MD, and Ken K. Lee, MD

119 Appendage Tumors and Hamartomas of the Skin 1068
R. Stan Taylor, MD, Jennifer B. Perone, MD, Steven Kaddu, MD, and Helmut Kerl, MD

120 Merkel Cell Carcinoma 1087
Paul Nghiem, MD, PhD, and Natalia Jaimes, MD

121 Mammary and Extramammary Paget Disease 1094
Isaac M. Neuhaus, MD, and Roy C. Grekin, MD

SECTION 22. Melanocytic Tumors 1099

122 Benign Neoplasias and Hyperplasias of Melanocytes 1099
James M. Grichnik, MD, PhD, Arthur R. Rhodes, MD, MPH, and Arthur J. Sober, MD

123 Atypical Melanocytic Nevi 1122
Margaret A. Tucker, MD

124 Cutaneous Melanoma 1134
Sandra C. Paek, MD, Arthur J. Sober, MD, Hensin Tsao, MD, PhD, Martin C. Mihm, Jr., MD, and Timothy M. Johnson, MD

SECTION 23. Tumors and Hyperplasias of the Dermis and Subcutaneous Fat 1159

125 Malignant Fibrous Tumors of the Dermis 1159
Jennifer Z. Cooper, MD, and Marc D. Brown, MD

126 Vascular Tumors 1164
Tara Miller, MD, and Ilona J. Frieden, MD

127 Neoplasias and Hyperplasias of Muscular and Neural Origin 1172
Lucile E. White, MD, Ross M. Levy, MD, and Murad Alam, MD

128 Kaposi Sarcoma 1183
Erwin Tschachler, MD

129 Neoplasms of Subcutaneous Fat 1190
Thomas Brenn, MD, PhD

Volume Two

PART 8 1199

THE SKIN IN SYSTEMIC DISEASE

SECTION 24. Skin in Nutritional, Metabolic, and Heritable Disease 1201

130 Cutaneous Changes in Nutritional Disease 1201
Melinda Jen, MD, Kara N. Shah, MD, PhD, FAAP, and Albert C. Yan, MD

131 Cutaneous Changes in Errors of Amino Acid Metabolism 1219
Peter H. Itin, MD, and Lowell A. Goldsmith, MD

132 The Porphyrias 1228
David R. Bickers, MD, and Jorge Frank, MD

133 Amyloidosis and the Skin 1257
Helen J. Lachmann, MD, and Philip N. Hawkins, MD

134 Systemic Autoinflammatory Diseases 1265
John G. Ryan, MB, MRCPI, and Daniel L. Kastner, MD

135 Xanthomatoses and Lipoprotein Disorders 1272
Lucile E. White, MD

136 Fabry Disease 1281
Margarita M. Larralde, MD, and Paula C. Luna, MD

137 Lipoid Proteinosis 1288
Jonathan A. Dyer, MD

138 Cutaneous Mineralization and Ossification 1293
John S. Walsh, MD, and Janet A. Fairley, MD

139 Heritable Disorders of Connective Tissue with Skin Changes 1297
Mario E. Lacouture, MD, and Amy S. Paller, MD

140 Hereditary Disorders of Genome Instability and DNA Repair 1311
Thomas M. Rünger, MD, John J. DiGiovanna, MD, and Kenneth H. Kraemer, MD

141 Tuberous Sclerosis Complex 1325
Thomas N. Darling, MD, PhD

142 The Neurofibromatoses 1331
Robert Listernick, MD, and Joel Charrow, MD

143 Ectodermal Dysplasias 1339
Virginia P. Sybert, MD

144 Genetic Immunodeficiency Diseases 1348
Amy S. Paller, MD, and Melissa Abrams, MD

SECTION 25. Skin Manifestations of Bone Marrow and Blood Disorders 1373

145 Hematologic Diseases 1373
Bina A. Rashid, MD, Elizabeth Bahar Houshmand, MD, and Michael P. Heffernan, MD

146 Cutaneous Lymphoma 1386
Chalid Assaf, MD, and Wolfram Sterry, MD

147 Inflammatory Diseases That Simulate Lymphomas: Cutaneous Pseudolymphomas 1402
Gary S. Wood, MD

148 Langerhans Cell Histiocytosis 1414
Ruggero Caputo, MD, and Carlo Gelmetti, MD

149 Non–Langerhans Cell Histiocytosis 1424
Carlo Gelmetti, MD, and Ruggero Caputo, MD

150 Biology of Mast Cells and the Mastocytosis Syndromes 1434
Melody C. Carter, MD, and Dean D. Metcalfe, MD

SECTION 26. Skin Manifestations of Internal Organ Disorders 1445

151 The Skin and Disorders of the Alimentary Tract, the Hepatobiliary System, Kidney, and Cardiopulmonary System 1445
Graham A. Johnston, MB ChB, FRCP, and Robin A. C. Graham-Brown, MD

152 Diabetes Mellitus and Other Endocrine Diseases 1461
Andrea A. Kalus, MD, Andy J. Chien, MD, PhD, and John E. Olerud, MD

153 Sarcoidosis 1484
Richard M. Marchell, MD, Bruce Thiers, MD, and Marc A. Judson, MD

154 Cutaneous Manifestations of Internal Malignant Disease: Cutaneous Paraneoplastic Syndromes 1493
Christine A. DeWitt, MD, Lucinda S. Buescher, MD, and Stephen P. Stone, MD

SECTION 27. The Skin in Vascular and Connective Tissue and Other Autoimmune Disorders 1509

155 Mechanisms of Autoimmune Disease 1509
Insoo Kang, MD, and Joe Craft, MD

156 Lupus Erythematosus 1515
Melissa I. Costner, MD, and Richard D. Sontheimer, MD

157 Dermatomyositis 1536
Richard D. Sontheimer, MD, and Melissa I. Costner, MD

158 Scleroderma (Systemic Sclerosis) 1553
Christopher P. Denton, MD, and Carol M. Black, MD

159 Scleredema and Scleromyxedema 1562
Roger H. Weenig, MD, MPH, and Mark R. Pittelkow, MD

160 Relapsing Polychondritis 1567
Camille Frances, MD

161 Rheumatoid Arthritis, Rheumatic Fever, and Gout 1569
Christina L. Haverstock, MD, MS, and Joseph L. Jorizzo, MD

162 Sjögren Syndrome 1577
Stamatina Danielides, MD, and Gabor Illei, MD

SECTION 28. The Skin in Inflammatory and Other Vascular Disorders 1585

163 Endothelium in Inflammation and Angiogenesis 1585
Peter Petzelbauer, MD, Lisan S. Peng, MD, and Jordan S. Pober, MD

164 Cutaneous Necrotizing Venulitis 1599
Nicholas A. Soter, MD, and Jose L. Diaz-Perez, MD

165 Systemic Necrotizing Vasculitis 1606
Carmen E. Gota, MD, and Brian F. Mandell, MD, PhD, FACR

166 Erythema Elevatum Diutinum 1616
Nneka I. Comfere, MD, and Lawrence E. Gibson, MD

167 Adamantiades-Behçet Disease 1620
Christos C. Zouboulis, MD, PhD

168 Kawasaki Syndrome 1626
Donald Y. M. Leung, MD, PhD, H. Cody Meissner, MD, and Anne W. Lucky, MD

169 Pigmented Purpuric Dermatoses 1633
Theresa Schroeder-Devere, MD

170 Cryoglobulinemia and Cryofibrinogenemia 1637
Milan J. Anadkat, MD, Lynn A. Cornelius, MD, and Thomas J. Lawley, MD

171 Raynaud Phenomenon 1643
John H. Klippel, MD

172 Malignant Atrophic Papulosis (Degos Disease) 1648
Dan Lipsker, MD, PhD, and Jean-Hilaire Saurat, MD

173 Vascular Malformations 1651
Laurence M. Boon, MD, PhD, and Miikka Vikkula, MD, PhD

174 Cutaneous Changes in Peripheral Vascular Arterial Disease 1667
Mandeep Dhadly, MD, FACC, Steven M. Dean, DO, FACP, and Robert T. Eberhardt, MD

175 Cutaneous Changes in Venous and Lymphatic Insufficiency 1679
Claude S. Burton, MD, Craig N. Burkhart, MD, and Lowell A. Goldsmith, MD

PART 9 1687

DISEASE DUE TO MICROBIAL AGENTS, INFESTATIONS, BITES, AND STINGS

SECTION 29: Bacterial Disease 1689

176 General Considerations of Bacterial Diseases 1689
Timothy G. Berger, MD

177 Superficial Cutaneous Infections and Pyodermas 1694
Noah Craft, MD, PhD, Peter K. Lee, MD, PhD, Matthew T. Zipoli, MD, Arnold N. Weinberg, MD, Morton N. Swartz, MD, and Richard Allen Johnson, MD

178 Gram-Positive Infections Associated with Toxin Production 1710
Jeffrey B. Travers, MD, PhD, and Nico Mousdicas, MD

179 Soft-Tissue Infections: Erysipelas, Cellulitis, Gangrenous Cellulitis, and Myonecrosis 1720
Arturo Saavedra, MD, PhD, Arnold N. Weinberg, MD, Morton N. Swartz, MD, and Richard Allen Johnson, MD

180 Gram-Negative Coccal and Bacillary Infections 1731
Morton N. Swartz, MD

181 The Skin in Infective Endocarditis, Sepsis, Septic Shock, and Disseminated Intravascular Coagulation 1744
Laura Korb Ferris, MD, PhD, and Joseph C. English III, MD

182 Bartonellosis 1749
Timothy G. Berger, MD, and Francisco G. Bravo, MD

183 Miscellaneous Bacterial Infections with Cutaneous Manifestations 1755
Scott A. Norton, MD, MPH

184 Tuberculosis and Infections with Atypical Mycobacteria 1768
Gerhard Tappeiner, MD

185 Actinomycosis, Nocardiosis, and Actinomycetoma 1778
Francisco G. Bravo, MD, Roberto Arenas, MD, and Daniel Asz Sigall, MD

186 Leprosy 1786
Thomas H. Rea, MD, and Robert L. Modlin, MD

187 Lyme Borreliosis 1797
Meera Mahalingam, MD, PhD, FRCPath, Jag Bhawan, MD, Anne-Marie Chomat, MD, and Linden Hu, MD

SECTION 30. Fungal Diseases 1807

188 Superficial Fungal Infection: Dermatophytosis, Onychomycosis, Tinea Nigra, Piedra 1807
Shannon Verma, MD, and Michael P. Heffernan, MD

189 Yeast Infections: Candidiasis and Tinea (Pityriasis) Versicolor 1822
Matthew P. Janik, MD, and Michael P. Heffernan, MD

190 Deep Fungal Infections 1831
Roderick J. Hay, MD

SECTION 31. Viral and Rickettsial Diseases 1845

191 Viral Diseases: General Considerations 1845
Ammar M. Ahmed, MD, Vandana K. Madkan, MD, Natalie Mendoza, MD, Stephen K. Tyring, MD, PhD, MBA and Douglas R. Lowy, MD

192 Exanthematous Viral Diseases 1851
Leah Belazarian, MD, Mayra E. Lorenzo, MD, Nicole C. Pace, MD, Susan M. Sweeney, MD, and Karen M. Wiss, MD

193 Herpes Simplex 1873
Adriana R. Marques, MD, and Stephen E. Straus, MD

194 Varicella and Herpes Zoster 1885
Stephen E. Straus, MD, Michael N. Oxman, MD, and Kenneth E. Schmader, MD

195 Poxvirus Infections 1899
Wynnis Tom, MD, and Sheila Fallon Friedlander, MD

196 Warts 1914
Elliot J. Androphy, MD, and Douglas R. Lowy, MD

197 Human Retroviral Disease: Human T-Lymphotropic Viruses 1923
Erwin Tschachler, MD

198 Cutaneous Manifestations of Human Immunodeficiency Virus Disease 1927
Arturo Saavedra, MD, PhD, and Richard Allen Johnson, MD

199 The Rickettsioses, Ehrlichioses, and Anaplasmoses 1940
Analisa V. Halpern, MD, Justin J. Green, MD, and Warren R. Heymann, MD

SECTION 32. Sexually Transmitted Diseases 1955

200 Syphilis 1955
Miguel R. Sanchez, MD

201 Endemic (Non-Venereal) Treponematoses 1977
Miguel R. Sanchez, MD

202 Chancroid 1983
Stephan Lautenschlager, MD

203 Lymphogranuloma Venereum 1987
Samer H. Ghosn, MD, and Amal K. Kurban, MD

204 Granuloma Inguinale 1990
Abdul-Ghani Kibbi, MD, FACP, and Myrna El-Shareef, MD

205 Gonorrhea and Other Venereal Diseases 1993
Annabelle L. Garcia, BS, Vandana K. Madkan, MD, and Stephen K. Tyring, MD, PhD, MBA

SECTION 33. Infestations, Bites, and Stings 2001

206 Leishmaniasis and Other Protozoan Infections 2001
Samer H. Ghosn, MD, and Amal K. Kurban, MD

207 Helminthic Infections 2011
Mary Elizabeth Wilson, MD, and Eric Caumes, MD

208 Scabies, Other Mites, and Pediculosis 2029
Stephen P. Stone, MD, Jonathan N. Goldfarb, MD, and Rocky E. Bacelieri, MD

209 Bites and Stings of Terrestrial and Aquatic Life 2037
Jennifer S. Daly, MD, and Mark Jordan Scharf, MD

210 Arthropod Bites and Stings 2054
Christopher J. Steen, MD, and Robert A. Schwartz, MD, MPH

PART 10 2065

OCCUPATIONAL SKIN DISEASES AND SKIN DISEASES DUE TO BIOLOGIC WARFARE

SECTION 34. Occupational Skin Diseases 2067

211 Occupational Skin Diseases Due to Irritants and Allergens 2067
James S. Taylor, MD, Apra Sood, MD, and Antoine Amado, MD

212 Occupational Noneczematous Skin Diseases Due to Biologic, Physical, and Chemical Agents 2074
Apra Sood, MD, and James S. Taylor, MD

SECTION 35. The Skin in Bioterrorism and Biologic Warfare 2081

213 Cutaneous Manifestations of Biologic, Chemical, and Radiologic Terrorism Attacks 2081
Scott A. Norton, MD, MPH

PART 11 2089

THERAPEUTICS

SECTION 36. Topical Therapy 2091

214 Principles of Topical Therapy 2091
Kendra G. Bergstrom, MD, and Bruce E. Strober, MD

215 Pharmacokinetics and Topical Applications of Drugs 2097
Hans Schaefer, MD, Thomas E. Redelmeier, MD, Gerhard J. Nohynek, MD, and Jürgen Lademann, MD

216 Topical Corticosteroids 2102
Isabel C. Valencia, MD, and Francisco A. Kerdel, MD

217 Topical Retinoids 2106
Sewon Kang, MD, and John J. Voorhees, MD

218 Topical Antibiotics 2113
Mark W. Bonner, MD, Paul M. Benson, MD, and William D. James, MD, PhD

219 Topical Antifungal Agents 2116
Whitney A. High, MD, and James E. Fitzpatrick, MD

220 Topical and Intralesional Cytotoxic Agents 2122
Megan M. Moore, MD, and Bruce E. Strober, MD

221 Topical Immunomodulators 2125
Robert Sidbury, MD, and Jon M. Hanifin, MD

222 Other Topical Medications 2130
Craig N. Burkhart, MD, and Kenneth A. Katz, MD

223 Photoprotection and Sun Protective Agents 2137
Henry W. Lim, MD

224 Special Considerations for Topical Therapy of Ethnic Skin 2142
Roopal V. Kundu, MD

SECTION 37. Systemic Therapy 2147

225 Systemic Glucocorticoids 2147
Victoria P. Werth, MD

226 Dapsone 2154
Joni G. Sago, MD, and Russell P. Hall III, MD

227 Aminoquinolines 2157
Jeffrey R. LaDuca, MD, PhD, and Anthony A. Gaspari, MD

228 Cytotoxic and Antimetabolic Agents 2163
Whitney A. High, MD, and James E. Fitzpatrick, MD

229 Retinoids 2181
Anders Vahlquist, MD, PhD, Stéphane Kuenzli, MD, and Jean-Hilaire Saurat, MD

230 Antihistamines 2186
Susan L. Limb, MD, and Robert A. Wood, MD

231 Antibiotics 2194
Christopher C. Gasbarre, DO, Steven K. Schmitt, MD, and Kenneth J. Tomecki, MD

232 Antiviral Drugs 2203
Christine M. Hay, MD, and Richard C. Reichman, MD

233 Oral Antifungal Agents 2211
Margaret S. Lee-Bellantoni, MD, PhD, and Nellie Konnikov, MD

234 Immunosuppressive and Immunomodulatory Drugs 2217
Carlos H. Nousari, MD, and Grant J. Anhalt, MD

235 Immunobiologicals, Cytokines, and Growth Factors in Dermatology 2223
Stephen Richardson, MD, and Joel Gelfand, MD

236 Anti-Angiogenic Agents 2231
Kalpana Reddy, BS, and Jack Arbiser, MD

237 Drug Interactions 2236
Stephen E. Wolverton, MD

SECTION 38. Physical Treatments 2243

238 Therapeutic Photomedicine: Phototherapy 2243
Jean Krutmann, MD, and Akimichi Morita, MD, PhD

239 Photochemotherapy and Photodynamic Therapy 2249
Herbert Hönigsmann, MD, Rolf-Markus Szeimies, MD, and Robert Knobler, MD

240 Lasers and Flashlamps in Dermatology 2263
Fernanda H. Sakamoto, MD, Tomi Wall, MD, Mathew M. Avram, MD, and R. Rox Anderson, MD

241 Radiotherapy 2279
Renato Panizzon, MD

SECTION 39. Complementary and Alternative Dermatology 2285

242 Complementary and Alternative Medicine in Dermatology 2285
Alan Dattner, MD

SECTION 40. Surgery in Dermatology 2289

243 Dermatologic Surgery: Introduction to Anatomy and Approach 2289
Sumaira Z. Aasi, MD, and Brent Pennington, MD

244 Excisional Surgery and Repair, Including Flaps and Grafts 2302
June K. Robinson, MD

245 Mohs Micrographic Surgery 2315
Ken K. Lee, MD, Valencia D. Thomas, MD, and Neil A. Swanson, MD

246 Nail Surgery 2320
Robert Baran, MD

247 Cryosurgery and Electrosurgery 2330
Justin J. Vujevich, MD, and Leonard H. Goldberg, MD

248 Surgical Complications 2336
Richard Bennett, MD

249 Wound Repair: Mechanisms and Practical Considerations 2342
Vincent Falanga, MD, FACP, and Satori Iwamoto, MD, PhD

250 Treatment for Varicose and Telangiectatic Leg Veins 2349
Robert A. Weiss, MD, and Margaret A. Weiss, MD

SECTION 41. Cosmetic Dermatology 2357

251 Cosmetics and Skin Care in Dermatology 2357
Leslie Baumann, MD

252 Skin Resurfacing: Ablative Lasers, Chemical Peels, and Dermabrasion 2364
Elizabeth L. Tanzi, MD, and Tina S. Alster, MD

253 Cosmetic Applications of Non-Ablative Lasers and Other Light Devices 2372
Anne M. Chapas, MD, and Roy G. Geronemus, MD

254 Liposuction 2378
Aimee L. Leonard, MD, and C. William Hanke, MD, MPH, FACP

255 Soft-Tissue Augmentation 2380
Lisa M. Donofrio, MD

256 Botulinum Toxin 2388
Richard G. Glogau, MD

257 Hair Transplantation and Alopecia Reduction 2394
Walter P. Unger, MD, FRCP(C), FACP, Robin H. Unger, MD, and Mark Unger, MD

Index I-1

CONTRIBUTORS

Sumaira Z. Aasi, MD
Assistant Professor, Department of Dermatology
Yale University School of Medicine
New Haven, Connecticut

Melissa Abrams, MD
Departments of Dermatology and Pediatrics
Northwestern University
Chicago, Illinois

Ammar M. Ahmed, MD
Department of Dermatology
Baylor College of Medicine
Houston, Texas

Murad Alam, MD
Chief, Section of Cutaneous and Aesthetic Surgery
Associate Professor, Departments of Dermatology and Otolaryngology–Head & Neck Surgery
Feinberg School of Medicine
Northwestern University
Chicago, Illinois

L. Valeyrie-Allanore, MD
Department of Dermatology
Henri Mondor Hospital
University of Paris
Paris, France

Tina S. Alster, MD
Clinical Professor, Department of Dermatology
Johns Hopkins Medical Center
Baltimore, Maryland
Georgetown University Medical Center
Washington Institute of Dermatological Laser Surgery
Washington, D.C.

Antoine Amado, MD
Contact Dermatitis Fellow
Department of Dermatology
The Cleveland Clinic Foundation
Cleveland, Ohio

Milan J. Anadkat, MD
Division of Dermatology
Department of Medicine
Washington University School of Medicine
St. Louis, Missouri

R. Rox Anderson, MD
Professor of Dermatology
Harvard Medical School
Wellman Center for Photomedicine
Massachusetts General Hospital
Boston, Massachusetts

Elliot J. Androphy, MD
Barbara and Nathan Greenberg Chair in Biomedical Research
University of Massachusetts Medical School
Worcester, Massachusetts

Grant J. Anhalt, MD
Consultant, Department of Dermatology
Johns Hopkins Institutes of Medicine
Baltimore, Maryland

Jack Arbiser, MD
Department of Dermatology
Emory University
Atlanta, Georgia

Roberto Arenas, MD
Department of Dermatology
Mycology Section
Dr. Manuel Gea Gonzalez General Hospital
Mexico City, Mexico

Chalid Assaf, MD
Associate Professor, Department of Dermatology and Allergy
Charite-Universitatsmediczin, Berlin
Skin Cancer Center, Charite University of Medicine
Berlin, Germany

Mathew M. Avram, MD
Director, MGH Dermatology Laser and Cosmetics Center
Massachusetts General Hospital
Professor, Department of Dermatology
Harvard Medical School
Boston, Massachusetts

Rocky E. Bacelieri, MD
Division of Dermatology
Department of Internal Medicine
Southern Illinois University School of Medicine
Springfield, Illinois

Christine Bangert, MD
Department of Dermatology
Medical University of Vienna
Vienna, Austria

Robert Baran, MD
Nail Disease Centre
Cannes, France

Nicole Basset-Séguin, MD
Service de Dermatologie
Hôpital Saint-Louis
Paris, France

Eugene A. Bauer, MD
Lucy Becker Professor in Medicine Emeritus
Stanford University School of Medicine
Stanford, California

Leslie Baumann, MD
Professor, Department of Dermatology
Director, University of Miami Cosmetic Center
University of Miami Miller School of Medicine
Miami, Florida

Lisa A. Beck, MD
Associate Professor, Department of Dermatology
University of Rochester School of Medicine
Rochester, New York

Michael H. Beck, FRCP, MB ChB
Consultant Dermatologist and Honorary Clinical Lecturer
University of Manchester School of Medicine
Hope Hospital
Manchester, England

Leah Belazarian, MD
Resident, Department of Dermatology
University of Massachusetts Medical School
Worcester, Massachusetts

Donald V. Belsito, MD
Clinical Professor of Medicine (Dermatology)
University of Missouri, Kansas City
Kansas City, Missouri

Richard Bennett, MD
Clinical Professor, Department of Dermatology
University of Southern California
Clinical Professor, Department of Medicine
University of California at Los Angeles
Los Angeles, California

Paul M. Benson, MD
TriCities Skin & Cancer
Johnson City, Tennessee

Timothy G. Berger, MD
Professor of Clinical Dermatology
Department of Dermatology
University of California, San Francisco
San Francisco, California

Paul R. Bergstresser, MD
James N. Gilliam Chair, Department of Dermatology
University of Texas Southwestern Medical Center
Dallas, Texas

Kendra G. Bergstrom, MD
Resident Physician, The Ronald O. Perelman Department of Dermatology
New York University Medical Center
New York, New York

Jeffrey D. Bernhard, MD
Professor of Medicine
Division of Dermatology
University of Massachusetts Medical School
University of Massachusetts Memorial Health Care
Worcester, Massachusetts

Megan L. Bernstein, MD
Intern, Mt. Sinai Hospital
New York, New York

Jag Bhawan, MD
Professor of Dermatology and Pathology
Head, Dermatopathology Section
Department of Dermatology
Boston University School of Medicine
Boston, Massachusetts

David R. Bickers, MD
Carl Truman Nelson Professor and Chair
Department of Dermatology
Columbia University
New York, New York

Michael Bigby, MD
Associate Professor, Dermatology
Harvard Medical School
Department of Dermatology
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Carol M. Black, MD
Professor of Rheumatology
Centre for Rheumatology
Royal Free and University College Medical School
Hampstead Campus
London, England

Andrew Blauvelt, MD
Professor, Department of Dermatology and Department of Molecular Microbiology and Immunology
Oregon Health & Science University
Portland, Oregon

Mark Boguniewicz, MD
Department of Pediatrics
National Jewish Medical and Research Center
University of Colorado School of Medicine
Denver, Colorado

Mark W. Bonner, MD
Georgia Dermatology
Warner Robins, Georgia

Laurence M. Boon, MD, PhD
Center for Vascular Anomalies, Division of Plastic Surgery
Cliniques Universitaries St. Luc
Brussels, Belgium

Barbara Boone, MD
Department of Dermatology
University Hospital Ghent
Ghent, Belgium

Vladimir Botchkarev, MD, PhD
Associate Research Professor
Departments of Dermatology, Pathology and Laboratory Medicine
Boston University School of Medicine
Boston, Massachusetts

Douglas E. Brash, PhD
Professor, Department of Therapeutic Radiology
Yale University School of Medicine
New Haven, Connecticut

Francisco G. Bravo, MD
Associate Professor of Dermatology and Pathology
Universidad Peruana Cayetano Heredia
Lima, Peru

Thomas Brenn, MD, PhD
Consultant Dermatopathologist, Department of Pathology
Western General Hospital
The University of Edinburgh
Edinburgh, Scotland
University of Manchester
Salford, United Kingdom

Lieve Brochez, MD, PhD
Professor, Department of Dermatology
University Hospital Ghent
Ghent, Belgium

Robert T. Brodell, MD
Professor of Internal Medicine
Dermatology Section
Clinical Professor, Dermatopathology in Pathology
Northeastern Ohio Universities College of Medicine
Associate Clinical Professor of Dermatology
Case Western Reserve School of Medicine
Warren, Ohio

Marc D. Brown, MD
Professor, Department of Dermatology
Director, Division of Dermatologic Surgery, Oncology, and Mohs Surgery
University of Rochester School of Medicine
Strong Memorial Hospital
Rochester, New York

Daniela Bruch-Gerharz, MD
Professor, Department of Dermatology
Heinrich-Heine University
University Hospital of Duesseldorf
Duesseldorf, Germany

Leena Bruckner-Tuderman, MD
Professor and Chair, Department of Dermatology
University of Freiburg
Freiburg, Germany

Lucinda S. Buescher, MD
Associate Professor, Division of Dermatology
Department of Internal Medicine
Southern Illinois University School of Medicine
Springfield, Illinois

Christopher Barry Bunker, MA, MD, FRCP
Professor of Dermatology and Consultant Dermatologist
Imperial College School of Medicine
Chelsea & Westminster and Royal Marsden Hospitals
London, United Kingdom

Walter H. C. Burgdorf, MD
Clinical Lecturer
Department of Dermatology
Ludwig Maximilian University
Munich, Germany

Susan Burgin, MD
Instructor, Department of Dermatology
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, Massachusetts

Craig N. Burkhart, MD
Department of Dermatology
University of North Carolina
Chapel Hill, North Carolina

Claude S. Burton, MD
Department of Dermatology
Duke University Medical Center
Durham, North Carolina

Ruggero Caputo, MD
Professor of Dermatology
Institute of Dermatological Sciences
Milan, Italy (d. 2007)

Melody C. Carter, MD
Adjunct Faculty
National Institute of Allergy and Infectious Diseases
National Institutes of Health
Bethesda, Maryland

John A. Carucci, MD
Chief, Mohs Micrographic and Dermatologic Surgery
Weill Medical College of Cornell University
New York Presbyterian Hospital
New York, New York

Eric Caumes, MD
Professor of Infectious and Tropical Diseases
University Pierre et Marie Curie
Department of Infectious and Tropical Diseases
Hôpital Pitié-Salpêtrière
Paris, France

Lorenzo Cerroni, MD
Professor, Department of Dermatology
Medical University of Graz
Graz, Austria

Sarah L. Chamlin, MD
Associate Professor, Division of Dermatology
Children's Memorial Hospital
Northwestern University
Chicago, Illinois

Mary Wu Chang, MD
Chief, Pediatric Dermatology
Connecticut Children's Medical Center
Associate Professor of Dermatology & Pediatrics
University of Connecticut School of Medicine
Hartford, Connecticut

Anne M. Chapas, MD
Clinical Assistant Professor, The Ronald O. Perelman Department of Dermatology
Laser and Skin Surgery Center of New York
New York University Medical Center
New York, New York

Joel Charrow, MD
Associate Professor, Department of Pediatrics
Feinberg School of Medicine
Northwestern University
Head, Division of Genetics
Children's Memorial Hospital
Chicago, Illinois

Mei Chen, PhD
Department of Dermatology
Keck School of Medicine
University of Southern California
Los Angeles, California

Andy J. Chien, MD, PhD
Acting Assistant Professor, Division of Dermatology
University of Washington
Seattle, Washington

Anne-Marie Chomat, MD
Fellow in Infectious Diseases
Tufts-New England Medical Center
Boston, Massachusetts

Mary-Margaret Chren, MD
Professor in Residence
Department of Dermatology
University of California, San Francisco
Staff Dermatologist
Veterans Affairs Medical Center
San Francisco, California

David H. Chu, MD, PhD
Instructor, The Ronald O. Perelman Department of Dermatology
New York University School of Medicine
New York, New York

Mon-Li Chu, PhD
Professor and Vice Chair of Research
Department of Dermatology and Cutaneous Biology
Jefferson Medical College
Jefferson Institute of Molecular Medicine
Thomas Jefferson University
Philadelphia, Pennsylvania

David E. Cohen, MD, MPH
Associate Professor, The Ronald O. Perelman Department of Dermatology
The New York University School of Medicine
New York, New York

Philip R. Cohen, MD
Clinical Associate Professor, Department of Dermatology
University of Texas-Houston Medical School
Houston, Texas

Nneka I. Comfere, MD
Assistant Professor
Mayo Clinic College of Medicine
Consultant in Dermatology
Mayo Clinic
Rochester, Minnesota

Jennifer Z. Cooper, MD
Assistant Professor, Department of Dermatology
University of Maryland School of Medicine
Baltimore, Maryland

Lynn A. Cornelius, MD
Associate Professor and Chief, Division of Dermatology
Washington University
St. Louis, Missouri

Rosamaria Corona, DSc, MD
Istituto Dermopatico dell'Immacolata
Divisione di Immunodermatologia
Rome, Italy

Melissa I. Costner, MD
Assistant Professor, Department of Dermatology
University of Texas Southwestern Medical School at Dallas
Dallas, Texas

George Cotsarelis, MD
Associate Professor, Department of Dermatology
University of Pennsylvania Medical Center
Philadelphia, Pennsylvania

Pierre A. Coulombe, PhD
Professor, Departments of Biological Chemistry and Dermatology
Director, Graduate Program in Cellular and Molecular Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland

Joe Craft, MD
Section of Immunobiology
Department of Internal Medicine
Yale University
New Haven, Connecticut

Noah Craft, MD, PhD
Associate Program Director, Division of Dermatology
Harbor UCLA Medical Center
Los Angeles, California

Jennifer S. Daly, MD
Department of Medicine
Division of Infectious Diseases and Immunology
University of Massachusetts Medical School
Worcester, Massachusetts

Stamatina Danielides, MD
Sjögren's Syndrome Clinic
Gene Therapy and Therapeutics Branch
National Institute of Dental and Craniofacial Research
National Institutes of Health
Bethesda, Maryland

Mazen S. Daoud, MD
Fort Myers Dermatology
Fort Myers, Florida

Thomas N. Darling, MD, PhD
Associate Professor, Department of Dermatology
Uniformed Services University of the Health Sciences
Bethesda, Maryland

Alan Dattner, MD
New Rochelle, New York

Aerlyn G. Dawn, MD, MBA
Department of Dermatology
Wake Forest University School of Medicine
Winston-Salem, North Carolina

Steven M. Dean, DO, FACP
Division of Cardiovascular Medicine
Ohio State University
Columbus, Ohio

Nicole M. DeLauro, DPM
New York College of Podiatric Medicine
New York, New York

Thomas M. DeLauro, DPM
Professor
New York College of Podiatric Medicine
New York, New York

Christopher P. Denton, MD
Professor of Experimental Rheumatology
Centre for Rheumatology
Royal Free and University College Medical School
Hampstead Campus
London, England

Sofie De Schepper, MD
Department of Dermatology
University Hospital Ghent
Ghent, Belgium

Christine A. DeWitt, MD

Professor, Division of Dermatology
Director, Division of Dermatopharmacology
Brown University Medical School
Rhode Island Hospital
Providence, Rhode Island

Andrzej A. Dlugosz, MD
Professor, Department of Dermatology
Comprehensive Cancer Center
University of Michigan
Ann Arbor, Michigan

Lisa M. Donofrio, MD
Assistant Clinical Professor
Department of Dermatology
Yale University School of Medicine
New Haven, Connecticut

Daven N. Doshi, MD
Department of Dermatology
Harvard Medical School
Boston, Massachusetts

Karynne O. Duncan, MD
St. Helena, California

Jonathan A. Dyer, MD
Assistant Professor, Department of Dermatology
University of Missouri-Columbia
Columbia, Missouri

Robert T. Eberhardt, MD
Division of Cardiovascular Medicine
Boston University Medical Center
Boston, Massachusetts

Libby Edwards, MD
Chief, Division of Dermatology
Carolinas Medical Center
Charlotte, North Carolina
Clinical Associate Professor
Department of Dermatology
University of North Carolina
Chapel Hill, North Carolina

Lawrence F. Eichenfield, MD
Chief, Division of Pediatric and Adolescent Dermatology
Children's Hospital and Departments of Pediatrics and Medicine (Dermatology)
University of California San Diego
San Diego, California

Arthur Z. Eisen, MD
Winfred and Emma Showman
Professor, Division of Dermatology
Department of Medicine
Washington University Medical Center
St. Louis, Missouri

James T. Elder, MD
Professor, Department of Dermatology
University of Michigan
Ann Arbor Veterans Affairs Hospital
Ann Arbor, Michigan

Myrna El-Shareef, MD
Department of Dermatology
American University of Beirut Medical Center
Beirut, Lebanon

Dirk M. Elston, MD
Department of Dermatology
Geisinger Medical Center
Danville, Pennsylvania

Joseph C. English III, MD
Associate Professor, Department of Dermatology
University of Pittsburgh
Pittsburgh, Pennsylvania

Janet A. Fairley, MD
Professor, Department of Dermatology
Medical College of Wisconsin
Milwaukee, Wisconsin

Vincent Falanga, MD, FACP
Department of Dermatology and Skin Surgery
Roger Williams Medical Center
Providence, Rhode Island
Department of Dermatology and Biochemistry
Boston University
Boston, Massachusetts

Robert D. Fealey, MD
Assistant Professor, Department of Neurology
Mayo Clinic Medical School
Rochester, Minnesota

James Ferguson, MD
Photobiology Unit
Ninewells Hospital
Dundee, Scotland

Laura Korb Ferris, MD, PhD
Assistant Professor, Department of Dermatology
University of Pittsburgh
Pittsburgh, Pennsylvania

James E. Fitzpatrick, MD
Professor, Dermatology & Dermatopathology
University of Colorado Health Sciences Center
Denver, Colorado;
Dermatopathology Consultants, Anschutz Cancer Center
Department of Dermatology
Aurora, Colorado

Philip Fleckman, MD
Professor, Division of Dermatology
University of Washington
Seattle, Washington

Carsten Flohr, MRCPCH
Center of Evidence-Based Dermatology
Nottingham University Hospitals NHS Trust
Nottingham, United Kingdom

Camille Frances, MD
Université Paris VI
Service de Dermatologie-Allergologie
Hôpital Tenon
Paris, France

Jorge Franks, MD
Department of Dermatology
Maastricht University Center for Molecular Dermatology (MUCMD)
Maastricht, The Netherlands

Ilona J. Frieden, MD
Professor, Department of Dermatology
University of California, San Francisco
San Francisco, California

Sheila Fallon Friedlander, MD
Clinical Professor of Pediatrics and Medicine
University of California San Diego School of Medicine
Children's Hospital, San Diego
San Diego, California

Richard Gallo, MD, PhD
Chief, Adult Dermatology
Associate Clinical Professor, Pediatrics and Medicine
Department of Medicine
University of California, San Diego
La Jolla, California

Annabelle L. Garcia, BS
University of Texas Health Science Center
Houston, Texas

Amit Garg, MD
Assistant Professor of Medicine
Division of Dermatology
University of Massachusetts Medical School
University of Massachusetts Memorial Health Care
Worcester, Massachusetts

Andrea L. Garrett, MD
Department of Dermatology
University of Wisconsin
Madison, Wisconsin

Christopher C. Gasbarre, DO
Senior Resident in Dermatology
The Cleveland Clinic Foundation
Cleveland, Ohio

Anthony A. Gaspari, MD
Department of Dermatology
The Cleveland Clinic Foundation
Cleveland, Ohio

John K. Geisse, MD
Associate Clinical Professor
Departments of Dermatology and Pathology
University of California, San Francisco
San Francisco, California

Joel Gelfand, MD
Assistant Professor, Department of Dermatology
University of Pennsylvania
Philadelphia, Pennsylvania

Carlo Gelmetti, MD
Professor of Dermatology
Institute of Dermatological Sciences
Milan, Italy

Roy G. Geronemus, MD
Clinical Professor, The Ronald O. Perelman Department of Dermatology
New York University Medical Center
Laser and Skin Surgery Center of New York
New York, New York

Samer H. Ghosn, MD
Assistant Professor, Department of Dermatology
American University of Beirut Medical Center
Beirut, Lebanon

Lawrence E. Gibson, MD
Professor of Dermatology
Mayo Clinic College of Medicine
Consultant in Dermatology
Mayo Clinic
Rochester, Minnesota

Barbara A. Gilchrest, MD
Professor and Chair of Dermatology
Department of Dermatology
Boston University School of Medicine
Boston, Massachusetts

Richard G. Glogau, MD
Clinical Professor of Dermatology
University of California, San Francisco
San Francisco, California

Raphaela Goldbach-Mansky, MD
National Institute of Arthritis and Musculoskeletal and Skin Disease
National Institutes of Health
Bethesda, Maryland

Division of Dermatology
Department of Internal Medicine
Southern Illinois University School of Medicine
Springfield, Illinois

Lowell A. Goldsmith, MD
Professor of Dermatology
University of North Carolina School of Medicine
Chapel Hill, North Carolina
Dean Emeritus
University of Rochester School of Medicine and Dentistry
Rochester, New York

Carmen E. Gota, MD
Staff, Department of Rheumatology
Center for Vasculitis Care and Research
The Cleveland Clinic Foundation
Cleveland, Ohio

Emmy M. Graber, MD
Chief Resident, Department of Dermatology
The Pennsylvania State University College of Medicine
Hershey, Pennsylvania

Robin A. C. Graham-Brown, MD
Consultant Dermatologist
Honorary Senior Lecturer, Department of Dermatology
Leicester Royal Infirmary
Leicester, England

Jane Margaret Grant-Kels, MD
Professor and Chair
Department of Dermatology
University of Connecticut Health Center
Farmington, Connecticut

Malcolm W. Greaves, MD, PhD, FRCP
Emeritus Professor of Dermatology
National Skin Centre
Singapore

Justin J. Green, MD
Department of Dermatology
University of Medicine and Dentistry of New Jersey–Robert Wood Johnson Medical School at Camden
Camden, New Jersey

Roy C. Grekin, MD
Clinical Professor of Dermatology
Dermatologic Surgery Unit
University of California, San Francisco
San Francisco, California

James M. Grichnik, MD, PhD
Associate Professor, Department of Dermatology
Duke University Medical Center
Durham, North Carolina

Douglas Grossman, MD, PhD
Associate Professor
Departments of Dermatology and Oncological Sciences
Huntsman Cancer Institute
University of Utah
Salt Lake City, Utah

Johann E. Gudjonsson, MD, PhD
Fellow, Department of Dermatology
University of Michigan
Ann Arbor, Michigan

Bridget C. Hackett, MRCPI
Regional Centre of Dermatology
Mater Misericordiae Hospital
Dublin, Ireland

Rebat M. Halder, MD
Professor and Chair, Department of Dermatology
Howard University Hospital
Washington, D.C.

Russell P. Hall III, MD
J. Lamar Callaway Professor of Dermatology
Chief, Division of Dermatology
Duke University Medical Center
Durham, North Carolina

Allan C. Halpern, MD
Dermatology Academic Offices
Memorial Sloan-Kettering Cancer Center
New York, New York

Analisa V. Halpern, MD
Department of Dermatology
University of Medicine and Dentistry of New Jersey–Robert Wood Johnson Medical School
Cooper University Hospital
Camden, New Jersey

C. William Hanke, MD, MPH, FACP
Laser and Skin Surgery Center of Indiana
Carmel, Indiana

Jon M. Hanifin, MD
Professor, Department of Dermatology
Oregon Health and Sciences University
Portland, Oregon

Mandy Harting, MD
Resident, Department of Dermatology
Baylor College of Medicine
Houston, Texas

Christina L. Haverstock, MD, MS
Resident, Department of Dermatology
Wake Forest University Medical Center
Winston-Salem, North Carolina

John L. M. Hawk, MD
Chair, Photobiology Unit
St. John's Institute of Dermatology
St. Thomas' Hospital
King's College London
London, England

Philip N. Hawkins, MD
National Amyloidosis Centre,
Department of Medicine
Royal Free Hospital
London, England

Christine M. Hay, MD
Infectious Diseases Division
University of Rochester Medical Center
Rochester, New York

Roderick J. Hay, MD
Faculty of Medicine and Health
Queen's University Belfast
Belfast, Northern Ireland

Michael P. Heffernan, MD
Associate Professor and Chief, Division of Dermatology
Wright State University
Boonshoft School of Medicine
Dayton, Ohio

Timothy Heffernan, PhD
Department of Medical Oncology
Dana Farber Cancer Institute
Harvard Medical School
Boston, Massachusetts

Stephen E. Helms, MD
Associate Professor of Internal Medicine, Dermatology Section
Northeastern Ohio University College of Medicine
Case Western Reserve College of Medicine
Warren, Ohio

Ulrich R. Hengge, MD
Professor, Department of Dermatology
Heinrich-Heine University
University Hospital of Duesseldorf
Duesseldorf, Germany

Frédérique Henry, MD
Dermatopathology Service
University Hospital of Liège
Liège, Belgium

Warren R. Heymann, MD
Department of Dermatology
University of Medicine and Dentistry of New Jersey–Robert Wood Johnson Medical School at Camden
Camden, New Jersey

M. John Hicks, MD, DDS, PhD
Professor, Department of Pathology
Director of Anatomic Pathology
Texas Children's Hospital
Baylor College of Medicine
Houston, Texas

Whitney A. High, MD
Assistant Professor, Dermatology & Dermatopathology
University of Colorado Health Sciences Center
Denver, Colorado

Steven M. Holland, MD
Chief, Laboratory of Clinical Infectious Diseases
National Institutes of Health
Bethesda, Maryland

Herbert Hönigsmann, MD
Professor and Chair, Department of Dermatology
Medical University of Vienna
Vienna, Austria

Thomas D. Horn, MD
Professor and Chair, Department of Dermatology
University of Arkansas for Medical Sciences
Little Rock, Arkansas

***Thomas J. Hornyak, MD, PhD**
Investigator, Dermatology Branch
Center for Cancer Research
National Cancer Institute
National Institutes of Health
Bethesda, Maryland

Elizabeth Bahar Houshmand, MD
Associate Professor and Chief, Division of Dermatology
Wright State University
Boonshoft School of Medicine
Dayton, Ohio

Alain Hovnanian, MD, PhD
Professor, Department of Medical Genetics
University Paul Sabatier
Purpan Hospital
Toulouse, France

Chung-Hong Hu, MD
Department of Dermatology
University of Wisconsin
Madison, Wisconsin

Linden Hu, MD
Division of Geographic Medicine and Infectious Disease
Tufts New England Medical Center
Boston, Massachusetts

***Sam T. Hwang, MD, PhD**
Senior Investigator
Dermatology Branch
Center for Cancer Research, National Cancer Institute
National Institutes of Health
Bethesda, Maryland

Gabor Illei, MD
Sjögren's Syndrome Clinic
Gene Therapy and Therapeutics Branch
National Institute of Dental and Craniofacial Research
National Institutes of Health
Bethesda, Maryland

Alan D. Irvine, MD, FRCPI, MRCP
Consultant Paediatric Dermatologist
Our Lady's Hospital for Sick Children
Dublin, Ireland

Peter H. Itin, MD
Professor and Head, Department of Dermatology
University Hospital Basel
Basel, Switzerland

Satori Iwamoto, MD, PhD
Department of Dermatology and Biochemistry
Boston University
Boston, Massachusetts

Sharon E. Jacob, MD
Assistant Professor, Department of Dermatology and Cutaneous Surgery
University of Miami Miller Medical School
Miami, Florida

Natalia Jaimes, MD
Resident in Dermatology
Universidad Pontificia Bolivariana
Medellín, Colombia

William D. James, MD, PhD
Department of Dermatology
University of Pennsylvania
Philadelphia, Pennsylvania

Matthew P. Janik, MD
Department of Dermatology
Wright State University and Boonshoft School of Medicine
Dayton, Ohio

Thomas Jansen, MD
Professor, Department of Dermatology, Venereology, and Allergology
University of Essen
Essen, Germany

Melinda Jen, MD
Resident, Department of Pediatrics
Section of Pediatric Dermatology
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Jens-Michael Jensen, MD
Professor, Department of Dermatology
University of Kiel
University Hospitals of Kiel
Kiel, Germany

Richard Allen Johnson, MD
Instructor in Dermatology
Harvard Medical School
Clinical Associate in Dermatology
Massachusetts General Hospital
Boston, Massachusetts

Timothy M. Johnson, MD
Department of Dermatology
University of Michigan
Ann Arbor, Michigan

Graham A. Johnston, MB ChB, FRCP
Consultant Dermatologist, Department of Dermatology
Leicester Royal Infirmary
Leicester, England

Joseph L. Jorizzo, MD
Former (Founding) Chair, Department of Dermatology
Wake Forest University Medical Center
Winston-Salem, North Carolina

Marc A. Judson, MD
Professor, Division of Pulmonary and Critical Care Medicine
Medical University of South Carolina
Charleston, South Carolina

Steven Kaddu, MD
Department of Dermatology
Medical University of Graz
Graz, Austria

Andrea A. Kalus, MD
Acting Assistant Professor, Division of Dermatology
University of Washington
Seattle, Washington

Insoo Kang, MD
Associate Professor, Section of Rheumatology
Department of Medicine
Yale University School of Medicine
New Haven, Connecticut

Sewon Kang, MD
Professor, Department of Dermatology
University of Michigan
Ann Arbor, Michigan

Allen P. Kaplan, MD
National Allergy Asthma and Urticaria Centers of Charleston
Charleston, South Carolina

Julie K. Karen, MD
Resident, The Ronald O. Perelman Department of Dermatology
New York University School of Medicine
New York, New York

Daniel L. Kastner, MD
Chief, Genetics and Genomics Branch
National Institute of Arthritis and Musculoskeletal and Skin Disease
National Institutes of Health
Bethesda, Maryland

Kenneth A. Katz, MD
Department of Dermatology
University of Pennsylvania
Philadelphia, Pennsylvania

***Stephen I. Katz, MD, PhD**
Director, National Institute of Arthritis and Musculoskeletal and Skin Diseases
National Institutes of Health
Bethesda, Maryland

Lynda Kauls, MD
Assistant Professor, Department of Dermatology
Oregon Health and Science University
Portland, Oregon

Andrew Keat, MD
Consultant Physician
Northwick Park Hospital
Harrow, Middlesex, England

Dean L. Kellogg, Jr., MD, PhD
Associate Professor, Division of Geriatrics and Gerontology
Department of Medicine
University of Texas Health Science Center at San Antonio, Texas
San Antonio, Texas

David P. Kelsell, MD
The Royal London Hospital
London, England

Francisco A. Kerdel, MD
Voluntary Faculty
Department of Dermatology and Cutaneous Surgery
University of Miami Miller School of Medicine
Miami, Florida

Helmut Kerl, MD
Professor and Chairman, Department of Dermatology
Medical University of Graz
Graz, Austria

Abdul-Ghani Kibbi, MD, FACP
Professor and Chair, Department of Dermatology
American University of Beirut Medical Center
Beirut, Lebanon

Christina E. Killoran, MD
Department of Dermatology and Skin Surgery
Roger Williams Medical Center
Providence, Rhode Island

Jenny Kim, MD, PhD
Assistant Clinical Professor, Division of Dermatology
David Geffen School of Medicine
University of California at Los Angeles
Los Angeles, California

Alexa B. Kimball, MD, MPH
Department of Dermatology
Harvard Medical School
Boston, Massachusetts

John H. Klippel, MD
Arthritis Foundation
Atlanta, Georgia

Robert Knobler, MD
Associate Professor of Dermatology
Department of Dermatology
Division of Special & Environmental Dermatology
Medical University of Vienna
Vienna, Austria

Sandra R. Knowles, BScPhm
Division of Dermatology
Sunnybrook Health Sciences Center
University of Toronto
Toronto, Ontario, Canada

Irene E. Kochevar, PhD
Professor, Department of Dermatology
Harvard University School of Medicine
Wellman Center for Photomedicine
Massachusetts General Hospital
Boston, Massachusetts

Thomas Koenig, MD
Associate Dean for Student Affairs
Assistant Professor of Psychiatry and Behavioral Sciences
The Johns Hopkins University School of Medicine
Baltimore, Maryland

Nellie Konnikov, MD
Department of Dermatology
Boston Veterans Affairs Medical Center
Boston, Massachusetts

Kenneth H. Kraemer, MD
Researcher
National Institutes of Health
Center for Cancer Research
Bethesda, Maryland

Jean Krutmann, MD
Professor of Dermatology and Environmental Medicine
Director, Institut für Umweltmedizinische Forschung (IUF) at the Heinrich-Heine-University
Düsseldorf, Germany

Stéphane Kuenzli, MD
Uppsala, Sweden

Roopal V. Kundu, MD
Assistant Professor of Dermatology
Northwestern University
Director, Northwestern Center for Ethnic Skin
Feinberg School of Medicine
Northwestern University
Chicago, Illinois

Thomas S. Kupper, MD
Director, Harvard Skin Disease Research Center
Harvard Institute of Medicine
Brigham and Women's Hospital
Boston, Massachusetts

Amal K. Kurban, MD
Department of Dermatology
Boston University School of Medicine
Boston, Massachusetts

Razelle Kurzrock, MD, FACP
Director, Phase One Program
Division of Cancer Medicine
University of Texas
M.D. Anderson Cancer Center
Houston, Texas

Daniel Kusnir, MD
Director of the Multicultural Psychotherapy Training and Research Institute
Program Director
La Familia Children's Day Treatment
Hayward, California

Heinz Kutzner, MD
Dermatopathologische Gemeinschaftspraxis
Friedrichshafen, Germany

Helen J. Lachmann, MD
National Amyloidosis Centre
Department of Medicine
Royal Free and University College Medical School
London, England

Mario E. Lacouture, MD
Assistant Professor, Department of Dermatology
Feinberg School of Medicine
Northwestern University
Chicago, Illinois

Jürgen Lademann, MD
Dermatology Department
Charite Hospital/Humboldt University Berlin
Berlin, Germany

Jeffrey R. LaDuca, MD, PhD
Finger Lakes Dermatology
Auburn, New York

Jo Lambert, MD, PhD
Professor, Department of Dermatology
University Hospital Ghent
Ghent, Belgium

Sinéad Langan, MRCP
Center of Evidence-Based Dermatology
Nottingham University Hospitals NHS Trust
Nottingham, United Kingdom

Hilde Lapeere, MD
Department of Dermatology
University Hospital Ghent
Ghent, Belgium

Margarita M. Larralde, MD
Pediatric Dermatology Department
Hospital Ramos Mejía
Chief of Dermatology Department
Hospital Alemán
Buenos Aires, Argentina

Anne Laumann, MB ChB, MRCP
Associate Professor, Department of Dermatology
Feinberg School of Medicine
Northwestern University
Chicago, Illinois

Stephan Lautenschlager, MD
Head, Outpatient Clinic of Dermatology and Venereology
Triemli Hospital and University of Zurich
Zurich, Switzerland

Leslie P. Lawley, MD
Pediatric Dermatology Fellow
Division of Dermatology
Children's Memorial Hospital
Northwestern University
Chicago, Illinois

Thomas J. Lawley, MD
Department of Dermatology
Emory University School of Medicine
Atlanta, Georgia

Celeste Lebbé, MD
Service de Dermatologie
Hôpital Saint-Louis
Paris, France

Mark Lebwohl, MD
Professor and Chairman, Department of Dermatology
Mount Sinai School of Medicine
New York, New York

Jin Lee, MD, MBA
Resident, Department of Dermatology
Boston University
Boston, Massachusetts

Ken K. Lee, MD
Associate Professor, Department of Dermatology
Director of Dermatologic Surgery
Oregon Health and Science University
Portland, Oregon

Lela A. Lee, MD
Professor of Dermatology and Medicine
University of Colorado School of Medicine
Chief of Dermatology
Denver Health Medical Center
Denver, Colorado

Peter K. Lee, MD, PhD
Assistant Professor, Department of Dermatology
University of Minnesota
Minneapolis, Minnesota

Margaret S. Lee-Bellantoni, MD, PhD
Department of Dermatology
Boston University and Tufts–New England Medical Center
Boston, Massachusetts

David J. Leffell, MD
Professor of Dermatology and Surgery
Chief, Section of Dermatologic Surgery and Cutaneous Oncology
Department of Dermatology
Yale University School of Medicine
New Haven, Connecticut

Kristin M. Leiferman, MD
Professor, Department of Dermatology
University of Utah Health Sciences Center
Salt Lake City, Utah

Irene M. Leigh, MD
Centre for Cutaneous Research
St. Bartholomew's & the Royal London School of Medicine
Queen Mary & Westfield College
London, England

Aimee L. Leonard, MD
New England Dermatology and Laser Center
Springfield, Massachusetts

Donald Y. M. Leung, MD, PhD
Head, Division of Pediatric Allergy and Immunology
National Jewish Medical and Research Center
University of Colorado Medical School
Denver, Colorado

Nikki A. Levin, MD, PhD
Assistant Professor of Medicine
Division of Dermatology
University of Massachusetts Medical School
University of Massachusetts Memorial Health Care
Worcester, Massachusetts

Moise L. Levy, MD
Professor, Departments of Pediatrics and Dermatology
Baylor College of Medicine
Chief, Dermatology Service
Texas Children's Hospital
Houston, Texas

Ross M. Levy, MD
Chief Resident, Department of Dermatology
Feinberg School of Medicine
Northwestern University
Chicago, Illinois

Henry W. Lim, MD
Chairman, Department of Dermatology
Henry Ford Hospital
Detroit, Michigan

Susan L. Limb, MD
Johns Hopkins University School of Medicine
Baltimore, Maryland

Dan Lipsker, MD, PhD
Clinique Dermatologique
Hôpitaux Universitaires
Strasbourg Cedex, France

Robert Listernick, MD
Professor, Department of Pediatrics
Feinberg School of Medicine
Northwestern University
Divisions of General Academic Pediatrics
The Children's Memorial Hospital
Chicago, Illinois

Mayra E. Lorenzo, MD
Resident, Department of Dermatology
University of Massachusetts Medical School
Worcester, Massachusetts

James Loveless, MD
Dermatology Resident
Department of Dermatology
Johns Hopkins Medical Institutions
Baltimore, Maryland

Douglas R. Lowy, MD
Head, Signaling and Oncogenesis Section
Laboratory Chief, Laboratory of Cellular Oncology
National Cancer Institute
National Institutes of Health
Bethesda, Maryland

Anne W. Lucky, MD
Dermatology Research Associates, Inc.
Cincinnati, Ohio

Thomas A. Luger, MD
Professor and Chairman, Department of Dermatology
University of Münster
Münster, Germany

Paula C. Luna, MD
Dermatology Department
Churruca-Visca Hospital
Buenos Aires, Argentina

Calum C. Lyon, FRCP, MB BChir
Consultant Dermatologist and Honorary Clinical Tutor
Hull and York Medical School
York Hospital
York, United Kingdom

Catherine Maari, MD
Department of Dermatology
University of Montreal
Montreal, Quebec, Canada

Vandana K. Madkan, MD
Clinical Research Fellow
Center for Clinical Studies
University of Texas Health Science Center
Houston, Texas

Meera Mahalingam, MD, PhD, FRCPath
Associate Professor and Director, Dermatopathology
Division of Dermatology
University of Massachusetts Medical School
University of Massachusetts Memorial Health Care
Worcester, Massachusetts

Frederick D. Malkinson, MD
Department of Dermatology
University Hospital
Centre Hospitalier Universitaire Vaudois
Lausanne, Switzerland

Brian F. Mandell, MD, PhD, FACR
Vice Chairman, Division of Medicine
Staff, Department of Rheumatology
Center for Vasculitis Care and Research
The Cleveland Clinic Foundation
Cleveland, Ohio

Richard M. Marchell, MD
Assistant Professor, Department of Dermatology
Medical University of South Carolina
Charleston, South Carolina

M. Peter Marinkovich, MD
Associate Professor, Department of Dermatology
Program in Epithelial Biology
Stanford University School of Medicine
Stanford, California

Adriana R. Marques, MD
Laboratory of Clinical Infectious Diseases
National Institute of Allergy and Infectious Diseases
National Institutes of Health
Bethesda, Maryland

Dieter Maurer, MD
Professor
Department of Dermatology
Medical University of Vienna
Vienna, Austria

Theodora M. Mauro, MD
Associate Professor, Department of Dermatology
University of California, San Francisco
San Francisco Veterans Hospital
San Francisco, California

John A. McGrath, MD
Professor, Division of Skin Sciences
Kings College London
St. John's Institute of Dermatology
St. Thomas' Hospital
London, England

W. H. Irwin McLean, MD
Wellcome Trust Senior Research Fellow
Professor and Head, Human Genetics Research
Director, Epithelial Genetics Group
Human Genetics Unit
Division of Pathology and Neuroscience
Ninewells Hospital, University of Dundee
Dundee, Scotland

Darius R. Mehregan, MD
Assistant Professor of Dermatology
Wayne State University
Detroit, Michigan
Director of Dermatopathology
Pinkus Dermatopathology Laboratory, P.C.
Monroe, Michigan

David A. Mehregan, MD
Assistant Professor of Dermatology
Wayne State University
Detroit, Michigan
Director of Dermatopathology
Pinkus Dermatopathology Laboratory, P.C.
Monroe, Michigan

H. Cody Meissner, MD
Professor, Department of Pediatrics
Tufts New England Medical Center
Boston, Massachusetts

Natalie Mendoza, MD
Center for Clinical Studies
Houston, Texas

Andrew G. Messenger, MD
Honorary Senior Clinical Lecturer
University of Sheffield
Sheffield, England, U.K.

Dean D. Metcalfe, MD
Chief, Laboratory of Allergic Diseases
National Institute of Allergy and Infectious Diseases
National Institutes of Health
Bethesda, Maryland

Martin C. Mihm, Jr., MD
Clinical Professor of Pathology
Senior Dermatopathologist
Harvard Medical School
Massachusetts General Hospital
Boston, Massachusetts

Stanley J. Miller, MD
Associate Professor, Dermatology and Otolaryngology–Head and Neck Surgery
Johns Hopkins Hospital
Baltimore, Maryland

Tara Miller, MD
Dermatology Resident
University of California, San Francisco
San Francisco, California

Ginat Wintermeyer Mirowski, DMD, MD
Associate Professor, Department of Dermatology
Feinberg School of Medicine
Northwestern University
Chicago, Illinois
Adjunct Associate Professor
Department of Oral Pathology, Medicine, Radiology
Indiana University School of Dentistry
Indianapolis, Indiana

Robert L. Modlin, MD
Klein Professor and Chief, Department of Dermatology
Professor of Microbiology, Immunology, and Molecular Genetics
David Geffen School of Medicine
University of California, Los Angeles
Los Angeles, California

The Ronald O. Perelman Department of Dermatology
New York University School of Medicine
New York, New York

Akimichi Morita, MD, PhD
Professor and Chairman, Department of Geriatric and Environmental Dermatology
Nagoya City University Graduate School of Medical Sciences
Nagoya, Japan

Nico Mousdicas, MD
Departments of Dermatology, Pediatrics, Pharmacology and Toxicology
Indiana University School of Medicine
Indianapolis, Indiana

Ulrich Mrowietz, MD
Professor
Department of Dermatology
University of Kiel
Kiel, Germany

Sarah A. Myers, MD
Division of Dermatology
Duke University Medical Center
Durham, North Carolina

Jean-Marie Naeyaert, MD, PhD
Professor, Department of Dermatology
University Hospital Ghent
Ghent, Belgium

Amanda M. Nelson, PhD
Postdoctoral Scholar, Department of Dermatology
The Jake Gittlen Cancer Research Foundation
The Pennsylvania State University College of Medicine
Hershey, Pennsylvania

Isaac M. Neuhaus, MD
Assistant Professor of Clinical Dermatology
Department of Dermatology
University of California, San Francisco
San Francisco, California

Paul Nghiem, MD, PhD
Assistant Professor, Division of Dermatology
Affiliate Investigator, Fred Hutchinson Cancer Research Center
Seattle, Washington

Gerhard J. Nohynek, MD
Department of Dermatology
Charite Hospital/Humboldt University Berlin
Berlin, Germany

Scott A. Norton, MD, MPH
Professor, Department of Dermatology
Uniformed Services University of the Health Sciences
Bethesda, Maryland

Carlos H. Nousari, MD
Dermpath Diagnostics South Florida
Pompano Beach, Florida

Lilian M. Odo, MD
Department of Dermatology of Santo Amaro University
Odo Clinics of Dermatology
São Paulo, Brazil

John E. Olerud, MD
George F. Odland Professor
Department of Medicine
Head, Division of Dermatology
University of Washington
Seattle, Washington

Elise A. Olsen, MD
Professor of Medicine
Divisions of Dermatology and Oncology
Duke University Medical Center
Durham, North Carolina

Katia Ongenae, MD, PhD
Professor, Department of Dermatology
University Hospital Ghent
Ghent, Belgium

Grainne M. O'Regan, MRCPI
Our Lady's Children's Hospital
Dublin, Ireland

Seth J. Orlow, MD, PhD
Chairman, The Ronald O. Perelman Department of Dermatology
Samuel Weinberg Professor of Dermatology, Pediatrics, and Cell Biology
New York University School of Medicine
New York, New York

Anthony E. Oro, MD, PhD
Associate Professor, Department of Dermatology
Program in Epithelial Biology
Stanford University, School of Medicine
Stanford, California

Michael N. Oxman, MD
Professor of Medicine and Pathology
University of California at San Diego
Staff Physician (Infectious Diseases)
San Diego Veterans Affairs Healthcare System
San Diego, California

Nicole C. Pace, MD
Pediatric Dermatology Fellow
Dartmouth-Hitchcock Medical Center
Lebanon, New Hampshire

Sandra C. Paek, MD
Chief Resident, Department of Dermatology
University of Michigan
Ann Arbor, Michigan

Amy S. Paller, MD
Walter J. Hamlin Professor and Chair of Dermatology
Professor of Pediatrics
Feinberg School of Medicine
Northwestern University
Chicago, Illinois

Renato G. Panizzon, MD
Professor and Chairman, Department of Dermatology
University Hospital
Centre Hospitalier Universitaire Vaudois
University of Lausanne
Lausanne, Switzerland

Hee-Young Park, PhD
Associate Research Professor, Department of Dermatology
Boston University School of Medicine
Boston, Massachusetts

Eva Rawlings Parker, MD
Assistant Professor, Division of Dermatology
Loyola University Medical Center
Maywood, Illinois

Ralf Paus, MD
Professor and Head, Experimental Dermatology
University Hospital Schleswig-Holstein
Campus Luebeck
University of Luebeck
Luebeck, Germany

Michelle T. Pelle, MD
Assistant Clinical Professor, Division of Dermatology
University of California, San Diego
San Diego, California

Lisan S. Peng, MD
Interdepartmental Program in Vascular Biology and Transplantation
Yale University School of Medicine
New Haven, Connecticut

Brent Pennington, MD
Department of Dermatology
Yale University School of Medicine
New Haven, Connecticut

Jennifer B. Perone, MD
Assistant Professor, Department of Dermatology
University of Texas Southwestern Medical School
Dallas, Texas

Margot S. Peters, MD
Rochester, Minnesota

Peter Petzelbauer, MD
Professor, Department of Dermatology
Medical University of Vienna
Vienna, Austria

Tania J. Phillips, MD
Professor, Department of Dermatology
Boston University School of Medicine
Boston, Massachusetts

Gérald E. Piérard, MD, PhD
Chief, Dermatopathology Service
Department of Dermatology
University Hospital of Liège
Liège, Belgium

Claudine Piérard-Franchimont, MD, PhD
Laboratory Chief, Dermatopathology Service
University Hospital of Liège
Liège, Belgium

Bianca Maria Piraccini, MD
Department of Dermatology
University of Bologna
Bologna, Italy

Mark R. Pittelkow, MD
Consultant, Department of Dermatology
Mayo Clinic
Professor, Departments of Dermatology, Biochemistry, and Molecular Biology
Mayo Clinic College of Medicine
Rochester, Minnesota

Gerd Plewig, MD
Professor, Department of Dermatology
Ludwig-Maximilian-University of Munich
Munich, Germany

Jordan S. Pober, MD
Interdepartmental Program in Vascular Biology and Transplantation
Yale University School of Medicine
New Haven, Connecticut

PREFACE

We are proud to present this Seventh Edition of *Fitzpatrick's Dermatology in General Medicine* (DIGM), which has been reorganized and substantially rewritten to reflect the current state of the science, practice, and art of dermatology. More than 50 percent of the text and figures of our 257 chapters are new to this edition, as are 50 percent of the authors. Integration of the basic and clinical science remains the DIGM signature, and the organization of the book is intended to promote understanding of the skin as an adaptive organ that changes throughout the life span. Clinical disease chapters are now grouped within sections by pathogenic and causative mechanism, and each section is introduced by the relevant basic science chapters.

To achieve the goal of making the text truly encyclopedic and readily accessible to readers at all levels of expertise, there are now two versions of the book, a concise printed version and an on-line version. Throughout the text, when additional on-line content is available, the following icon is present in the text to alert the reader: To save space in print, the majority of references are available on-line only. The on-line edition and the on-line references can be found at www.digm7.com. Without sacrificing its focus on the skin as integral to and reflective of overall health, the new edition provides increased emphasis on therapy, dermatologic surgery, and cosmetic dermatology. The on-line edition provides additional detailed text for full and exhaustive coverage of each subject, many additional images, charts, and algorithms, and comprehensive up-to-date literature references.

The layout of DIGM has also changed. Readers will now find an "At a Glance" overview at the beginning of each chapter; algorithms for diagnosis and therapy to expedite decision making; boxes on differential diagnosis; and a wealth of diagrams, charts, and additional new images to enhance understanding of the text. Many more additional images can be found in the electronic version.

The new features and improved aspects of DIGM showcase the wealth of the contributing authors' knowledge. We have endeavored to integrate that knowledge into a single comprehensive and consistent reference that will serve the educational and reference needs of the entire dermatology community. We hope that you will find this goal achieved and use DIGM for this purpose for many years to come.

ACKNOWLEDGMENTS

We are very grateful to the contributing authors who worked closely with us and one another under great time constraints to maintain the excellent standards of DIGM in a radically new format. We are also indebted to our families for their understanding and support, as well as the time with us they gave up during the development of the new edition. Support staff at our institutions who helped us with this edition—Renate Kosma, Jacy Bernal, and Grace Camire—deserve special recognition for their extraordinary level of assistance with manuscripts throughout the process of review and publication. The vibrancy of the new diagrams, algorithms, and charts is the work of Susan Gilbert, CMI, to whom we are grateful for her diligent efforts done within a very difficult schedule. Finally, we wish to acknowledge the excellent guidance and hard work of the McGraw-Hill team, especially Anne M. Sydor, Robert Pancotti, Sherri Souffrance, Charissa Baker, Armen Ovsepyan, Kevin Moran, Helen Parr, and Alexa Blondell.

SECTION 1

GENERAL CONSIDERATIONS

CHAPTER 1

The Epidemiology and Burden of Skin Disease

Martin A. Weinstock
Mary-Margaret Chren

Scientists in health-related fields focus on phenomena at different levels. For laboratory scientists, the focus is at the molecular, cellular, or organ system level; for clinical scientists, the focus is on the patient; and for public health practitioners, the focus is on the population. Epidemiology is the basic science of public health.

Epidemiology has many subdivisions and offshoots. Often the *epidemiology of a disease* in a clinical review refers primarily to its frequency and distribution in the population and estimates of its morbidity and mortality. These data are derived by descriptive epidemiology. Case-control, cohort, and cross-sectional studies may seek to identify risk factors and causes of disease and form the core of analytical epidemiology. Evaluations of public health interventions (experimental epidemiology) constitute the third major branch of classic epidemiology. The basic principles of epidemiology have found broad application in many areas, including understanding the public health implications of naturally occurring and synthetic compounds (molecular epidemiology), the complex interactions of genetic and environmental factors in disease (genetic epidemiology), the formulation of better diagnostic and treatment strategies for patients based on available evidence (clinical epidemiology), and the structuring of health care delivery for better outcomes and greater efficiency (health services research). The reader is referred to other sources for a more detailed discussion of various topics in dermatoepidemiology.[1–3]

TYPES OF EPIDEMIOLOGIC STUDIES

Three of the many types of epidemiologic studies are mentioned here because of their prominence in epidemiologic research. The randomized, controlled trial is a particularly rigorous type of study appropriate to the evaluation of public health interventions. In general, the intervention is performed on a random sample of the study population, and the entire study population is then observed for the occurrence of the outcome in question. The random assignment of intervention allows the more rigorous application of many statistical techniques and reduces the potential for bias. Elimination of biases permits these studies to evaluate the efficacy and impact of an intervention more accurately than trials that do not assign the intervention randomly. Standards for reporting have been published[4] (http://www.consort-statement.org; last accessed June 29, 2006) and adopted by leading dermatology journals to improve assessment of their validity and their use in subsequent systematic reviews[5] (see Chap. 2).

When evaluating risk factors for disease, it is frequently impossible to assign the risk factor randomly. Hence, inference is based on observational studies. In classical cohort studies, a group with exposure to the risk factor and a group without are chosen and observed over time. Occurrences of the study outcome are counted and compared between groups. Although more vulnerable to bias than randomized trials, cohort studies, in which exposure to the risk factor is known well before the study outcome is knowable, avoid potentially serious biases. In a cohort study, the incidence of the study outcome can be measured directly in each group, and the relative risk can be measured directly as the ratio of the incidence between the two groups.

Cohort studies often are quite expensive to conduct because they require following a large population over time and may be impossible if the outcome being studied is uncommon. Hence, observational studies often use the case-control approach, in which cases with the outcome being studied and appropriate controls are investigated to determine their past exposure to the risk factor. Relative risks generally can be estimated by this approach, although incidence of the disorder cannot. Readers are referred to standard texts for more detail regarding epidemiologic study designs.[6] Case-control and cohort study methods in dermatology also have been reviewed.[7–9]

BIAS AND CONFOUNDING

The problem with inference from observational studies is that one may be led to draw erroneous conclusions. In particular, an association that is found between an exposure and a disease may be an artifact due to one or more of the many forms of bias or confounding. Proper inference regarding cause and effect requires understanding these possible artifacts and their potential impacts.[10]

Selection bias occurs when factors that lead to selection of the study population affect the likelihood of the outcomes or exposures evaluated. For example, a case-control study of cutaneous lymphoma may recruit its cases from sources that typically include a high proportion of referred patients. If controls are recruited from a local clinic population, their socio-

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

economic status and location of residence may be substantially different from those of the cases simply due to the method of recruitment. Under these circumstances, an association of cutaneous lymphoma with occupation may be noted. It then becomes important to note that the observed association may be due not to a carcinogenic chemical in the workplace but rather to the method by which cases and controls were selected. Similarly, if one were conducting a cohort study of the effect of breast-feeding on the risk of atopic dermatitis, it would be important to select breast-fed and bottle-fed infants from similar environments.

Information bias occurs when the assessment of exposure or outcome may differ between the groups being compared. People who were exposed to a publicized environmental toxin may be more likely to seek care for minor symptoms or signs (and hence be more likely to be diagnosed and treated) than those who were not so exposed, even if the exposure had no biologic effect. Similarly, people who are diagnosed with a disease may be more likely to recall past exposures than healthy controls.

Confounding occurs when an observed association (or lack thereof) between exposure and disease is due to the influence of a third factor on both the exposure and the disease. For example, people who use sunscreens may have more intense sun exposure than those who do not, and intense sun exposure is one cause of melanoma. Hence, observational studies may mistakenly conclude that sunscreen use is a cause of melanoma when the observed association is due to sunscreen use serving as an indicator of a lifestyle involving intense sun exposure.

CAUSAL INFERENCE

Key issues in the public health arena often must rely on observational data for inferring cause and effect; in these situations, the validity and generalizability of the individual studies and of the totality of the evidence must be carefully examined. The following criteria generally are applied for causal inference when an association is found. Although they are described for inferring causality between an exposure and a disease, they are more generally applicable to epidemiologic causal inference.

Time Sequence

The exposure must precede the disease. This concept is simple and obvious in the abstract but sometimes difficult to establish in practice because the onset of disease may precede the diagnosis of disease by years, and the timing of exposure is often not well defined.

Consistency on Replication

Replication of the observed association is key and provides the strongest evidence if the replications are many and diverse and with consistent results. The diversity of the replications refers to varied contexts as well as to study designs with different potential weaknesses and strengths.

Strength of Association

True causal relationships may be strong (i.e., high relative risk) or weak, but artifactual associations are unlikely to have a high relative risk. If the association between factors x and y is due to the association of both with confounding variable z, the magnitude of the association between x and y always will be less than the magnitude of the association of either with z.

Graded Association

Also described as *biologic gradient*, this criterion refers to an association of the degree of exposure with occurrence of disease, in addition to an overall association of presence of exposure with disease. This dose-response relation may take many forms, as degree of exposure may, for example, refer to intensity, duration, frequency, or latency of exposure.

Coherence

Coherence refers to plausibility based on evidence other than the existence of an association between this exposure and this disease in epidemiologic studies. Coherence with existing epidemiologic knowledge of the disease in question (e.g., other risk factors for the disease and population trends in its occurrence) and other disorders (including but not limited to related disorders) supports inference. Coherence with existing knowledge from other fields, particularly those relevant to pathogenesis, is critically important when those fields are well developed. It may involve direct links, which are preferred, or analogy. Just as observations in the laboratory assume greater significance when their relevance is supported by epidemiologic data, the reverse is equally true.

Experiment

Experimental support is critical when feasible. As noted in Types of Epidemiologic Studies, the strongest inferences derive from results of randomized trials, although other experimental designs and quasi-experimental designs may contribute useful evidence.

More detailed discussions of these issues are available.[11,12]

INVESTIGATION OF DISEASE OUTBREAKS

Although outbreaks of disease vary tremendously, use of a standard framework for investigation is important to address the public health issues efficiently (see Chap. 3). The Centers for Disease Control and Prevention has outlined this framework as a series of 10 steps, which are described in more detail at http://www.cdc.gov.

1. *Preparation*. Before initiating fieldwork, background information on the disease must be gathered, and appropriate interinstitutional and interpersonal contacts should be made.
2. *Confirm the outbreak*. Publicity, population changes, or other circumstances may lead to an inaccurate perception that more cases than expected have occurred. Hence, local or regional data should be sought to confirm the existence of an increased frequency of disease.
3. *Confirm the diagnosis*. Symptoms and signs of persons affected should be determined and laboratory findings confirmed, perhaps with the assistance of reference laboratories.
4. *Establish a case definition, and find cases*. Careful epidemiologic investigation will involve precise and simple case definitions that can be applied in the field. Efforts to find and count additional cases beyond those reported initially is key to defining the scope of the outbreak.
5. *Establish the descriptive epidemiology*. The cases can now be characterized in terms of *time*, including development of an epidemic curve that describes the changes in magnitude of the outbreak; *place*, including mapping the distribution of cases; and *person*, the demographic and potential exposure characteristics of cases.
6. *Develop hypotheses*. On the basis of the data gathered in steps 1 through 5 and the input of other individuals, plausible hypotheses about causality can be developed for further evaluation.

7. *Conduct analytical epidemiologic investigations*. If the data gathered do not yet clearly prove a hypothesis, cohort and case-control investigations can be conducted to verify or disprove the hypotheses.
8. *Revise hypotheses and obtain additional evidence as needed*. Steps 6 and 7 are repeated, each building on prior iterations, to establish the causal chain of events.
9. *Implement control measures*. As soon as the causal chain of events is understood, prevention and control measures are initiated.
10. *Communicate results*. An outbreak investigation is not complete until the results have been appropriately communicated to the relevant communities.

DESCRIPTIONS OF DISEASE IN POPULATIONS: MEASURES OF DISEASE BURDEN

No single number can completely describe the burden of skin disease because that burden has many dimensions and because the term *skin disease* itself is rather ambiguous. Many disorders with substantial morbidity or mortality, such as melanoma or lupus erythematosus, affect multiple organ systems. The degree of skin involvement may vary widely from patient to patient and within the same patient from time to time. Diseases not typically treated by dermatologists, such as thermal burns, often are excluded from estimates of the burden of skin disease even though they primarily involve the skin. In addition, some diseases treated most often by dermatologists may be classified in a different category by funding agencies or others [e.g., melanoma is classified as an oncologic disorder as opposed to a disease of the skin by the National Institutes of Health and by the *International Classification of Diseases,* (http://www.who.int/classifications/apps/icd/icd10online/, accessed June 29, 2006) even though it almost always arises in the skin]. Organ systems are interrelated, and the overlap is sufficiently great that any definition of skin disease is necessarily arbitrary, and any global estimate of the public health burden of these diseases is therefore open to challenge. Typical measures of disease burden are discussed in the following sections.

Mortality

Mortality is a critical measure of disease impact. Death certification is universal in the United States, and the *International Classification of Diseases* code of the underlying cause of each death is recorded. For the year 2002, there were 14,968 deaths reported as due to "skin disease" in the United States, of which most were due to melanoma (Table 1-1). Additional major causes included other skin cancers (primarily keratinocyte carcinomas), infections of the skin, and skin ulcers (primarily decubitus ulcers). Bullous disorders represented about 1 percent of these deaths. The total number of skin disease deaths, of course, depends critically on the definition of skin disease, as noted in Descriptions of Disease in Populations: Measures of Disease Burden.

TABLE 1-1
Skin Disease Deaths, United States, 2002

DISEASE	DEATHS (N)
Cancers	11,031
Melanoma	7514
Genital	1017
Lymphoma	109
Other cancers	2391[a] (primarily basal and squamous cell carcinoma)
Ulcers	1671
Bacterial infections	1283
Bullous disorders	164
Other causes	819
Total	14,968

[a]We estimate that approximately one-half of these are misclassified squamous cell carcinomas arising from mucosal surfaces in the head and neck.[16]
Adapted from http://wonder.cdc.gov/mortICD10J.html (verified June 13, 2006).

In addition to the total number of deaths, mortality typically is expressed as an age-adjusted rate to facilitate comparisons among populations with different age distributions. Statements of age-adjusted rates of mortality (or other results standardized by age) should be accompanied by an indication of the standard used in the adjustment to avoid potentially misleading inferences. For example, when 1998 melanoma mortality rates are estimated using the 2000 U.S. population standard, the result is 50 percent higher than if the 1940 U.S. standard population is used (1.8 vs. 1.2 per 100,000 per year for women and 4.1 vs. 2.7 per 100,000 per year for men). Similarly, when years of potential life lost is reported, the reader must be wary of different definitions that may be applied. In one analysis, a decline in mortality from melanoma was noted by one definition that was not observed with another.[13]

Careful analyses of mortality include assessment of the validity of the data. Melanoma mortality statistics appear to be reasonably accurate.[14,15] However, deaths from keratinocyte carcinomas are overestimated by a factor of 2 (mostly due to the erroneous inclusion of mucosal squamous cell carcinomas of the head and neck region),[16,17] and deaths from cutaneous lymphoma are underestimated by about 40 percent.[15]

Incidence

Incidence refers to the number of new cases of a disorder. Mortality is low for most skin diseases; hence, incidence may be a more useful measure for the assessment of burden of skin disease. However, many features of skin diseases make their incidence difficult to measure. For example, for many skin disorders, there are no diagnostic laboratory tests, and, in fact, some disorders may evade physician diagnosis (e.g., allergic reactions). Incidence for reportable communicable diseases in the United States is published periodically based on reports to health departments, although under-reporting of skin diseases due to failure to present for medical care or to misdiagnosis is a concern (Table 1-2). Incidences of melanoma and cutaneous lymphoma have been published based on data from a system of nationwide cancer registries, yet under-reporting remains a potential concern with these data.[18,19] Special surveys have been conducted to estimate incidence of other disorders, such as keratinocyte carcinomas, although a system of sentinel registries would be required for nationwide assessment.[20] For some diseases unlikely to evade medical detection due to their severity, such as toxic epidermal necrolysis, efforts to estimate incidence have met with considerable success.[21,22] Specific contexts that permit more accurate incidence estimates include the workplace; for example, where occupational skin disease is a prevalent problem.[23]

Cohort Patterns

Cohort patterns of changes in mortality or incidence typically are observed when exposures determined in childhood predict frequency of disease throughout the life span. A classic example is melanoma mortality, for which sun exposure in childhood is an important determinant. A birth cohort is defined as the group of individuals born

TABLE 1-2
New Cases of Selected Reportable Diseases in the United States

	1940	1950	1960	1970	1980	1990	2000	2005

within a defined (e.g., 10-year) period. Melanoma mortality generally increases as a power function of age within a birth cohort. Until recent decades, each successive birth cohort had higher risk than its predecessor; hence, the curves of mortality versus age were shifted upward. Thus the cross-sectional relationship of mortality versus age and the increase in mortality risk during most of the twentieth century followed a cohort pattern. For many countries in the past several decades a decline in melanoma mortality has been observed in younger age groups despite an increase in older age groups, suggesting a lower baseline in these mortality-versus-age curves for recent cohorts and hence a likely future decline in overall melanoma mortality.

Prevalence

Prevalence refers to the proportion of the population affected by a disorder. Because many skin diseases are nonlethal yet chronic, prevalence is a particularly important measure of frequency in dermatology. Population-based data on prevalence of skin disease for the United States were obtained in the first Health and Nutrition Examination Survey, which was conducted in the early 1970s.[24] Despite its limitations, this study was notable because the sample was representative of the general U.S. population, the number surveyed was large (over 20,000), and the entire surveyed population was examined by physicians (primarily dermatology residents), so the resulting estimates were not dependent on patients' ability or inclination to seek medical care. Indeed, one of the findings of the survey was that nearly one-third of those examined had one or more skin conditions judged to be significant enough to merit a visit to a physician. The most common conditions and their age- and gender-specific prevalences are indicated in Table 1-3 and Fig. 1-1. A similar survey in the United Kingdom of over 2000 Londoners in 1975 noted that almost one-quarter of adults had a skin condition serious enough to warrant medical care.[25] Other efforts have focused on obtaining prevalence estimates of specific conditions with special surveys.[26,27]

Lifetime Risk

Lifetime risks for certain disorders are quoted commonly, although their validity can be questioned. Lifetime risk can be measured only in retrospect, and even then it reflects competing causes of mortality in addition to incidence. It is commonly quoted for disorders such as cutaneous malignancies that are changing substantially in incidence, yet those changes are frequently ignored in its calculation, and, in any case, projections of future changes are quite speculative and may be misleading.[28]

Number of Physician Visits

Number of physician visits for a condition is one practical measure of its frequency that may reflect its incidence, prevalence, and severity, as well as access to health care. Table 1-4 lists frequencies of dermatologist and other physician outpatient visits for some of the most common skin conditions. A

TABLE 1-3
Prevalence of Skin Conditions—United States, 1971–1974[a]

	Male	Female	Both Sexes
• Dermatophytosis	131	34	81
• Acne (vulgaris and cystic)	74	66	70
• Seborrheic dermatitis	30	26	28
• Atopic dermatitis/eczema	20	18	19
• Verruca vulgaris	9	6	8
• Malignant tumors	6	5	6
• Psoriasis	6	5	6
• Vitiligo	6	4	5
• Herpes simplex	4	5	4

feature of this measure of disease frequency is its direct relation to expenditures for care of the disease.

Other Measures of Morbidity: Conceptual Issues

The consequences of skin disease for a population may be difficult to determine comprehensively because these conditions most often do not affect survival.[29] Furthermore, the most important gauges of skin disease status and progression (i.e., the physical examination and patients' reports) are difficult to measure and compile. For example, a patient with psoriasis may have thickening and scaling of the palms (a bodily impairment), which affects his or her functioning (e.g., use of the hands), activities (role at work), and quality of life. Moreover, the challenges in measuring these complex constructs are further compounded because people understand and value these aspects of health very differently because of age, gender, cultural conceptions, or access to health care. In fact, the measurement of nonfatal consequences of disease is the subject of much international scientific and political attention (http://www3.who.int/icf/icftemplate.cfm, accessed July 3, 2006).

A crucial point for skin diseases is that a patient's experiences of effects of skin disease on his or her activities and well-being are important for determining the overall consequences of that disease. These experiences may not be assessed with global measures that focus on single aspects of health. For example, skin diseases that are visible and affect appearance may result in social stigma and mood changes, which would not be measured with metrics that are based on dysfunction.[30]

TABLE 1-4
Visits to Non-Federal Office-Based Physicians in the United States, 2003[a]

	Type of Physician		
Diagnosis	Dermatologist[b]	Other	All Physicians
Acne Vulgaris	3772 (12.7%)	[c]	4402 (0.5%)
Eczematous dermatitis	2452 (8.2%)	5676 (0.7%)	8128 (0.9%)
Warts	1400 (4.7%)	1567 (0.2%)	2967 (0.3%)
Skin cancer	2103 (7.1%)	1459 (0.2%)	3562 (0.4%)
Psoriasis	1100 (3.7%)	[c]	1268 (0.1%)
Fungal infections	[c]	2104 (0.2%)	2555 (0.3%)
Hair disorders	772 (2.6%)	[c]	1690 (0.2%)
Actinic keratosis	2653 (8.9%)	[c]	3031 (0.3%)
Benign neoplasm of the skin	2791 (9.4%)	[c]	3935 (0.4%)
All disorders	29,801 (100%)	876,222 (100%)	906,023 (100%)

Other Measures of Morbidity: Issues in Quantification

Like all assays, measures of the nonfatal consequences of diseases must have certain characteristics of accuracy.[31] For example, they must be *reliable* in that the variability in results among subjects who truly differ should be greater than the variability when a stable subject is examined repeatedly. The measures must have evidence of *validity*, which refers to the extent to which an instrument measures what it is supposed to measure and does not measure something else. Finally, health outcome measures also must demonstrate *responsiveness*, the ability to detect clinical change. In general, the accuracy of measures of disease status and morbidity in dermatology has not been evaluated adequately.[32] Furthermore, even when a validated instrument exists, the clinical significance of scores or changes in scores often cannot be judged until the tool is used widely and scores are available for many patients with disease of varying severity. Finally, a significant challenge is developing a consensus among dermatologists about the specific clinical features of an individual disease that are important to include in such measures. For example, criteria for clinically important improvement have been developed for some rheumatologic conditions[33] that, like skin diseases, are chronic and are best assessed using clinical rather than laboratory criteria.

Impairment

The extent to which a specific skin disease disrupts the skin itself is related both to the percentage of body surface area involved and to physical signs of the eruption, such as the amount of induration and the degree of scale. Given the pleomorphism of skin eruptions and lesions, most dermatologic severity-of-disease measures are disease-specific. Among the most studied instruments to measure clinical severity of disease are the Psoriasis Area and Severity Index (PASI)[34] and the Severity Scoring of Atopic Dermatitis (SCORAD) index.[35] With the PASI, severity of disease is assessed by judgment of the degree of involvement of four body regions with signs of erythema, induration, and des-

quamation. The SCORAD index combines an assessment of disease area with six clinical signs of disease intensity (scales to measure pruritus and sleep loss also can be included). These instruments share certain problems; for example, estimates of body surface area are often unreliable,[36] and investigators (and patients) may not agree that the selected clinical signs represent the important features of disease severity.[37]

Functioning and Quality of Life

Substantial progress has been made in the development and testing of patients' reports of the effects of their skin diseases on their activities and quality of life. Several generic instruments are available to measure skin-related quality of life associated with dermatologic disease of any sort.[38–41] Data continue to be accumulated about the performance of these instruments (including the use of sophisticated psychometric methods[42] and the interpretation of their scores.[43] An important conclusion from these studies is that correlations between the quality-of-life effects of skin diseases and their clinical severity as assessed by physicians are modest at best and may in fact be quite low. This finding is also typical of many nondermatologic diseases and implies that a comprehensive assessment of patients with skin disease should include measurement of clinical severity as well as its effects on quality of life.[44]

Utilities

A utility is a numeric measure of the value a patient places on a given health state compared with other health states. In the measurement of utilities, a variety of procedures are used (such as visual analog scales and time tradeoff exercises) to assign a numerical value (or utility) to health states. This value reflects patients' preferences for the health states, in which 1.0 represents perfect health and 0.0 represents death. Utilities are advantageous because they permit the incorporation of patient preferences into medical care decisions. Also, because they describe improvements in morbidity with a single weighted metric, utilities are used for the evaluation of complex tradeoffs such as the calculation of cost-effectiveness, in which the costs of treatments are compared with the values of the health states they make possible. Utilities are controversial, however, because they can be difficult to measure and can vary widely among patients in unpredictable ways. An increasing number of studies exist that formally measure utilities of patients with skin diseases.[45]

Costs

Costs of skin disease depend on the perspective from which they are measured, because the costs to insurers and patients may be quite different from the overall cost to society. Also, because most skin diseases are chronic and are cared for in the outpatient setting, estimation of both their monetary and intangible costs is difficult. A recent study estimated the overall direct and indirect cost to payers, patients, and society of 22 skin diseases.[46] In addition, costs for individual skin conditions have been calculated, and therapies have been evaluated in relation to their benefits and effectiveness.[47,48]

QUALITY OF CARE IN DERMATOLOGY

Health services research uses many of the scientific methods from epidemiology, clinical epidemiology, and the quantitative social sciences to study and improve the quality of health care. From the perspective of health services research, the processes involved in the provision of health care, as well as the particular therapeutic interventions and patient and provider characteristics, are all potentially important determinants of the quality of care. Dermatologic health services research is still new, and much attention has focused on studies of the effectiveness of care (i.e., outcomes of health care as it is usually practiced). To inform standard care, however, efficacy of interventions is also important (i.e., the results of interventions implemented in the idealized circumstances of a randomized clinical trial). Many of the examples cited earlier demonstrate a sharpened focus in dermatology on accurate measurement of the clinical encounter. This capacity to measure the progress of chronic diseases and their care will permit rigorous efforts to evaluate and improve the quality of that care.

CHAPTER 2

Evidence-Based Dermatology

Michael Bigby
Rosamaria Corona
Moyses Szklo

BRIEF HISTORY OF EVIDENCE-BASED MEDICINE

Hundreds of randomized controlled clinical trials were conducted between 1950 and the 1970s. However, their results were not catalogued or used systematically to inform medical decision making. In 1972 Archie Cochrane, a British epidemiologist and physician, published his response to being asked to evaluate the effectiveness of the British National Health Service in delivering health care to the population of the United Kingdom. In his analysis he concluded that medical science was poor at distinguishing interventions that were effective from those that were not and that physicians were not using available evidence from clinical research to inform their decision making.[6] See http://www.cochrane.org/cochrane/archieco.htm for more information on Archie Cochrane.

Groups of like-minded epidemiologists and physicians responded to Archie Cochrane's challenge by examining the methods by which medical decisions and conclusions were reached and proposed an alternative approach based on finding, appraising, and using available data from clinical research involving intact patients.[7] In 1985 Sackett et al. published *Clinical Epidemiology: A Basic Science for Clinical Medicine*, which detailed the rationale and techniques of this evidence-based approach.[7] These authors and others reduced the rules of evidence to a small subset of principles that were eas-

EVIDENCE-BASED MEDICINE AT A GLANCE

- Evidence-based medicine (EBM) is the use of the best current evidence in making decisions about the care of individual patients.
- EBM is predicated on asking clinical questions, finding the best evidence to answer the questions, critically appraising the evidence, applying the evidence to the treatment of specific patients, and saving the critically appraised evidence.
- The EBM approach is most appropriate for frequently encountered conditions.
- Results from well-designed clinical studies involving intact patients are at the pinnacle of the hierarchy of evidence used to practice evidence-based medicine.
- Recommendations about treatment, diagnosis, and avoidance of harm should take into account the validity, magnitude of effect, precision, and applicability of the evidence on which they are based.

ier to teach and to understand, and reintroduced the concept in 1992.[8] They named this technique *evidence-based medicine* (EBM). It was defined as the conscientious, explicit, and judicious use of the best current evidence in making decisions about the care of individual patients.[8] Whereas making decisions about therapy has been the primary focus of EBM, its principles have been extended to diagnosis, prognosis, avoidance of the harmful effects of interventions, determination of cost effectiveness, and economic analyses.

The introduction of EBM was met with considerable hostility. It was perceived as cookbook medicine, old hat, too restrictive, and an insult to those already trying to practice good medical care. The definition was softened to include the integration of independent clinical expertise, best available external clinical evidence from systematic research, and the patient's values and expectations.[2]

The Cochrane Collaboration was formed to some extent in response to Archie Cochrane's challenge to generate critical summaries, organized by specialty or subspecialty and updated periodically, of all relevant randomized controlled trials.[9] Created and maintained through the collaborative efforts of volunteers, the Cochrane Library is an impressive and useful compendium of systematic reviews, abstracts of systematic reviews, and the Cochrane Central Register of Controlled Trials, a database of over 473,000 controlled clinical trials (http://www3.interscience.wiley.com/cgi-bin/mrwhome/106568753/HOME). The Cochrane Library is the most complete and best index database of randomized controlled clinical trials and controlled clinical trials and is the best and most efficient place to find evidence about therapy.

The acceptance of EBM in the specialty of dermatology has been slow and reluctant. The term and principles are understood by few and misunderstood by many. EBM is perceived as an attempt to cut costs, impose rigid standards of care, and restrict dermatologists' freedom to exercise individual judgment. Practicing EBM in dermatology is hampered by the continued belief among dermatologists that clinical decisions can be guided by an understanding of the pathophysiology of disease, logic, trial and error, and nonsystematic observation.[1,10] It is hampered also by a lack of sufficient data in many areas. As with EBM in general, therapy is often primarily emphasized; however, evidence-based approaches to diagnosis and avoidance or evaluation of harm are also important considerations.

WHAT IS "THE BEST EVIDENCE"?

Practicing EBM is predicated on finding and using the best evidence. Potential sources of evidence include knowledge regarding the etiology and pathophysiology of disease, logic, personal experience, the opinions of colleagues or experts, textbooks, articles published in journals, and systematic reviews. An important principle of EBM is that the quality (strength) of evidence is based on a hierarchy. The precise hierarchy of evidence depends on the type of question being asked (Table 2-1).[11] This hierarchy consists of results of well-designed studies (especially if the studies have findings of similar magnitude and direction, and if there is statistical homogeneity among studies), results of case series, expert opinion, and personal experience, in descending order.[9,10] The hierarchy was created to encourage the use of the evidence that is most likely to be accurate and useful in clinical decision making. The ordering in this hierarchy has been widely discussed, actively debated, and sometimes hotly contested.[12]

A systematic review is an overview that answers a specific clinical question; contains a thorough, unbiased search of the relevant literature; uses explicit criteria for assessing studies; and provides a structured presentation of the results. A systematic review that uses quantitative methods to summarize results is a meta-analysis.[13,14] A meta-analysis provides an objective and quantitative summary of evidence that is amenable to statistical analysis.[13] Meta-analysis is credited with allowing the recognition of important treatment effects by combining the results of small trials that individually lacked the power to demonstrate differences among treatments. For example, the benefits of intravenous streptokinase in treating acute myocardial infarction were recognized by means of a cumulative meta-analysis of smaller trials at least a decade before this treatment was recommended by experts and before it was demonstrated to be efficacious in large clinical trials.[15,16] Meta-analysis has been criticized because of the discrepancies between the results of meta-analysis and those of large clinical trials.[16–19] For example, results of a meta-analysis of 14 small studies of the use of calcium to treat preeclampsia showed a benefit to treatment, whereas a large trial failed to show a treatment effect.[16] The frequency of such discrepancies ranges from 10 percent to 23 percent.[16] Discrepancies can often be explained by differences in treatment protocols, heterogeneity of study populations, or changes that occur over time.[16]

Publication bias is an important concern regarding systematic reviews. It results when factors other than the quality of the study are allowed to influence its acceptability for publication. Several studies have shown that factors such as sample size, direction and statistical significance of findings, and investigators' perceptions of whether the findings are "interesting" are related to the likelihood of publication.[20,21]

For example, in a study by Dickersin et al., the reasons given by investigators that results of completed studies were not published included "negative results" (28 percent), "lack of interest" (12 percent), and "sample size problems" (11 percent).[20] Results of studies with small samples are less likely to be published, especially if they have negative results.[20,21] This type of publication bias jeopardizes one of the main goals of meta-analysis (i.e., an increase in power through pooling of the results of small studies). Creation of study registers and advance publication of research designs have been proposed as ways to prevent publication bias.[22,23] Publication bias can be detected by using a simple

TABLE 2-1
Grades of Evidence[a,b]

Grade	Level of Evidence	Therapy/Harm	Diagnosis
A	1a	Systematic review (with homogeneity[c]) of RCTs	Systematic review (with homogeneity) of level 1 (see column 2) diagnostic studies, or a CPG validated on a test set.
	1b	Individual RCT (with narrow confidence intervals)	Independent blind comparison of an appropriate spectrum of consecutive patients, all of whom have been evaluated by both the diagnostic test and the reference standard.
	1c	All or none[d]	Very high sensitivity or specificity
B	2a	Systematic review (with homogeneity) of cohort studies	Systematic review (with homogeneity) of level 2 or better (see column 2) diagnostic studies
	2b	Individual cohort study [including low-quality RCT (e.g., < 80% follow-up)]	Independent blind comparison but either in non-consecutive patients or confined to a narrow spectrum of study individuals (or both), all of whom have been evaluated by both the diagnostic test and the reference standard or a diagnostic CPG not validated in a test set
	2c	"Outcomes" research[e]	
	3a	Systematic review (with homogeneity) of case-control studies	Systemic review (with homogeneity) of 3b (see column 2) and better studies
	3b	Individual case-control study	Independent blind comparison of an appropriate spectrum, but the reference standard was not applied to all study patients
C	4	Case series (and poor-quality cohort and case-control studies)	Reference standard was not applied independently or not applied blindly
D	5	Expert opinion without explicit critical appraisal, or based on physiology, bench research, or logical deduction	

CPG = clinical practice guideline, a systematically developed statement designed to help practitioners and patients make decisions about appropriate health care for specific clinical circumstances; RCT = randomized controlled trial.
[a]These levels were generated in a series of iterations among members of the NHS R&D Centre for Evidence-Based Medicine (Chris Ball, Dave Sackett, Bob Phillips, Brian Haynes, and Sharon Straus). For details see Levels of Evidence and Grades of Recommendation, http://www.cebm.net/levels_of_evidence.asp, May 2001.
[b]Recommendations based on this approach apply to "average" patients and may need to be modified in light of an individual patient's unique biology (e.g., risk, responsiveness) and preferences about the care he or she receives.
[c]*Homogeneity* means lacking variation in the direction and magnitude of results of individual studies.
[d]*All or none* means interventions that produced dramatic increases in survival or outcome, such as the use of streptomycin to treat tubercular meningitis.
[e]Outcomes research includes cost-benefit, cost-effectiveness, and cost-utility analysis.

graphic test (funnel plot) or by several other statistical methods."[24,25] In addition, for many diseases, the studies published are dominated by drug company–sponsored trials of new, expensive treatments. The need for studies to answer the clinical questions of most concern to practitioners is not addressed because sources of funding are inadequate.

Not all systematic reviews and meta-analyses are equal. A systematic review can be only as good as the clinical trials that it encompasses. The criteria for critically appraising systematic reviews and meta-analyses are shown in Table 2-2. Detailed explanations of each criterion are available.[13,26]

The type of clinical study that constitutes best evidence is determined by the category of question being asked. Questions about therapy and prevention are best addressed by randomized controlled trials.[13,26–28] Questions about diagnosis are best addressed by cohort studies.[13,26,29,30] Cohort studies, case-control studies, and post-marketing surveillance studies best address questions about harm.[13,26,31] Randomized controlled trials are a good source of evidence about the harmful effects of interventions for adverse events that occur frequently but not for rare adverse events. Case reports are often the first line of evidence regarding rare adverse events, and sometimes they are the only evidence. Methods for assessing the quality of each type of evidence are available.[13,26]

With regard to questions about therapy and prevention, the randomized controlled clinical trial has become the gold standard for determining treatment efficacy. Thousands of randomized controlled trials have been conducted. Studies have demonstrated that failure to use randomization or to provide adequate concealment of allocation resulted in larger estimates of treatment effects, caused predominantly by a poorer prognosis in non–randomly selected control groups than in randomly selected control groups.[32] However, studies comparing randomized and nonrandomized clinical trials of the same interventions have reached disparate and controversial results.[32–34] Some found that observational studies reported stronger treatment effects than randomized controlled trials.[32] Others found that the results of well-designed observational studies (with either a cohort or a case-control design) do not systematically overestimate the magnitude of the effects of treatment compared with randomized controlled trials on the same topic.[33,34] Examining the details of the controversy leads to the following limited conclusions. Trials using historical controls do yield larger estimates of treatment effects than do randomized controlled trials. Large, inclusive, fully blinded randomized controlled trials are likely to provide the best possible evidence about effectiveness.[12,35,36]

Although personal experience is an invaluable part of becoming a competent physician, the pitfalls of relying too heavily on personal experience have been widely documented.[7,37,38] Nisbett and Ross extensively reviewed people's ability to draw inferences from personal experience and describe several of these pitfalls.[39] These include the following:

- Overemphasis on vivid anecdotal occurrences and underemphasis on significant statistically strong evidence
- Bias in recognizing, remembering, and recalling evidence that supports pre-existing knowledge structures (e.g., ideas about disease etiology and pathogenesis) and parallel failure to recognize, remember, and recall evidence that is more valid

TABLE 2-2
Critical Appraisal of a Systematic Review

- Are the results of this systematic review valid?
  - Did the review address a focused clinical question?[a]
  - Were the criteria used to select articles for inclusion appropriate?[a]
  - Is it unlikely that important relevant studies were missed?[b]
  - Was the validity of the included studies appraised?[b]
  - Were assessments of studies reproducible?[b]
  - Were the results similar from study to study?[b]
- Are the valid results of this systematic review important?
  - What are the overall results of the review?
  - How precise were the results?
- Can you apply this valid, important evidence in caring for your patient?
  - Can the results be applied to your patient's care?
  - Were all clinically important outcomes considered?
  - Are the benefits worth the harms and costs?

[a]Primary guides.
[b]Secondary guides.
From Sackett D et al: *Evidence-Based Medicine: How to Practice and Teach EBM.* Edinburgh, Churchill Livingstone, 1996.

- Failure to accurately characterize population data because of ignorance of statistical principles, including sample size, sample selection bias, and regression to the mean
- Inability to detect and distinguish statistical association and causality
- Persistence of beliefs in spite of overwhelming contrary evidence

Nisbett and Ross provide examples from controlled clinical research. Simple clinical examples abound. Physicians may remember patients whose condition improved, often assume that patients who did not return for follow-up got better, and conveniently forget the patients whose condition did not improve. A patient treated with a given medication may develop a severe life-threatening reaction. On the basis of this single undesirable experience, the physician may avoid using that medication for many future patients, although on average it may be more efficacious and less toxic than the alternative treatments that the physician chooses. Few physicians keep adequate, easily retrievable records to codify results of treatments with a particular agent or treatments of a particular disease; and even fewer actually carry out analyses. Few physicians make provisions for tracking those patients who are lost to follow-up. Therefore, statements made about a physician's "clinical experience" may be biased. Finally, for many conditions, a single physician sees far too few patients with the given disorder to allow reasonably firm conclusions to be drawn about the response to treatments. For example, suppose that a physician has treated 20 patients with lichen planus using tretinoin and found that 12 (60 percent) had an excellent response. The confidence interval for this response rate (i.e., the true response rate for this treatment in the larger population from which this physician's sample was obtained) ranges from 36 percent to 81 percent. Thus the true response rate might well be substantially less (or more) than the physician concludes from personal experience.

Expert opinion can be valuable, particularly when the disorder is a rare condition in which the expert has the most experience or when other forms of evidence are not available. However, several studies have demonstrated that expert opinion often lags significantly behind conclusive evidence.[7] Experts suffer from relying on bench research, pathophysiology, and treatments based on logical deduction from pathophysiology as well as from the same pitfalls noted for reliance on personal experience. Experts should be aware of the quality of the evidence that exists.

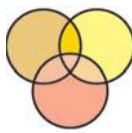
It is widely believed that clinical decisions can be made on the basis of an understanding of the etiology and pathophysiology of disease and logic.[1,10] This paradigm is problematic because the accepted hypothesis regarding the etiology and pathogenesis of disease changes over time. Therefore, the logically deduced treatments change over time. For example, in the last 20 years, hypotheses about the cause of psoriasis have shifted from a disorder of keratinocyte proliferation and homeostasis, to abnormal signaling of cyclic adenosine monophosphate, to aberrant arachidonic acid metabolism, to aberrant vitamin D metabolism, to the current favorite, T-cell–mediated autoimmune disease. Each of these hypotheses spawned logically deduced treatments. The efficacy of many of these treatments has been substantiated by rigorous controlled clinical trials, but others are used even in the absence of systematically collected observations. Therefore, we have many options for treating patients with severe psoriasis (e.g., ultraviolet B radiation, narrow-band ultraviolet B radiation, Goeckerman treatment, psoralen plus ultraviolet A radiation, methotrexate, cyclosporin, and the biologics) and mild to moderate psoriasis (e.g., anthralin, topical corticosteroids, calcipotriene, and tazarotene) (see Chap. 18). However, we lack a clear sense of which is best, in what order they should be used, and in what combinations.[10,40] Treatments based on logical deduction from pathophysiology may have unexpected consequences. For example, the observation that antiarrhythmic drugs could prevent abnormal ventricular depolarization after myocardial infarction logically led to their use to prevent sudden death after myocardial infarction. However, a randomized controlled clinical trial showed increased mortality among patients treated with antiarrhythmic drugs than among those given a placebo.[28,41,42]

Textbooks can be valuable sources of evidence, particularly for rare conditions and for conditions for which the evidence does not change rapidly over time. However, textbooks have several well-documented limitations. They tend to reflect the biases and shortcomings of the experts who write them. Because of the way they are written, produced, and distributed, most are approximately 2 years out of date at the time of publication. Most textbook chapters are narrative reviews that do not consider the quality of the evidence reported.[7,13]

FINDING THE BEST EVIDENCE

The ability to find the best evidence to answer clinical questions is crucial for the practice of EBM. Finding evidence requires access to electronic search tools, searching skills, and availability of relevant data. Evidence about therapy is the easiest to find. The most useful sources for locating the best evidence about treatment include the following:

- The Cochrane Library
- The MEDLINE (Medical Literature Analysis and Retrieval System On-Line) and EMBASE (*Exerpta Medica Database*) databases
- Primary journals
- Secondary journals
- Evidence-based dermatology and EBM books
- The National Guideline Clearinghouse (http://www.guideline.gov/)



- The National Institute for Health and Clinical Excellence (http://www.nice.org.uk)

The Cochrane Library contains the Cochrane Database of Systematic Reviews, the Database of Abstracts of Reviews of Effectiveness, the Cochrane Central Register of Controlled Trials, and the Health Technology Assessment Database, among other databases (http://www3.interscience.wiley.com/cgi-bin/mrwhome/106568753/HOME). Volunteers write the systematic reviews in the Cochrane Library according to strict guidelines developed by the Cochrane Collaboration. Issue 1, 2007, of the Cochrane Library contained 4655 completed systematic reviews. The number of reviews of dermatologic topics is steadily increasing.

The Database of Abstracts of Reviews of Effectiveness contains abstracts of systematic reviews published in the medical literature. It provides abstracts and bibliographic details on 5931 published systematic reviews. The Database of Abstracts of Reviews of Effectiveness is the only database to contain abstracts of systematic reviews that have been assessed for quality. Each abstract includes a summary of the review together with a critical commentary about the overall quality. The Health Technology Assessment Database consists of completed and ongoing health technology assessments (studies of the medical, social, ethical, and economic implications of health care interventions) from around the world. The aim of the database is to improve the quality and cost effectiveness of health care.

The Cochrane Library is the best source for evidence about treatment. It can be easily searched using simple Boolean combinations of search terms as well as more sophisticated search strategies. The Cochrane Database of Systematic Reviews, Database of Abstracts of Reviews of Effectiveness, Central Register of Controlled Trials, and Health Technology Assessment Database can be searched simultaneously.

The Cochrane Library is available on CD-ROM by personal or institutional subscription and on the World Wide Web from Wiley InterScience (http://www3.interscience.wiley.com/cgi-bin/mrwhome/106568753/HOME). Subscribers to the Cochrane Library are provided with quarterly updates. The Cochrane Library is offered free of charge in many countries by national provision and by many medical schools in the United States. It should be available at your medical library.

The second best method for finding evidence about treatment and the most useful source for finding most other types of best evidence in dermatology is searching the MEDLINE database by computer.[44,45] MEDLINE is the National Library of Medicine's bibliographic database covering the fields of medicine, nursing, dentistry, veterinary medicine, the health care system, and the pre-clinical sciences. The MEDLINE database contains bibliographic citations and author abstracts from approximately 5000 current biomedical journals published in the United States and 80 foreign countries. The database contains approximately 15 million records dating back to the mid-1950s.[46]

MEDLINE searches have inherent limitations that make their reliability less than ideal.[45] Specific search strategies, or filters, have been developed to aid in finding relevant references and excluding irrelevant references to locate the best evidence about diagnosis, therapy, prognosis, harm, and prevention.[48]

These filters have been incorporated into the PubMed Clinical Queries search engine of the National Library of Medicine and are available at http://www.ncbi.nlm.nih.gov/entrez/query/static/clinical.shtml.[49]

The use of PubMed Clinical Queries (http://www.ncbi.nlm.nih.gov/entrez/query/static/clinical.shtml) is the preferred method for searching the MEDLINE database to locate the best clinically relevant evidence. It can be used freely by anyone with Internet access.

More than 20 vendors provide MEDLINE systems on-line and on CD-ROM. Haynes et al.[50] compared several vendors of MEDLINE on-line and on CD-ROM to determine which system was best in terms of locating relevant articles and excluding irrelevant articles. As assessed from combined rankings for the highest number of relevant and the lowest number of irrelevant citations retrieved, SilverPlatter MEDLINE clinical journal subset on CD-ROM performed best for librarian searches, whereas the PaperChase on-line system worked best for clinician searches. When judged by cost per relevant citation, Dialog's Knowledge Index performed best for both librarian and clinician searches.[50]

EMBASE is *Excerpta Medica*'s database covering pharmacology and biomedical specialties.[13] EMBASE has better coverage of European and non–English language sources and may be more up to date.[13] The overlap in journals covered by MEDLINE and EMBASE is approximately 34 percent (range, 10 percent to 75 percent depending on the subject).[51,52]

EMBASE is available on-line through the major database vendors [e.g., DataStar, Dialog, DIMDI (Deutschen Institut für Medizinische Dokumentation und Information), Ovid Online, and STN]. For more information, see http://www.elsevier.com/wps/find/bibliographicdatabasedescription.cws_home/523328/description#description. Personal and institutional subscriptions are available.

Structured abstracts of articles are published in secondary journals (e.g., the Evidence-Based Dermatology section of *Archives of Dermatology*). The articles are strictly selected on the basis of methodologic quality and are accompanied by commentary putting the information in clinical perspective. *Evidence-Based Dermatology* (Williams H et al., editors, Oxford, Blackwell Publishing Ltd., 2002) is a compendium of "mini" systematic reviews of the treatment of skin diseases. *Clinical Evidence* is a compendium of evidence on the effects of common clinical interventions that is updated every 6 months. It is available through the American College of Physicians and the British Medical Association.

Full-text versions of many primary journals are now available on the Internet. Available vendors include DataStar, Dialog, DIMDI, Ovid Online, and STN, among others. The National Guideline Clearinghouse maintains a database of guidelines for the treatment of disease written by panels of experts following strict criteria for evidence. The database is accessible through the Internet (http://www.guidelines.gov). Current coverage of dermatologic topics is limited.

The National Institute for Health and Clinical Excellence produces guidance on public health, health technologies, and clinical practice based on the best available evidence. It is accessible on-line at http://www.nice.org.uk.

CRITICALLY APPRAISING THE EVIDENCE

After evidence is found, the next step in practicing EBM is critically appraising the quality of the evidence and determining the magnitude of effects and the precision of the evidence. The criteria for critically appraising papers about treatment, diagnostic tests, and harmful effects of exposures are shown in Tables 2-3, 2-4, and 2-5, respectively.[13,26] Papers that meet

TABLE 2-3
Critical Appraisal of a Paper About Therapy

Are the results of this single preventive or therapeutic trial valid?
- Was the assignment of patients to treatments randomized and was the randomization list concealed?
- Were all patients who entered the trial accounted for at its conclusion and were their data analyzed in the groups to which they were randomly assigned?
- Were patients and clinicians kept blind as to which treatment was being received?
- Aside from the experimental treatment, were the groups treated equally?
- Were the groups similar at the start of the trial?

Are the valid results of this randomized trial important?
- Calculations:

Intervention Response Rate (IRR)	Comparison (Intervention) Response Rate (CRR)	Difference in Response Rates (DRR) (IRR – CRR)	Number Needed to Treat (NNT) (1/DRR)

- What is the 95% confidence interval of the difference in response rates (DRR)?[a]
- What is the 95% confidence interval of the NNT?[b]

Can you apply this valid, important evidence in caring for your patient?
- Do these results apply to your patient?
  - Is your patient so different from those in the trial that its results can't help you?
  - How great would the potential benefit of therapy actually be for your individual patient?
- Do the regimen and its consequences satisfy your patient's values and preferences?
  - Do your patient and you have a clear assessment of your values and preferences?
  - Are this regimen and its consequences consistent with them?

[a]The 95% confidence interval of the DRR is from

$$\text{DRR} - 1.96 \times \text{SE to DRR} + 1.96 \times \text{SE}$$

$$\text{where SE (standard error)} = \sqrt{\frac{IRR\ (1 - \text{IRR})}{\text{No. intervention patients}} + \frac{CRR\ (1 - CRR)}{\text{No. comparison patients}}}$$

[b]The 95% confidence interval of the NNT = 1/limits on the confidence interval of its DRR.
From Sackett D et al: *Evidence-Based Medicine: How to Practice and Teach EBM.* Edinburgh, Churchill Livingstone, 1996.

TABLE 2-4
Critical Appraisal of a Paper About a Diagnostic Test

Are the results of this diagnostic study valid?
- Was there an independent, blind comparison with a reference (gold) standard of diagnosis?
- Was the diagnostic test evaluated in an appropriate spectrum of patients (like those in whom it would be used in practice)?
- Was the reference standard applied regardless of the diagnostic test result?

Are the valid results of this diagnostic study important?
- Calculations:

		Target Disorder	
		Present	Absent
Diagnostic Test Result	Positive	a	b
	Negative	c	d

- Sensitivity = a/(a + c)
- Specificity = d/(b + d)
- Likelihood ratio for a positive test result = [a/(a + c)]/[b/(b + d)] = sensitivity/(1 – specificity)
- Likelihood ratio for a negative test result = [c/(a + c)]/[d/(b + d)] = (1 – sensitivity)/specificity

Can you apply this valid, important evidence about a diagnostic test in caring for your patient?
- Is the diagnostic test available, affordable, accurate, and precise in your setting?
- Can you generate a clinically sensible estimate of your patient's pre-test probability (from practice data, from personal experience, from the report itself, or from clinical speculation)?
- Will the resulting post-test probabilities affect your management and help your patient? (Could it move you across a test-treatment threshold? Would your patient be a willing partner in carrying out your recommendations?)
- Would the consequences of the test help your patient?

From Sackett D et al: *Evidence-Based Medicine: How to Practice and Teach EBM.* Edinburgh, Churchill Livingstone, 1996.

these criteria are more likely to provide information that is accurate and useful in the care of patients.[13,26] A detailed explanation of each criterion[13,26] and an example involving a patient with a dermatologic complaint are available.[45]

Critically appraising evidence consists of the three steps of determining whether the results have each of the following characteristics:

- Validity (i.e., they are as unbiased as possible)
- Clinical importance
- Applicability to the specific patient being seen

Determining the validity of evidence centers on ascertaining whether the evidence was produced in a manner most likely to eliminate and avoid bias. The critical questions to ask to determine the validity of papers about therapy, diagnostic tests, and harmful effects are shown at the tops of Tables 2-3, 2-4, and 2-5, respectively.

Evidence About Therapy and Prevention

Studies of therapy should randomly assign patients to treatment groups (using a table of random numbers or pseudo-random numbers generated by computer) and ensure concealed allocation (e.g., by using opaque envelopes so that the treating physician cannot guess to which treatment group the patient has been assigned). In addition, there should be nearly complete follow-up of all patients entered into the study; intention-to-treat analysis of results; masking of investigators, patients, and statisticians where possible; equal treatment of groups; and similarity between treatment groups with regard to the distributions of prognostic variables. These criteria represent only a small subset of the features of a well-designed and well-reported clinical trial.[37] A more complete set of criteria has been published, and adherence to these criteria is required by many of the leading medical journals.[53]

Important terms and concepts that must be understood to determine whether the results of a paper about therapy are clinically important include the following:

- The magnitude of the treatment effect
- The precision of this value
- The difference in response rates
- Its reciprocal, the number needed to treat (NNT)
- The confidence interval

TABLE 2-5
Critical Appraisal of a Paper About Harm

Are the results of this harm study valid?
- Were there clearly defined groups of patients, similar in all important ways other than exposure to the treatment or other cause?
- Were treatment exposures and clinical outcomes measured the same ways in both groups? [For instance, was the assessment of outcomes either objective (e.g., death) or blinded to exposure?]
- Was the follow-up of study patients complete and long enough?

Do the results satisfy some "diagnostic tests for causation"?
- Is it clear that the exposure preceded the onset of the outcome?
- Is there a dose-response gradient?
- Is there positive evidence from a "dechallenge-rechallenge" study?
- Is the association consistent from study to study?
- Does the association make biologic sense?

Are the valid results from this harm study important?

Calculations:

		Adverse Outcome	
		Present (Case)	Absent (Control)
Exposed to the Treatment	Yes (cohort)	a	b
	No (cohort)	c	d

- In a randomized trial or cohort study, relative risk = [a/(a + b)]/[c/(c + d)].
- In a case-control study, odds ratio (or relative odds) = ad/bc.

Should these valid, potentially important results of a critical appraisal about a harmful treatment change the treatment of your patient?
- Can the study results be extrapolated to your patient?
- What are your patient's risks of the adverse outcome?
- What are your patient's preferences, concerns, and expectations from this treatment?
- What alternative treatments are available?

From Sackett D et al: *Evidence-Based Medicine: How to Practice and Teach EBM.* Edinburgh, Churchill Livingstone, 1996.

In evaluating a clinical trial, the physician should look for clinical outcome measures that are clear-cut and clinically meaningful to the physician and his or her patients.[37] For example, in a study of a systemic treatment for warts, complete disappearance of warts is a meaningful outcome, whereas a decrease in the volume of warts is not. Historically, two principal methods have been used to determine patient outcomes in dermatologic clinical trials. The first involves examining the patient before, during, and at the conclusion of treatment and reporting how the patient appears at the various time points. The second involves determining the degree of improvement during treatment.[54] A third method, determining the impact of therapy on the quality of the patient's life, is being increasingly used in dermatologic trials.[37]

An example of the first method is commonly encountered in therapeutic trials of psoriasis. A common practice is to assign numerical values to the amount of erythema, the amount of scaling, the degree of infiltration, and the body surface area involved, and to formulate an "index" by calculating a derivative of some product of these four numbers.[55,56] The overall condition of the patient can then be represented by this index. A common index is the psoriasis area and severity index, which ranges from 0 to 72.[55] The major problem with indices is that they confound area of involvement with severity of disease.[54] For instance, a patient with thick plaque-type psoriasis of the knees, elbows, and scalp may have the same index as a patient with diffuse but minimal psoriasis of the trunk and arms. Whereas the former condition is notoriously difficult to treat, the latter will generally respond rapidly and easily to many forms of therapy.[54] The second problem with indices is that they lend an air of precision to the analysis and presentation of data that is not warranted.[54] For instance, Tiling-Grosse and Rees demonstrated that physicians and medical students were poor at estimating the area of involvement of skin disease, and therefore some of the components that make up indices may be inaccurate.[57] Finally, calculations of the means, differences in means, and percentages of change in indices in response to treatment often do not convey an accurate clinical picture of the changes that have occurred.[54]

The second method of assessment groups patients according to their degree of improvement. Treatments are then compared in terms of their ability to move patients into categories representing higher degrees of improvement. There are two major problems with this form of assessment. The first is that the categories of improvement are often not well defined. The second problem is that the categories are not additive.[54] That is, 60 percent to 80 percent improvement is often assumed to be twice as good as 20 percent to 40 percent improvement, but no such numerical relationship exists between these subjectively defined categories.

To be most useful, the outcome variables to be measured must be clearly defined, must be as objective as possible, and must have clinical and biologic significance.[37,54] The best indices and scales are the ones that accurately reflect the state of the disease and the ones whose validity and reliability have been verified by previous work.[37,54,58] The development of scales and indices for assessing cutaneous diseases and the testing of their validity, reproducibility, and responsiveness have been inadequate.[37,54,59] Therefore, a lack of clearly defined and useful outcome variables remains a major problem in interpreting dermatologic clinical trials.

Until better scales are developed, trials with the simplest and most objective outcome variables are the best. They lead to the least amount of confusion and support the strongest conclusions. Thus, trials in which a comparison is made between death and survival, recurrence of disease and no recurrence, or cure and lack of cure are studies whose outcome variables are easily understood and verified. For trials in which the outcomes are less clear-cut and more subjective, a simple ordinal scale is probably the best choice.[54] The best ordinal scales involve a minimum of human judgment, have a precision that is much smaller than the differences being sought, and are sufficiently standardized so that they can be used by others and produce similar results.[38]

In addition to being clearly defined, outcome variables should have clinical and biologic significance.[27,28] For example, in a therapeutic trial of patients with severe acne, treatment was associated with a decrease in lesion count from a mean of 400 to a mean of 350.

This numerical difference may be of statistical significance, but it does not convey the biologic significance of the change in lesion number.[54] This result may mean that some patients with severe acne experienced complete clearance, whereas in others the acne remained the same or got worse. It could also mean that in most patients the acne got slightly better. Furthermore, does an individual patient look better when the lesion number has been reduced from 400 to 350? Is there less scarring and fewer complications?

To strengthen clinical trials and help validate their conclusions, investigators should select only a few outcome variables and should choose them before initiation of the study. Measurement of many outcome variables increases the likelihood that spurious, chance differences will be detected. An ineffective treatment may be found efficacious when tested using poorly designed outcome assessment tools. Conversely, an effective therapy may be found ineffective when an insensitive scale is used.

Special precautions are recommended to recognize and remain skeptical of substitute or surrogate endpoints, especially when no differences are detected in clinically important outcomes.[28,60] Examples of such endpoints include CD4/CD8 ratios instead of survival rates in studies of treatments for acquired immunodeficiency syndrome, anti-nuclear antibody levels or sedimentation rates instead of clinical measures of disease activity in lupus erythematosus, and volume of warts instead of proportion of patients cleared of warts. The use of carefully chosen and validated surrogate endpoints often allows studies to provide answers to questions that would typically require much larger or longer trials if the targeted clinical endpoint were used. For example, a well-designed short clinical trial may be sufficient to demonstrate that a new drug effectively lowers serum cholesterol level or that a given drug is effective in controlling hypertension. In both cases, much longer and larger studies would be required to demonstrate that the cholesterol-lowering drug and the antihypertensive drug reduced morbidity and mortality from atherosclerotic and hypertensive cardiovascular diseases, respectively. Surrogate endpoints must correlate with clinical outcomes, however, and their validity must have been demonstrated in prior studies.

Once sound, clinically relevant outcome measures are chosen, the magnitude of the difference between the treatment groups in achieving these meaningful outcomes should be determined. The precision of the estimate of the differences among treatments should be assessed. Useful measures of the magnitude of the treatment effect are the difference in response rate and its reciprocal, the NNT.[13,26,45] The NNT represents the number of patients one would need to treat to achieve one additional cure.

The confidence interval provides a useful measure of the precision of the treatment effect.[13,26,45,61,62] The calculation and interpretation of confidence intervals have been extensively described.[63] In simple terms, the reported result (known as the *point estimate*) provides the best estimate of the treatment effect. Values become less and less likely as they move away from the reported result within the confidence interval.[13,26,45] The confidence interval provides a range of values in which the "population" or true response to treatment is likely to lie.

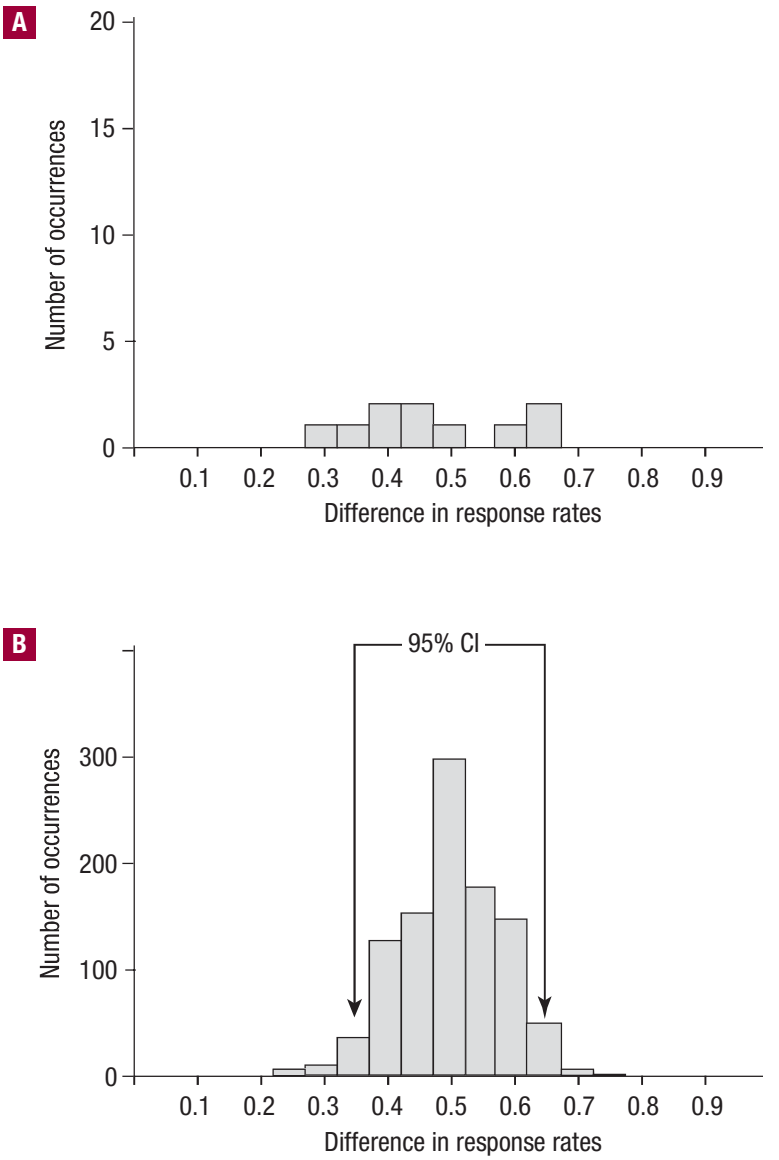
Examples of the application of the concepts of NNT and confidence interval are given in a paper identified through a search of the Cochrane Library that reported the results of a randomized controlled trial comparing the use of a placebo, acyclovir, prednisone, and acyclovir plus prednisone in the treatment of herpes zoster.[64] At day 30 of the trial, 48 of 52 patents treated with acyclovir experienced total healing compared with 22 of 52 patients who received a placebo. The response rates for acyclovir and placebo were 0.92 and 0.42, respectively, and the difference in response rates was 0.5. The NNT was 2 (1/0.5). This result means that for every two patients treated with acyclovir instead of placebo, one additional patient would show total healing by day 30. The 95 percent confidence interval for the difference in response rates is 0.35 to 0.65, and the 95 percent confidence interval for the NNT is 2 to 3.

What does it actually mean that the confidence interval for the difference in response rates in the foregoing example is 0.35 to 0.65? If the investigators in this study had the opportunity to repeat the study many times using the same design and procedures, sampling variability would prevent obtaining the same results in each study. Repeated trials were simulated using resampling (resampling is a computer-intensive method that uses the reported results of a trial to simulate the results that would be obtained if the trial were repeated a number of times).[45,65] The results when the trial was repeated 10 and 1000 times are shown in Fig. 2-1A and B, respectively. A 95 percent confidence interval of 0.35 to 0.65 means that if the trial is repeated many times and a confidence interval is calculated for each trial, the true result or response to treatment will be included in 95 percent of the confidence intervals so produced. Alternatively, if the trial were repeated multiple times, the results would lie within that interval (0.35 to 0.65) 95 percent of the time.

The population or true response to treatment will most likely lie near the middle of the confidence interval and will rarely be found at or near the ends of the interval. The population or true response to treatment has only a 1 in 20 chance of being outside of the 95 percent confidence interval. Unless a given patient is very different from the patients included in the study, his or her response will most likely lie near the middle of the confidence interval. If the 95 percent confidence interval of the difference in response rates excludes zero difference, one can reject the null hypothesis that the two treatments are the same.[26,45,61,62]

Misinterpreting trials that fail to show statistically significant differences among treatments is a common error in dermatologic clinical trials. It is important to remember that "not statistically significant" means that a difference has a reasonably high probability of having been due to chance; it does not mean that there is no difference or that treatment is necessarily ineffective.[37] Significant differences in treatment effects in comparison trials may be missed if the number of subjects tested is small. For example, in a 1978 survey of 71 published trials with negative results, Freiman et al. found that a 25 percent or 50 percent improvement in outcome might have been missed in 57 (80 percent) and 34 (48 percent) of the studies, respectively.[66] A follow-up study conducted by Moher, Dulberg, and Wells in 1994 indicated that a 25 percent or 50 percent improvement in outcome might have been missed in 84 percent and 64 percent, respectively, of 102 studies with negative results.[67] The sample sizes of many dermatologic trials are often inadequate to detect clinically important differences.

The acceptance of a significance level of .05 as the cutoff for rejecting the null hypothesis is a tradition based on quality control standards and is not an absolute truth. At times (e.g., when treatments have substantial side effects)



▲ **FIGURE 2-1** If the acyclovir trial were repeated 10 (**A**) or 1000 (**B**) times, the results in **A** and **B**, respectively, might be obtained. CI = confidence interval.

more stringent standards are required, and paradoxically, results that do not meet the p = 0.05 standard sometimes may be clinically significant. For example, consider a hypothetical trial of a new chemotherapeutic agent involving 30 patients with metastatic melanoma randomly assigned to treatment groups that produced a 5-year survival rate of 7 of 15 among patients treated with the new agent and 3 of 15 among control patients treated with conventional surgery, chemotherapy, and radiation. Whereas the result does not achieve statistical significance when analyzed by chi square testing (Yates corrected chi square = 1.35; p = 0.25), the result is nonetheless potentially significant. If the therapy is beneficial and the estimated difference in response rates is the true difference in response rates, it may result in the saving of 2400 lives annually (based on 7200 deaths from melanoma annually and the improvement in survival in this hypothetical example). Because of the biologic and clinical importance of the results suggested by the trial, the treatment should be investigated in a study that uses a larger patient group and has more power to detect a significant difference if one exists.[37]

The potential benefit of the treatment may be further revealed by the use of confidence intervals. To determine whether a treatment effect may have been missed in a study reporting negative (not statistically significant) results, one should look at the upper boundary of the 95 percent confidence interval. If this value would be clinically important if it were the true response, then an important treatment effect may have been missed in the study. Consider our hypothetical new treatment for metastatic melanoma. The cure rates for the new treatment and the conventional treatment were 47 percent and 20 percent, respectively, and the difference between them was thus 27 percent. The 95 percent confidence interval for the difference in cure rates was –10 percent to 51 percent. The upper boundary of the difference in cure rates was 51 percent. This difference would clearly have a significant impact on the treatment of patients with metastatic melanoma (the NNT is 2!), and therefore a significant treatment advance may have been missed in this study. Also note that the 95 percent confidence interval of the difference in cure rates includes zero difference; therefore, we cannot conclude with a high degree of confidence that the response rates of the two treatments are different. However, when zero is included as one of the values in the confidence interval, the inference that the therapy is not efficacious fails to consider the fact that the best estimate of effect is the point estimate (e.g., the observed difference in cure rates of 27 percent in our hypothetical example).[68] In other words, the values contained in the confidence interval are not equally likely and become less and less likely as they move away from the point estimate. Thus, in the example, a difference of 25 percent (close to the observed 27 percent) is much more likely than a difference of –5 percent (far from the observed 27 percent).[37]

Evidence About Diagnostic Tests

To be valid, studies of diagnostic tests should include blind comparison with a criterion (gold) standard, evaluation in an appropriate spectrum of patients, and consistent application of the criterion standard. Few studies in dermatology meet these criteria.

Important terms and concepts that must be understood to determine whether the results of a paper examining a diagnostic test are clinically important include the following:

- Likelihood ratio
- Pre-test probability
- Post-test probability
- Threshold for action

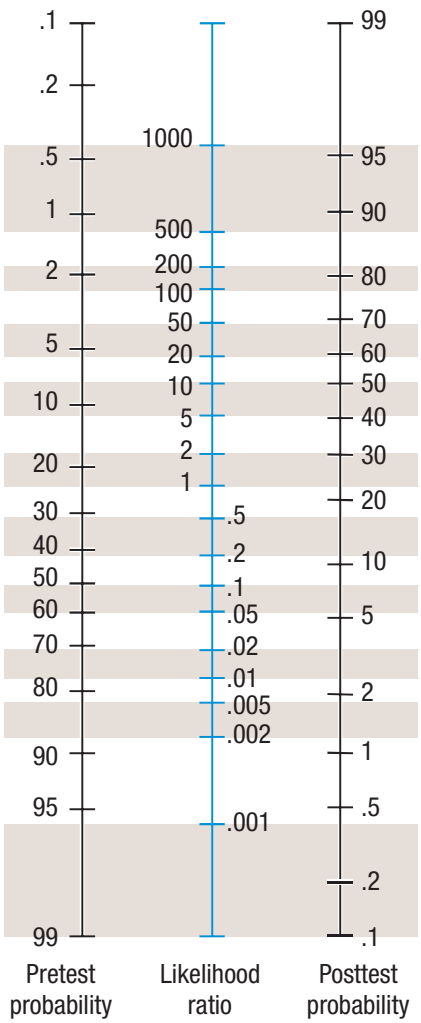
The likelihood ratio is the percentage of people with the given disease for whom the test result is positive divided

by the percentage of people who do not have the disease for whom the test result is positive.[45] The likelihood ratio is traditionally taught as the sensitivity divided by 1 minus the specificity [likelihood ratio = sensitivity/(1 – specificity)] and provides an estimation of how much higher the likelihood of the disease is, given a positive test result (post-test probability), compared with the probability before the test is done (pre-test probability).[13,26] An ideal test is one that will almost always yield positive results when the disease is present and negative results when the disease is absent. Thus, it is one with a high sensitivity and specificity. Such a test will have a very high likelihood ratio.

For the likelihood ratio to be useful, one must have an idea of how likely it is that the disease is present before the test is done (i.e., the pre-test probability) and a sense of how certain one needs to be to conclude that the patient has the disease and to act on this information (i.e., the threshold for action).[45,69] The pre-test probability is determined from available published data or based on physician experience and judgment.[26,45] Once the pre-test probability is known or estimated and the likelihood ratio is determined, a nomogram can be used to estimate the post-test probability (Fig. 2-2).[26]

If a nomogram is not available, the calculations can be done manually, but conversion of probabilities to odds is required. The odds of disease is defined as the probability of disease divided by 1 minus the probability [odds = probability/(1 – probability)]. For a defined group of individuals or patients, it can also be calculated as the ratio of the number of those with disease to those without disease. Thus, if the probability (proportion) of a disease is 0.20 (20 percent), the odds of that disease are 0.20/(1 – 0.20), or 0.20/0.80, or 1:4. This result means that for every person with the disease, there are four people without the disease. The post-test odds are equal to the pre-test odds times the likelihood ratio (post-test odds = pre-test odds × likelihood ratio).[26] The formula [probability = odds/(odds + 1)] is used to convert odds back to probability.

Whether formally or informally, physicians develop thresholds of certainty at or above which they are comfortable with establishing a diagnosis and acting on the diagnoses. Action may take the form of communicating the diagnosis or prognosis to the patient, prescribing treatment, or referring the patient. When



▲ **FIGURE 2-2** Nomogram for determining the post-test probability. To determine the post-test probability, draw a straight line through the pre-test probability and the likelihood ratio and read the post-test probability on the right.

historical and physical evidence leads a clinician to suspect a diagnosis but the degree of certainty does not exceed the threshold for establishing a diagnosis, a test is performed to raise the probability that the disease is present above the clinician's threshold for action.[69]

Evidence About Harm

To be valid, studies about the harmful effects of exposures should include cohorts with comparable groups of exposed and unexposed individuals, or cases and controls; objective outcome measures; and adequate follow-up. In addition, the results should make clinical and biologic sense.[13,26] Few dermatologic studies meet these criteria.

Important terms and concepts that must be understood to determine whether the results of a paper about harmful effects of exposures are clinically important include the following:

- Case-control and cohort studies
- Risk ratio
- Odds ratio

In a cohort study a group of individuals who are exposed to an agent is compared with an appropriately selected unexposed control group and both groups are followed until an event of interest occurs or for a pre-specified length of time. The association between exposure and the harmful outcome is expressed as the relative risk (see Table 2-5 for relative risk calculations). A relative risk of 1 implies no association. If the relative risk is greater than 1, then the result implies a positive association between exposure and the harmful outcome. If it is less than 1, then the implication is of an inverse association. However, to infer a causal association reflected by either an increase in risk (relative risk of more than 1) or a protective effect (relative risk less than 1), one must evaluate the validity and precision of the relative risk estimate. The precision can be readily assessed by means of the 95 percent confidence interval. A confidence interval that does not include 1.0 denotes a statistically significant association. Because the most likely result of a study is the point estimate (i.e., the reported result), the observed association (expressed by the point estimate) may be causal, even if the confidence interval includes 1.0 as a result of a small sample size.[13,26]

Case-control studies are used when the bad outcome is recognized and the causative agent is not yet discovered. They are also used when there is a very long time lag between exposure and outcome or when the frequency of adverse events is very small. In a case-control study, patients with a disease of interest are compared with appropriately selected controls. The odds of exposure to suspected etiologic agents are ascertained in cases and in controls (see Table 2-5). Recall that the odds of an event are calculated as the ratio of the number of events to the number of non-events.[70] Events are exposures to potentially harmful risk factors in case-control studies. The odds of exposure among cases are divided by the odds of exposure among controls to derive the odds ratio, which is a good estimate of the relative risk when the outcome (e.g., disease, death) is relatively rare (i.e., when it occurs in fewer than 5 percent of exposed subjects). The association between ex-

posure and outcome is expressed as the odds ratio in case-control studies. An odds ratio of 1 implies no association. If the odds ratio is higher than 1, then the result implies a positive association between exposure and the harmful outcome. If the odds ratio is less than 1, then the result implies a protective effect of the exposure.[13,26] As noted earlier, it is important to evaluate the validity and precision of the odds ratio estimate by examining the 95 percent confidence interval.

For example, suppose a case-control study was performed to study the relationship between limb deformity and exposure to thalidomide. The results of the study indicated that patients with limb deformities were more likely than controls to have been exposed to thalidomide in utero. The odds ratio for thalidomide exposure was 3.5 and the confidence interval was from 1.8 to 6.6. Thus the odds that patients with limb deformities were exposed to thalidomide in utero were 3.5 times the odds of thalidomide exposure in controls. Because the odds ratio is greater than 1 and its 95 percent confidence interval does not include 1, the result implies a positive association between thalidomide use and limb deformities not likely to have been due to random error. These results (an odds ratio of 3.5 and confidence interval of 1.8 to 6.6) were actually the findings of a study by Wolf et al., who studied the relationship between sunscreen use and melanoma in a case-control study in Austria.[71] Their results indicated that patients with melanoma were more likely than controls to have used sunscreen often. To infer causality it is important to assess whether the results could have occurred from bias and whether the results are biologically plausible.

To add confusion to an already difficult area, clinical researchers will often report results of meta-analyses, cohort studies, and randomized controlled trials using odds ratios. Odds ratios are used because they have stronger statistical properties than other measures.[70] For example, odds ratios can take any value between 0 and infinity, are symmetric in a log scale, and can be used to make adjustments for confounding factors using multiple regression.[70] Unfortunately, they are the measure of association least intuitively understood. If a meta-analysis, controlled trial, or cohort study is reported using odds ratios, the relative risk, difference in response rates, or NNT can often be calculated if the primary data are provided. Alternatively, these more readily understandable measures can be derived if the number of subjects in each group, odds ratio, and overall event rate are provided.

APPLYING EVIDENCE TO SPECIFIC PATIENTS

Applying the evidence to treatment of specific patients involves determining whether the evidence from studies is applicable to a given patient. This decision is based on the patient's condition and values. It involves asking a series of questions that are specific to the type of evidence being considered (see Tables 2-3, 2-4, and 2-5). When faced with the task of determining whether the results of a particular study are applicable to specific patients, physicians should determine whether there are any compelling reasons that the result should not be applied.[37] Applying evidence to specific patients always involves physician judgment.

SAVING THE CRITICAL APPRAISAL OF THE EVIDENCE

Once the physician has made the effort to ask a clinical question, find the best evidence, and critically appraise it, the physician should save the analysis in a place and format that allows it to be easily retrievable for future use. Worksheets for recording evidence from papers dealing with diagnosis, therapy and prevention, prognosis, and harm are available (http://www.cebm.utoronto.ca/teach/materials/caworksheets.htm).[26] These worksheets can be saved electronically or filed physically.

CHAPTER 3

Public Health in Dermatology

Hywel C. Williams
Sinéad Langan
Carsten Flohr

WHAT IS PUBLIC HEALTH MEDICINE ALL ABOUT?

Definition

The World Health Organization defines health as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity."[1] The key message of this definition is that health is a holistic measure that is influenced by socioeconomic factors and inequality. Public health is a discipline in which the level of focus is on the health of populations as opposed to that of individuals, as is the case in clinical medicine. A useful definition of public health is as follows:

> *Public health is the science and the art of preventing disease, prolonging life, and promoting physical health and mental health and efficiency through organized community efforts*

PUBLIC HEALTH IN DERMATOLOGY AT A GLANCE

- Public health dermatology is about promoting skin health and not just treating skin disease.
- Despite strong historical origins, modern public health dermatology is still relatively underdeveloped.
- Doctors can do a lot to help individual patients but have little influence on the health of entire populations.
- Conversely, the impact of large population benefits are rarely appreciated by individuals.
- Prevention is often more logical than treating sick individuals who come for medical care.
- Sometimes a "low-risk" approach of reducing risk for diseases such as melanoma in the entire population can achieve more than a "high-risk" approach of targeting just those who have skin cancer or who are at high risk of developing skin cancer.
- When entire populations are considered, a little bit of harm affecting a lot of people can add up to more than a lot of harm affecting a few people in absolute terms.
- Modern public health dermatology has had some success in reduction of skin cancer incidence and control of infectious diseases.
- Sometimes, low-technology educational interventions directed at entire communities can result in more benefit than high-technology drugs targeted at a few ill individuals.

toward a sanitary environment, the control of community infections, the education of the individual in principles of personal hygiene, the organization of medical and nursing service for the early diagnosis and treatment of disease and the development of the social machinery to ensure to every individual in the community a standard of living adequate for the maintenance of health.[2]

This definition articulates some of the roles of public health practitioners in relation to society and health. It also highlights the four key areas of public health action: (1) preventing disease and promoting health, (2) improving medical care, (3) promoting health-enhancing behavior, and (4) modifying the environment.[3]

Historical Perspectives

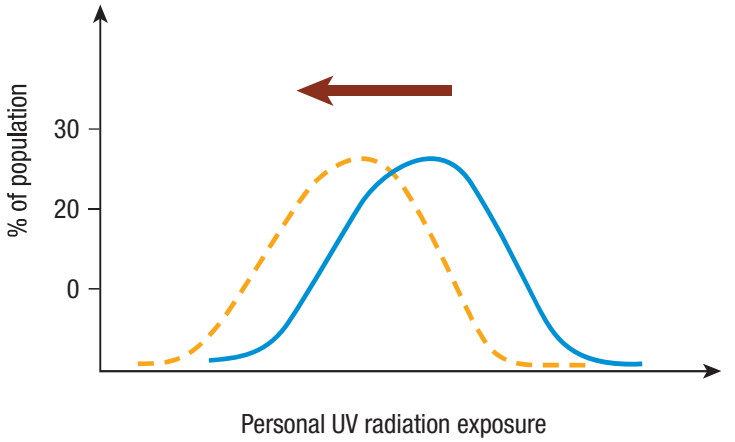
Public health has played a key role in the prevention and treatment of dermatologic diseases. One of the first historical examples is scurvy. In 1746, James Lind discovered through observation, analysis, and performance of a controlled trial that scurvy in sailors was a dietary disease that could be cured by administration of oranges and lemons[5] (see eFigs. 3-0.1 and 3-0.2 in on-line edition). Lind's treatise preceded the discovery of vitamin C by more than a century. In 1775, Percivall Pott was the first to describe an occupationally induced cancer by noting that the mortality from scrotal cancer was 200 times higher in chimney sweeps than in other workers.[6] He attributed the excess mortality to tar and soot exposure in combination with poor personal hygiene. The first carcinogenic polycyclic aromatic hydrocarbon was not discovered until 1933. In the early twentieth century, pellagra was a major public health problem (see eFig. 3-0.3 in on-line edition). There were 100,000 deaths from the disease in a 40-year period and over 3 million sufferers in the United States at that time. In 1914 Dr. Joseph Goldberger noticed that inmates at the Georgia State Sanatorium developed high rates of pellagra whereas the nurses and attendants did not, and concluded that the origin of pellagra was probably a disease caused by a dietary deficiency. He confirmed his hypothesis with controlled clinical trials.[7] The deficient dietary factor, niacin, was discovered in 1937.

Collectively these examples illustrate the importance of public health in the prevention of disease. These examples also highlight the fact that knowledge of disease pathophysiology (i.e., mechanisms) is not always a prerequisite to determining the cause or risk factors for a disease and the potential for effective public health interventions.

HIGH-RISK AND LOW-RISK APPROACHES TO PUBLIC HEALTH

Traditionally, dermatology, like other branches of specialist medicine, has concentrated on the treatment of those who have fallen ill or those who believe they are ill or at high risk of developing disease. For instance, we prescribe topical corticosteroids for those with atopic dermatitis and we may give advice on sun protection to patients who previously had a malignant melanoma. We may see such melanoma patients on a regular basis in skin cancer follow-up clinics to monitor treatment success and to be able to detect recurrences or new early second melanomas. Doctors and patients alike tend to be highly motivated when such an approach is used. The potential benefits seem obvious, and although there may be side effects associated with the prescribed treatment, such as skin thinning with prolonged use of topical corticosteroids, or a scar from excision of a melanoma, many patients will accept such risks, because appropriate treatment leads to a significant improvement of symptoms and improved quality of life or survival. Such an approach to tackling disease has often been referred to in the literature as the *high-risk* approach, because it focuses on the treatment and detection of those at high risk of developing disease and those who have already fallen ill.[8]

In contrast to the high-risk approach, the ultimate aim of public health medicine and public health dermatology is to prevent the development of disease in the first place whenever possible, not only by forestalling it in those identified as being at high risk (e.g., because of a strong family history), but by shifting the entire distribution of a certain exposure in a healthier direction for the whole population (population strategy). Such a low-risk approach can be implemented through large-scale public health education campaigns aimed at fundamentally changing the entire population's behavior and lifestyle. For example, based on the data of the Framingham study one can extrapolate that a reduction of everybody's blood pressure by 10 mm Hg would result in an overall reduction in mortality from heart disease of around 30 percent.[8] In dermatology, a good example of a such a population strategy is attempts to change the general population's sun exposure behavior to reduce exposure to ultraviolet light and ultimately skin cancer incidence and mortality through public health education campaigns that are national (e.g., Australia) or international (e.g., the World Health Organization's INTERSUN program, http://www.who.int/uv/intersunprogramme/en/) in scope (Fig. 3-1). This makes sense particularly in a country like Australia, because a strong association between ultra-



▲ **FIGURE 3-1** Distribution of ultraviolet (UV) radiation exposure before (*solid line*) and after (*dashed line*) implementation of a population strategy to reduce personal UV radiation exposure.

violet radiation and melanocytic and nonmelanocytic skin cancer is well established, and such risk is distributed widely through the predominantly fair-skinned population. Skin cancer is an important cause of death, and treatments for all forms of skin cancer pose an important burden on many countries' health care resources. Simple measures, such as avoiding sun exposure during peak hours of radiation and wearing suitable clothing, can provide adequate protection. The state of Victoria, Australia, has the most comprehensive population-based primary prevention campaign against skin cancer in the world (SunSmart campaign, http://www.sunsmart.com.au/), and it has been reported that this program's public investment was worthwhile. Not only has it resulted in a significant reduction in skin cancer incidence and mortality, but the returns from savings on skin cancer treatments have also exceeded the overall costs of the SunSmart campaign.[9]

It may seem obvious that upstream prevention is more desirable than treating sick individuals who come for treatment downstream after a long chain of pathologic events, some of which may be irreversible. Funding population prevention strategies may be difficult, yet the whole population will potentially benefit, as long as such interventions are evidence based and sustainable. However, it is generally more difficult to persuade healthy individuals to protect themselves against prolonged sun exposure than to persuade those who have already had a malignant melanoma excised. It is also worth pointing out that although a public health intervention such as vaccination against measles has dramatically reduced the incidence of disease at a population level, it is impossible to say which individuals have been helped by such a population intervention—a phenomenon known as the *prevention paradox*.

A population strategy is not suitable for trying to control all skin diseases at present, because such a strategy depends on knowledge of modifiable risk factors. In the many cases for which exposures that predispose to a particular skin condition are unknown, prevention through avoidance is not possible, and the only option available is treatment of disease rather than primary disease prevention.

A LOT OF HARM AFFECTING A FEW PEOPLE VERSUS A BIT OF HARM AFFECTING MANY

Making the conceptual jump from thinking about individual patients to thinking about entire populations can be challenging for practicing dermatologists, especially because such jumps can come up with some surprising results. For example, a dermatologist with an interest in contact dermatitis might see a case of severe hand dermatitis in a printer caused by allergic contact dermatitis from a chemical and then publicize such a case in a respected journal.[10] Another dermatologist reading such a case report might come to the conclusion that allergic contact dermatitis is an important cause of hand dermatitis in printers. Yet when this dermatologist visits the workplace to conduct a survey of all cases of hand eczema in printers, it becomes apparent that true allergic contact dermatitis is probably quite rare, and by far the most common cause of hand eczema is constant low-grade exposure to soap and water from repeated washing and friction from paper and dirt.[11] Thus, it is possible that a little bit of harm affecting a lot of individuals can add up to much more in absolute terms (the realm of the public health/occupational health physician) than a lot of harm affecting one or two workers (the realm of the dermatologist). Another well-known example of such a phenomenon is the effects of smoking on reduction in cardiovascular disease. Even though the association between tobacco smoking and lung cancer (relative risk of 14.0) is much stronger than that between smoking and cardiovascular disease (relative risk, 1.6), strategies for smoking cessation save around twice as many lives from cardiovascular disease than from lung cancer simply because heart disease is much more common than lung cancer.[12] From a public health perspective, therefore, the population-attributable risk (the proportion of the disease that may be attributable to a particular risk factor) is more important than other traditional measures of risk, such as the relative risk (whose magnitude may tell us something about the strength of a particular association). In a study of risk factors for psoriasis in Italy, Naldi et al. found that smoking accounted for up to 26 percent of all cases. In individuals with psoriasis who smoked who also had a family history of psoriasis, an increased body mass index might account for up to 48 percent of disease.[13] The fact that smoking and obesity are modifiable risk factors suggests that psoriasis is preventable, at least to some degree, in this population.

PUBLIC HEALTH APPROACH IN ACTION IN DERMATOLOGY

So far, we have illustrated the public health approach in dermatology using mainly historical examples. Yet although current dermatologic research is still relatively dominated by the pursuit of studies in which the unit of analysis is at a cellular or sub-cellular level, there are some good examples of public health dermatology in action.

One of the classic studies illustrating the public health approach in action for infectious skin disease was that conducted by Taplin and colleagues concerning scabies among Kuna Indians on the San Blas Archipelago.[14] These islands off the coast of Panama were plagued by very high rates of scabies in children in the 1980s, which led to misery and secondary bacterial infections. Despite the use of the best treatments available to combat the problem, the population burden of scabies remained largely unchanged. Only after the adoption of a public health approach in which everyone in defined areas was

treated did the prevalence of scabies fall dramatically from approximately 33 percent to approximately 1 percent. Similar dramatic decreases in scabies prevalence (from 25 percent to 1 percent) and in associated pyoderma and possibly post-streptococcal nephritis have been observed through the use of population-based treatment with ivermectin in the Solomon Islands.[15] Another example is the Global Alliance to Eliminate Lymphatic Filariasis (http://www.filariasis.org/), an alliance between the World Health Organization, ministries of health, and the private sector aimed at the worldwide eradication of this devastating disease. The Global Alliance to Eliminate Lymphatic Filariasis campaign is one of the most rapidly expanding public health programs in history and had regularly treated 25 million people in 12 countries by 2000 and 250 million in 39 countries by 2004. It is not restricted to mass treatment with antifilarial drugs but also includes public health education and advice on skin care of lymphedematous legs to prevent further morbidity.

Public health interventions are not restricted to administration of pharmaceutical drugs but can also include educational interventions such as the public education campaigns for reducing skin cancer through reduction in ultraviolet light exposure. One such successful program has been the introduction of basic dermatologic care in Mali through the development of a training program for general health care workers on the management of common skin diseases.[16] The proportion of patients with skin disease with a clear diagnosis and appropriate diagnosis increased from 42 percent before the training to 81 percent after it. Although such dramatic effects might be overestimated in a simple before-and-after study, the effects were sustained for up to 18 months after training. Paradoxically, these improvements in care were associated with a 25 percent reduction in prescription costs, which suggests that inappropriate empirical prescribing was a source of unnecessary expenditure before the training. Other researchers have also documented how scarce family income can be wasted on inappropriate treatment for skin diseases such as pyoderma and scabies in Mexico.[17] Ryan has described the role of educational clinics in the prevention of skin cancers as well as the management of early lesions in the albino population of 170,000 in Tanzania.[18]

Although many public health interventions may not sound as "high tech" as drugs targeted at specific biologic receptors, they may be more effective and appropriate for sick populations. The concept that a little bit of harm affecting a lot of people can add up to more than a lot of harm affecting a few people was developed earlier, but a similar maxim also holds true: sometimes a low-technology beneficial intervention that can be applied to a large population can add up to far greater benefit in population terms than a high-technology solution that will benefit only a few.

FUTURE OF PUBLIC HEALTH IN DERMATOLOGY

Some dermatologists have already conducted a population-based needs assessment for dermatologic care, followed by organization of the appropriate services at a population level, rather than just viewing the world of skin disease from within the narrow confines of a hospital-based practice. There are also increasing international collaborations to try to prevent and reduce the burden of skin diseases at a global level through health care planning and focused interventions. These are carried out through organizations such as the International Foundation for Dermatology (http://www.ifd.org/) in conjunction with the International League of Dermatological Societies (http://web.ilds.org/). The International League of Dermatological Societies is working to improve community dermatologic programs in developing countries, focusing on better diagnosis and clear evidence-based guidance for the management of common dermatoses. Training courses have been established, such as those at the Regional Dermatology Training Centre in Moshi, Tanzania (http://www.global-campus.org/rdtc) and short courses in Guerrero, Mexico and Mali. One of the key aims of these programs is to educate at the primary care level with the idea that the trainees will then multiply such knowledge by training others in their own countries. As Weinstock points out in Chapter 1, the burden of skin diseases is high. Many skin diseases can already benefit from a public health approach. What is needed to redress the relative paucity of public health dermatology is to understand the concept that populations are as important as individuals and to build on the sort of collaboration championed by the International Foundation for Dermatology.

SECTION 2

APPROACH TO DERMATOLOGIC DIAGNOSIS

CHAPTER 4

Structure of Skin Lesions and Fundamentals of Clinical Diagnosis

Amit Garg
Nikki A. Levin
Jeffrey D. Bernhard

What is most difficult of all? It is what appears most simple: To see with your eyes what lies in front of your eyes.

—Goethe

THE ART OF DIAGNOSIS

The diagnosis and treatment of diseases that affect the skin rest on the physician's ability to use the lexicon of dermatology, to recognize the basic and sequential lesions of the skin, and to recognize the various patterns in which they occur in a variety of diseases and syndromes. In this chapter, we discuss a fundamental approach to the patient presenting with a skin problem. We introduce the technical vocabulary of dermatologic description, the "dermatology lexicon"—a set of terms that denote types of skin lesions. It is important to know and use this standard terminology, as it is the first step in generating a differential diagnosis. Once a lesion has been described as a pearly, flesh-colored, telangiectatic, ulcerated nodule, the experienced physician puts basal cell carcinoma at the top of the differential diagnosis. It is also important to use standard dermatologic terminology for consistency in clinical documentation, in research, and in communication with other physicians.

The process of examining and describing skin lesions may be likened to that of viewing a painting. First, one stands back and takes in the whole "canvas," analogous to viewing the patient from a few feet away at which distance an overall assessment of the patient's general and cutaneous health may be made. One may note such findings as skin color and turgor, presence of pallor or jaundice, degree of sun damage, and the overall number and location of lesions. Next, one looks more closely at the "trees" or "mountains" that make up the landscape, analogous to describing and categorizing the specific lesions on the patient. Finally, one may closely examine the details of the canvas, taking in the texture and brushstrokes, analogous to using magnification to see the borders of a nevus or compressing a lesion to see if it blanches. Just as a knowledgeable viewer of art may recognize a work of Georges Seurat by its tiny, dot-like brush strokes, an experienced observer of the skin can recognize a melanoma by its asymmetry, irregular borders and multiple colors. This chapter aims to introduce the reader to the art and science of dermatologic diagnosis.

APPROACH TO THE PATIENT

History

Dermatology is a visual specialty, and some skin lesions may be diagnosed at a glance. Nonetheless, the history is important and in complex cases, such as the patient with rash and fever or the patient with generalized pruritus, it may be crucial. Dermatologists vary in whether they prefer to take a history before, during, or after performing a physical examination. In practice, many perform a brief examination initially, obtain some history, then return to a more focused examination.

For the following reasons, it is often useful to at least briefly examine the patient before taking a lengthy history:

- Certain skin conditions, such as classic plaque-type psoriasis or molluscum contagiosum, for example, present with such distinctive morphologies

SKIN LESIONS AND DIAGNOSIS AT A GLANCE

- A patient and thorough approach to the evaluation decreases the risk of making an incorrect diagnosis or overlooking another diagnosis.
- Knowledge and appropriate use of dermatology terminology are fundamental.
- Recognition of disease patterns requires repeated patient encounters.
- The history is indispensable in elucidating complex diagnoses.
- The entire mucocutaneous surface, as well as the hair and nails, should be examined whenever reasonable.
- Morphologic characteristics derived from cell type in skin must be carefully scrutinized.
- Diseases have characteristic morphology and distribution.
- Common pitfalls in dermatologic diagnosis exist and can be avoided.

TABLE 4-1
Approach to Dermatologic Diagnosis[a]

- Initial clinical impression: Does the patient appear ill?
- Physical examination: detailed examination of the skin, hair, nails, and mucous membranes
- Four cardinal features
  - Type of lesion: macule, papule, nodule, vesicle, etc. (see Table 4-2)
  - Shape of individual lesions: annular, iris, arciform, linear, round, oval, umbilicated, etc.
  - Arrangement of multiple lesions: isolated, scattered, grouped, linear, herpetiform, zosteriform, etc.
  - Distribution (be sure to examine scalp, mouth, palms, and soles)
    - Extent of involvement: circumscribed, regional, generalized, universal? What percentage of the body surface is involved?
    - Pattern: symmetry, exposed areas, sites of pressure, intertriginous areas?
- Characteristic locations: flexural, extensor, intertriginous, glabrous, palms and soles, dermatomal, trunk, lower extremities, exposed areas, etc.?
  - Three major characteristics
    - Color (see Table 4-3)
      - ~ If diffuse: red, brown, gray-blue, white, blue, orange-yellow, etc.; if circumscribed: red, violaceous, orange, yellow, lilac, livid, brown, black, blue, gray, white, etc.
      - ~ Does the color blanch with pressure (diascopy test)?
      - ~ Wood's lamp examination of pigmentary alterations: Is contrast enhanced?
    - Consistency and feel of lesion: soft, doughy, firm, hard, "infiltrated," dry, moist, mobile, tender, warm?
    - Anatomic components of the skin primarily affected: Is the process epidermal, dermal, subcutaneous, appendageal, or a combination of these?
- General physical examination as indicated by the clinical presentation and differential diagnosis, with particular attention to vital signs, lymphadenopathy, hepatomegaly, splenomegaly, joints, etc.
- History of a rash. Key questions:
  - When did it start?
  - Does it itch, burn, or hurt?
  - Where on the body did it start?
  - How has it spread (pattern of spread)?
  - How have individual lesions changed (evolution)?
  - Provocative factors?
  - Previous treatments and response?
- History of a growth. Key questions:
  - How long has the lesion been present?
  - Has it changed, grown, bled, itched, or failed to heal?
- General history of present illness as indicated by clinical situation, with particular attention to constitutional and prodromal symptoms
  - Acute illness syndrome (fever, sweats, chills, headache, nausea, vomiting, cough, runny nose, etc.)?
  - Chronic illness syndrome (fatigue, anorexia, weight loss, malaise)?
- Review of systems as indicated by clinical situation, with particular attention to symptoms indicating a possible connection between cutaneous signs and disease of other organ systems (e.g., rheumatic complaints: myalgias, arthralgias, Raynaud phenomenon, sicca symptoms)
- Review of systems for growths suspicious for, or associated with, malignancy: particular attention to symptoms of metastasis (weight loss, fevers, chills, night sweats, headache, swollen glands, abdominal pain, abnormal stooling, bone pain, etc.)
- Medication history: allergy; all prescription, nonprescription, and "complementary" medications, with particular attention to those that temporally correspond to the onset of the eruption
- Past medical history
  - Illnesses
  - Operations
  - Atopic history (asthma, hay fever, eczema)
  - Family medical history, particularly of skin disorders and of atopy
  - Family history of skin, or other, cancers
- Social history with particular reference to occupation, hobbies, sun exposure, pet exposure, tobacco smoking, alcohol consumption, recreational drugs, travel, sexual orientation and exposures
- Laboratory studies
  - Special procedures as determined by the individual clinical situation (see Chap. 5)
    - Dermatoscopy
    - Hand lens or 7× loupe magnification for identifying specific features
    - Biopsy for histopathologic and other analyses (e.g., electron microscopy, immunofluorescence, special stains) if indicated
    - Tissue to be minced for bacterial and fungal cultures
    - Gram stains of crust, scale, or exudates
    - Potassium hydroxide preparation for yeast or fungi
    - Cytologic preparation (Tzanck smear) in vesicular and bullous eruptions
    - Swab for bacterial, viral, and fungal cultures
    - Wood's lamp examination of urine for porphyrins and of hair and skin for fluorescence or for changes in pigmentation
    - Oil mount preparation of scraping for scabies mite
    - Patch testing for allergic contact dermatitis
  - General: hematology, chemistry, urinalysis, serologic tests (e.g., syphilis, antinuclear antibody), imaging studies, and others as indicated by the presentation
- Final diagnosis: re-examination over time and more than one biopsy may be required for definitive diagnosis

[a]This approach was developed by Thomas B. Fitzpatrick, Jeffrey D. Bernhard, and Harley A. Haynes. It has been modified by Amit Garg, Nikki Levin, and Jeffrey D. Bernhard.

that the diagnosis may be immediately obvious, rendering extensive history taking unnecessary.

- A patient's history may contain "red herrings," which lead the physician away from, rather than toward, the correct diagnosis. Examination of the patient before taking a history may yield a more complete and unbiased differential diagnosis.
- In certain situations, such as the evaluation of alopecia, initial examination of the patient to determine what type of hair loss is present allows the physician to pursue a line of questions pertinent to that type of alopecia.

In taking a history from a patient presenting with a new skin complaint, the physician's primary goal is to establish a diagnosis, with a secondary goal of evaluating the patient as a candidate for therapy. In patients whose diagnosis is already established, the physician's goals are to re-evaluate the original diagnosis, monitor disease progress and complications, and modify treatment accordingly. Table 4-1 is a guide useful in evaluating a patient with a rash or growth. The table is not an algorithmic

method of arriving at a diagnosis. Rather, it is meant to provide the learner with a fundamental and general approach to diagnosing an unknown.

Examination of the Dermatologic Patient

SCOPE OF THE COMPLETE CUTANEOUS EXAMINATION The complete cutaneous examination includes inspection of the entire skin surface, including often-overlooked areas such as the scalp, eyelids, ears, genitals, buttocks, perineal area, and interdigital spaces; the hair; the nails; and the mucus membranes of the mouth, eyes, anus, and genitals. In routine clinical practice, not all of these areas are examined unless there is a specific reason to do so, such as a history of melanoma or a particular localizing complaint.

ADVANTAGES TO PERFORMING A COMPLETE CUTANEOUS EXAMINATION Although it is not always essential or practical to perform a complete skin examination, there are many advantages to doing so, especially for new patients and challenging cases:

- Identification of potentially harmful lesions (e.g., skin cancers) of which the patient is unaware; any patient with a history of skin cancer or a chief complaint of a "new growth" deserves a full skin examination.
- Identification of benign lesions (e.g., seborrheic keratoses, angiokeratomas) that the patient was concerned about but reluctant to mention, thereby enabling the physician to provide reassurance.
- Finding hidden clues to diagnosis (e.g., scabies lesions on the penis, psoriatic plaques on the buttocks, Wickham striae of lichen planus on the buccal mucosa, nail pitting in alopecia areata).
- Opportunity for patient education (e.g., lentigines are a sign of sun damage and suggest the need for improved sun protection).
- Opportunity to convey the physician's concern about the patient's skin health as a whole. Patients appreciate this and also regard the physician as thorough.

BARRIERS TO PERFORMING A COMPLETE SKIN EXAMINATION Despite the advantages of performing a full cutaneous examination, numerous barriers exist that may prevent the dermatologist from performing such an evaluation for every patient. Understandably, patients may decline a full examination when their chief complaint is relatively minor or localized, such as a wart or acne. In other cases, patients may express resistance to disrobing for a full examination due to embarrassment, especially when the physician is of the opposite gender. Sometimes the physician is uncomfortable performing a complete skin examination with the concern that a patient may misinterpret the examination as improper. In many instances, time constraints and lack of personnel to serve as chaperones limit the ability to perform full skin examination.

IDEAL CONDITIONS FOR THE COMPLETE SKIN EXAMINATION A complete skin examination is most effective when performed under ideal conditions. It is most important to have excellent lighting, preferably bright, even light that simulates the solar spectrum. Without good lighting, subtle but important details may be missed. The patient should be fully undressed, wearing only a gown that is easily moved aside, with a sheet over the legs, if desired. Underwear, socks, and shoes should be removed, as should any makeup or eyeglasses. The examining table should be at a comfortable height, with a head that reclines, an extendable footrest, and gynecologic stirrups. The examining room should be at a comfortable temperature for the lightly dressed patient. It should contain a sink for hand washing and disinfecting hand foam, as patients are reassured by seeing their physician wash hands before the examination. If the patient and physician are of opposite genders, having a chaperone in the room can make the examination more comfortable for both.

RECOMMENDED TOOLS FOR THE COMPLETE SKIN EXAMINATION Although the physician's eyes and hands are the only essential tools for examination of the skin, the following are often useful and highly recommended:

- A magnifying tool such as a loupe, magnifying glass, or dermatoscope.
- A bright focused light such as a flashlight or penlight to sidelight lesions.
- Glass slides or a hand magnifier for diascopy.
- Alcohol pads to remove scale or surface oil.
- Gauze pads or tissues with water for removing makeup.
- Gloves to be used for examination when scabies or another highly infectious condition (secondary syphilis) is suspected, when examining mucus membranes, vulvar and genital areas, and when performing any procedure.
- A ruler for measuring lesions.
- Number 15 and number 11 scalpel blades for scraping or incising lesions, respectively.
- A camera for photographic documentation.
- A Wood's lamp (365 nm) for highlighting subtle pigmentary changes.

TECHNIQUE OF THE DERMATOLOGIC PHYSICAL EXAMINATION Just as there is no one correct way to perform a general physical examination, each physician approaches the complete skin examination with his or her own style. A common thread to effective styles of skin examination is consistency in the order of examining different body areas to ensure that no areas are overlooked. One approach to the complete skin examination is presented here. First, observe the patient at a distance for general impressions (e.g., asymmetry due to a stroke, obesity, pallor, fatigue, jaundice). Next, examine the patient in a systematic way, usually from head to toe, uncovering one area at a time to preserve patient modesty. Move the patient (e.g., from sitting to lying) and the illumination as needed for the best view of each body area. Palpate growths to determine whether they are soft, fleshy, firm, tender, or fluid-filled. Use of the hands to stretch the skin is especially useful in diagnosis of basal cell carcinoma, in which stretching skin reveals a "pearly" quality often not seen on routine inspection. A magnifier worn on the head leaves both hands free for palpation of lesions. Certain lesions, such as porokeratosis, are best examined with side lighting that reveals depth and the details of borders. During the examination, patients often find it reassuring for the physician to name and demystify benign lesions as they are encountered.

Special examination techniques for hair disorders are discussed in Chap. 86, but include having the patient sit in a chair so that the entire scalp is easily examined, parting the patient's hair at the front and occiput and gently tugging on hairs to determine the fraction of loose (telogen) hairs. Examination of the nails is discussed in Chap. 87.

After completing the examination, it is important to document the skin findings, including the type of lesions and their locations, either descriptively or on a body map. Careful documentation is

particularly important for suspicious lesions that are to be biopsied, so that the exact location may be found and definitively treated at a later date. Instant or digital photography is a useful adjunct for documentation.

INTRODUCTION TO MORPHOLOGY

Siemens (1891–1969) wrote, "he who studies skin diseases and fails to study the lesion first will never learn dermatology." His statement reinforces the notion that the primary skin lesion, or the evolution thereof, is the essential element on which clinical diagnosis rests. Joseph Jakob Edler von Plenck's (1738–1807) and Robert Willan's (1757–1812) work in defining basic morphologic terminology further permitted description and comparison of fundamental lesions, thereby facilitating characterization and recognition of skin disease. To read words, one must recognize letters; to read the skin, one must recognize the basic lesions. To understand a paragraph, one must know how words are put together; to arrive at a differential diagnosis, one must know what the basic lesions represent, how they evolve, and how they are arranged and distributed.

Variation and ambiguity in the morphologic terms generally accepted by the international dermatology community have engendered barriers to communication among physicians of all disciplines, including dermatologists. In dermatologic textbooks, the papule, for example, has been described as no greater than 1 cm in size, less than 0.5 cm, or ranging from the size of a pinhead to that of a split pea. Thus, in forming a mental image of a lesion or eruption after hearing its morphologic description, physicians sometimes remain irresolute. The mission of the Dermatology Lexicon Project is to create a universally accepted and comprehensive glossary of morphologic descriptive terms to support research, medical informatics, and patient care (http://www.DermatologyLexicon.org). Morphologic definitions in this chapter parallel and amplify those of the Dermatology Lexicon Project. In describing morphologic terms, our intent is simple: to provide the reader with a pure appreciation of the "letters that make up the alphabet" rather than detailing a "field guide" for diagnoses, which are covered in depth throughout the textbook. Table 4-2 is a summary of the lesions discussed.

TABLE 4-2
Morphologic Lesions

Raised	Depressed	Flat	Surface Change	Fluid Filled	Vascular
Papule	Erosion	Macule	Scale	Vesicle	Purpura
Plaque	Ulcer	Patch	Crust	Bulla	Telangiectasia
Nodule	Atrophy	Erythema	Excoriation	Pustule	Infarct
Cyst	Poikiloderma	Erythroderma	Fissure	Furuncle	
Wheal	Sinus		Lichenification	Abscess	
Scar	Striae		Keratoderma		
Comedo	Burrow		Eschar		
Horn	Sclerosis				
Calcinosis					

Raised Lesions

PAPULE A papule is a solid, elevated lesion less than 0.5 cm in size in which a significant portion projects above the plane of the surrounding skin. Oblique lighting with a flashlight in a darkened room is sometimes necessary to detect the slight elevation of embedded papules. Papules surmounted with scale are referred to as papulosquamous lesions. Sessile, pedunculated, dome-shaped, flat-topped, rough, smooth, filiform, mammillated, acuminate, and umbilicated constitute some common shapes and surfaces of papules. A clinical example is lichen planus (Fig. 4-1; see Chap. 26).

PLAQUE A plaque is a solid plateau-like elevation that occupies a relatively large surface area in comparison with its height above the normal skin level and has a diameter larger than 0.5 cm. The elevation need not be significant. Plaques, which may form by extension or confluence of papules, are further characterized by their size, shape, color, and surface change. A clinical example is psoriasis (Fig. 4-2; see Chap. 18).

NODULE Depending on the anatomic component(s) primarily involved, nodules are of five main types: (1) epidermal, (2) epidermal-dermal, (3) dermal, (4) dermal-subdermal, and (5) subcutaneous. On the skin, a nodule is a solid, round or ellipsoidal, palpable lesion that has a diameter larger than 0.5 cm. Size, however, is not the major consideration in the definition of nodule. Depth of involvement and/or substantive palpability, rather than diameter, differentiates a nodule from a large papule or plaque. *Tumor*, also sometimes included under the heading of nodule, is a general term for any mass, benign or malignant. A *gumma* is, specifically, the granulomatous nodular lesion of tertiary syphilis. For cases in which more than one term may be applicable, it is simply best to include measurements and descriptive terms that convey the important features of the lesion in question. Some additional features of a nodule that may help reveal a diagnosis include whether it is warm, hard, soft, fluctuant, movable, fixed, or painful. Similarly, different surfaces of nodules, such as smooth, keratotic, ulcerated, or fungating, also help direct diagnostic considerations. A clinical example is nodular basal cell carcinoma (Fig. 4-3; see Chap. 115).

▲ **FIGURE 4-1** Papule. Multiple, well-defined papules of varying sizes are seen. Flat tops and glistening surface are characteristic of lichen planus.

▲ **FIGURE 4-2** Plaque. Well-demarcated pink plaques with a silvery scale representing psoriasis vulgaris.

▲ **FIGURE 4-3** Nodule. A nodular basal cell carcinoma with well-defined, firm nodule with a smooth and glistening surface through which telangiectasia can be seen.

CYST A cyst is an encapsulated cavity or sac lined with a true epithelium that contains fluid or semisolid material (cells and cell products such as keratin). Its spherical or oval shape results from the tendency of the contents to spread equally in all directions. If the overlying skin is stretched enough by the cyst, follicular openings may be prominent. Sometimes, the cavity is so superficial that it gives the appearance of a vesicle that lacks encapsulation. A nodule or papule may be suspected of being a cyst if, on palpation, it is resilient; the eyeball, for example, feels similar to a cyst. Depending on the nature of the contents, cysts may be hard, doughy, or fluctuant. A clinical example is a cystic hidradenoma (Fig. 4-4; see Chap. 119).

▲ **FIGURE 4-4** Cyst. A bluish colored resilient cyst filled with a mucous-like material on the cheek is a cystic hidradenoma.

WHEAL A wheal is a swelling of the skin that is characteristically evanescent, disappearing within hours. These lesions, also known as *hives* or *urticaria*, are the result of edema produced by the escape of plasma through vessel walls in the upper portion of the dermis. Wheals may be tiny papules 2 mm to 4 mm in diameter or giant plaques measuring greater than 10 cm. Variable shapes (round, oval, serpiginous, or annular) may be noted, often in the same patient. Borders of a wheal, although sharp, are not stable and in fact move from involved to adjacent uninvolved areas over a period of hours. Wheals are pink to pale red in color. The flare, or ring of pink erythema, of a wheal may be intense if superficial vessels are dilated. If the amount of edema is sufficient to compress superficial vessels, wheals may in fact be white in the center or around the periphery, producing a zone of pallor. With associated inflammatory disruption of the vessels walls, wheals may have a deeper red color, may be purpuric, and are more persistent. Wheals are soft to firm depending on the extent of edema present.

▲ **FIGURE 4-5** Wheal. A sharply demarcated wheal with a surrounding erythematous flare occurring within seconds of the skin being stroked.

Angioedema is a deeper, edematous reaction that occurs in areas with very loose dermis and subcutaneous tissue such as the lip, eyelid, or scrotum. It may occur on the hands and feet as well, and result in grotesque deformity. A careful search for laryngeal edema should be made in cases of angioedema, as such cases may result in death from airway obstruction (see Chap. 37). A clinical example is dermatographism (Fig. 4-5; see Chap. 37).

SCAR A scar arises from proliferation of fibrous tissue that replaces previously normal collagen after a wound or ulceration breaches the reticular dermis. Scars have a deeper pink to red color early on before becoming hypo- or hyperpigmented. In most scars, the epidermis is thinned and imparts a wrinkled appearance at the surface. Adnexal structures, such as hair follicles, normally present in the dermis are destroyed. Hypertrophic scars typically take the form of firm papules, plaques, or nodules. Keloid scars are also elevated. Unlike hypertrophic scars (Fig. 4-6; see Chap. 64), keloids exceed,

▲ **FIGURE 4-6** Scar. A pink firm hypertrophic scar.

▲ **FIGURE 4-7** Comedo. Open and closed comedones on the face of this patient with acne.

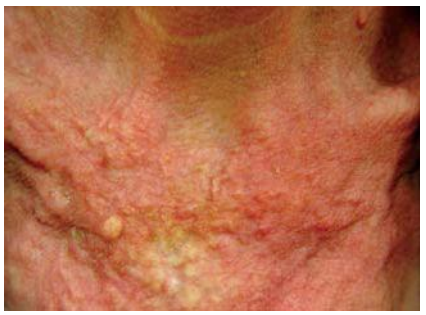
with web-like extensions, the area of initial wounding. Atrophic scars are thin depressed plaques.

COMEDO A comedo is a hair follicle infundibulum that is dilated and plugged by keratin and lipids. When the pilosebaceous unit is open to the surface of the skin with a visible keratinaceous plug, the lesion is referred to as an *open comedo*. The black color of the comedo is due to the oxidized sebaceous content of the infundibulum ("blackhead"). A closed infundibulum in which the follicular opening is unapparent accumulates whitish keratin and is called a *closed comedo*. These lesions are common on the face and trunk. A clinical example is comedonal acne (Fig. 4-7; see Chap. 78).

HORN A horn is a conical mass of cornified cells arising over an abnormally differentiating epidermis. Associated underlying pathologic states may include human papilloma virus replication in keratinocytes of a wart or the clonal expansion of mutated keratinocytes in squamous cell carcinoma. A clinical example is verruca vulgaris (Fig. 4-8; see Chap. 196).

CALCINOSIS Deposits of calcium in the dermis or subcutaneous tissue may be

▲ **FIGURE 4-8** Horn. A conical column of hyperkeratosis overlying a pink papule. This cutaneous horn represents a verruca vulgaris.



▲ **FIGURE 4-9** Calcinosis. Hard, whitish nodules on the chest representing dystrophic calcinosis in this patient with dermatomyositis.

appreciated as hard, whitish nodules or plaques, with or without visible alteration of the skin's surface. A clinical example is cutaneous calcinosis in dermatomyositis (Fig. 4-9; see Chap. 157).

Depressed Lesions

EROSION An *erosion* is a moist, circumscribed, depressed lesion that results from loss of a portion or all of the viable epidermal or mucosal epithelium. The defect extending to the most superficial part of the dermis may result in pinpoint bleeding in a sieve-like fashion. Erosions may result from trauma, detachment of epidermal layers with maceration, rupture of vesicles or bullae, or epidermal necrosis, for example. Extensive erosions may result in large areas of raw denudation. Unless they become secondarily infected, erosions do not scar. A clinical example is toxic epidermal necrolysis (Fig. 4-10; see Chap. 39).

ULCERS An ulcer is a defect in which the epidermis and at least the upper (papillary) dermis has been removed. Breach of the dermis and destruction of adnexal structures impede re-epithelialization, and the defect heals with scarring. There are numerous descriptive features helpful in determining the cause of ulcers. Location of the ulcer, such as on

▲ **FIGURE 4-10** Erosion. Sloughing of the skin in this patient with toxic epidermal necrolysis leaves behind a large erosion.

▲ **FIGURE 4-11** Ulcer. A large ulcer with a ragged base and heaped up pink erythematous border on the leg representing progressing pyoderma gangrenosum.

the medial aspect of the ankle or over pressure points, may be telling. Borders of the ulcer may be rolled, undermined, punched out, jagged, or angular. The base may be clean, ragged, or necrotic. Discharge may be purulent, granular, or malodorous. Surrounding skin may be red, purple, pigmented, reticulated, indurated, sclerotic, or infarcted. Other informative features include the presence of nearby nodules, surrounding excoriations, varicosities, hair, sweat, and the strength of adjacent pulses. A clinical example is pyoderma gangrenosum (Fig. 4-11; see Chap. 32).

ATROPHY *Atrophy* refers to a diminution in the size of a cell, tissue, organ, or part of the body. A decrease in the number of epidermal cells results in thinning of the epidermis. Atrophic epidermis is glossy, almost transparent, paper thin and wrinkled, and may not retain normal skin lines.

Epidermal atrophy may also be associated with similar alterations in the dermis. A decrease in the papillary or reticular dermal connective tissue manifests as a depression of the skin. In dermal atrophy occurring without epidermal involvement, the area of affected skin is normal in color and surface markings because the circumscribed depression is produced only by the decrease in dermal tissue.

Atrophy of the panniculus results in a more substantial depression of the skin. A thinned wrinkled surface indicates coexisting epidermal atrophy. Fig. 4-12 shows aged skin of the arm (see Chap. 108).

POIKILODERMA As a morphologic term, *poikiloderma* refers to the combination of atrophy, telangiectasia, and varied pigmentary changes (hyper- and hypo-) over an area of skin. This combination of features may give rise to a dappled appearance to the skin. The distribution

▲ **FIGURE 4-12** Atrophy. Thin, wrinkled atrophic skin that has lost its normal texture on the arm of this elderly woman.

of poikiloderma varies according to etiology. Because of some confusion in the past stemming from the use of the word *poikiloderma* in the naming of specific syndromes, it is probably best to restrict its use to a descriptive. A clinical example is chronic radiodermatitis (Fig. 4-13; see Chap. 95).

SINUS A sinus is a tract connecting deep suppurative cavities to each other or to the surface of the skin. The contents of the cavity, usually pus, fluid, or keratin, may drain to the surface when such communication exists. These tracts are usually noted on the scalp, neck, axillae, groin, and rectum. A clinical example is hidradenitis suppurativa (Fig. 4-14; see Chap. 83).

▲ **FIGURE 4-13** Poikiloderma. Poikiloderma with telangiectatic erythema, hyperpigmentation, hypopigmentation, and atrophy in chronic radiodermatitis.

▲ **FIGURE 4-14** Sinus. Suppurative communicating fibrous sinus tracts in the groin representing hidradenitis suppurativa.

STRIAE Striae are linear depressions of the skin that usually measure several centimeters in length and result from changes to the reticular collagen that occur with rapid stretching of the skin. The surface of striae may be thin and wrinkled. They may be pink to red in color and raised before becoming paler and flattened out. Striae are multiple and typically symmetrically distributed along lines of cleavage in the involved area. A clinical example is striae distensae (Fig. 4-15; see Chap. 107).

BURROW A burrow is a wavy, threadlike tunnel through the outer portion of the epidermis excavated by a parasite. Burrows measure only a few millimeters in length. A clinical example is scabetic burrow (Fig. 4-16; see Chap. 208).

SCLEROSIS *Sclerosis* refers to a circumscribed or diffuse hardening or induration in the skin that is a result of dermal fibrosis. It is detected more easily by palpation, on which the skin may feel board-like, immobile, and difficult to pick up. Hyperpigmentation or hypopigmentation may also distinguish the area of induration from normal skin. The epidermis overlying sclerotic dermis may be atrophic. Sclerosis may extend deep into the pannus, fascia, muscle, or bone with resulting musculoskeletal deformity and loss of function. A clinical example is morphea (Fig. 4-17; see Chap. 62).

▲ **FIGURE 4-15** Striae. Linear striae on the back of this woman who experienced a rapid growth spurt and weight gain.

▲ **FIGURE 4-16** Burrows. Several, slightly scaling, thread-like burrows on the medial aspect of the palm, associated with a more generalized eczematous process in this patient infested with scabies mites.

Flat and Macular Lesions

MACULE A macule is a flat lesion, even with the surface level of surrounding skin, perceptible as an area of color different from the surrounding skin or mucous membrane. Macules are non-palpable. Their shapes are varied and borders may be distinct or vague. Maculosquamous is a neologism invented to describe macules with fine non-palpable scaling, which may become apparent only after light scraping and scratching.

Perhaps the most important additional feature of a lesion other than primary morphology is color. Lesional color, which is often the first visual assessment made, is reliably reproducible with par-

▲ **FIGURE 4-17** Sclerosis. Firm, slightly depressed sclerotic plaque on the leg of a girl with morphea. The surface is atrophic and there are areas of hypo- and hyperpigmentation.

TABLE 4-3
Implications of Color Changes in Altered Skin

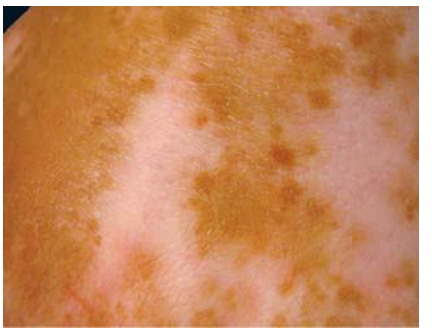
Color	Pathology	Diagnostic Consideration
Apple jelly	Granulomatous inflammation	Tuberculosis, sarcoidosis, leishmaniasis
Black	Melanin, necrosis	Melanoma, purpura fulminans, calciphylaxis
Blue	Deep dermal pigment, reduced hemoglobin, tattoo, medication	Blue nevus, amiodarone
Brown	Melanin, hemosiderin, chronic inflammation, post-inflammatory, dried serum	Nevus, melasma
Copper	Inflammation with plasma cells	Secondary syphilis
Green	Deep hemosiderin, pyocyanin pigment, tissue eosinophilia	*Pseudomonas* infection, tattoo, Wells syndrome
Grey	Deep melanin or other pigment deposition	Chloroquine toxicity, mongolian spot, erythema dyschromicum perstans
Lilac	Inflammation, dilatation of deep dermal blood vessels	Borders of evolving morphea, dermatomyositis
Orange	Granulomatous inflammation with histiocytes having abundant cytoplasm	Juvenile xanthogranuloma
Pearly	Epidermal proliferation without surface keratin	Basal cell carcinoma
Pink	Acute inflammation, dilatation of superficial dermal blood vessels, hemorrhage	Eczema
Red	Hemorrhage, acute inflammation, dilatation of blood vessels	Psoriasis, drug eruptions
Salmon pink	Inflammation with involvement of epidermis, dilatation of blood vessels inflammation with edema	Pityriasis rubra pilaris, psoriasis, urticaria
Violet	Hemorrhage, deep hemosiderin, lichenoid inflammation	Lichen planus, Kaposi sarcoma
White	Reduced or absent melanin synthesis, post-inflammatory	Tinea versicolor, albinism, vitiligo
Yellow	Superficial staphylococcus or streptococcus infection mixed with keratinized cells, carotenoids, hemosiderin, bile pigment, accumulated lipid	Impetigo, xanthomas, sebaceous hyperplasia, necrobiosis lipoidica diabeticorum, jaundice

ticular types of pathologies, such as destruction of melanocytes, dilatation of dermal blood vessels, or inflammation of vessel walls with extravasation of red blood cells. As such, color provides meaningful insight into pathologic processes of the skin and facilitates clinical diagnosis. Pigmentary changes represent an important and common type of macular color change and may be described as hyperpigmented (as in post-inflammatory hyperpigmentation), hypopigmented (as in tinea versicolor), or depigmented (as in vitiligo).

Table 4-3 describes characteristic colors that may be noted with inspection of altered skin. A clinical example is lentigo (Fig. 4-18; see Chap. 122).

PATCH A patch is similar to a macule; it is a flat area of skin or mucous membranes with a different color from its surrounding. A patch, however, is larger than 0.5 cm, and it may have a fine, very thin scale. Confluence of patches may cover large areas of the body. The term *patch* is also used to describe early lesions of cutaneous T-cell lymphoma that have a fine scale or are minimally atrophic. A clinical example is vitiligo (Fig. 4-19; see Chap. 72).

▲ **FIGURE 4-18** Macule. Uniform colored brown macule with slightly irregular, sharply defined borders representing a lentigo on the lip.



▲ **FIGURE 4-19** Patch. Depigmented patches within areas of normal skin tone representing vitiligo.

ERYTHEMA Erythema represents the blanchable change in color of skin or mucous membrane that is due to dilatation of arteries and veins in the papillary and reticular dermis. It exists in different colors, and to dub a primary lesion as *erythematous* alone is incomplete. Describing erythema with the color it most closely resembles provides a meaningful clue to diagnosis. For example, violaceous erythema brings to mind a differential unique from salmon pink–colored erythema, even if both types of erythema involve papules. A clinical example is dusky erythema, representing a fixed drug eruption (Fig. 4-20; see Chap. 40).

ERYTHRODERMA Erythroderma is a generalized deep redness of the skin involving more than 90 percent of the body surface within days to weeks. Scaling or desquamation generally follows establishment of the generalized erythema. The type of scale noted is suggestive of

▲ **FIGURE 4-20** Erythema. A large area of dusky red erythema in the gluteal region representing a fixed drug eruption.

TABLE 4-4
Types of Scale

Type of Scale	Description	Prototype Diagnosis
Crack-like/craquelé	Desquamation giving the appearance of dried, cracked skin.	Eczema craquelé
Exfoliative	Scales split of from the epidermis in finer scales or in sheets.	Drug reaction
Follicular	Scales appear as keratotic plugs, spines, or filaments.	Keratosis pilaris
Gritty	Densely adherent scale with a sandpaper texture.	Actinic keratosis
Ichthyosiform	Scales are regular polygonal plates arranged in parallel rows or diamond patterns (fish-like, tesselated).	Ichthyosis vulgaris
Keratotic	Scales appear as heaped up column of scale.	Cutaneous horn
Lamellar	Scales are thin large plates or shields attached in the middle and looser around the edges.	Lamellar ichthyosis
Pityriasiform	Scale is small and branny.	Pityriasis rosea
Psoriasiform (micaceous and ostraceous)	Scale is silvery and brittle and forms thin platelets in several loose sheets, like mica (micaceous scale). Large scales may accumulate in heaps, giving the appearance of an oyster shell (ostraceous scale).	Psoriasis vulgaris
Seborrheic	Scales are thick, waxy or greasy, yellow-to-brown, flakes.	Seborrheic dermatitis
Wickham striae	Scale appears as a lacy white pattern overlying violaceous flat-topped papules.	Lichen planus

the primary process (Table 4-4). A clinical example is Sézary syndrome (Fig. 4-21; see Chap. 23).

▲ **FIGURE 4-21** Erythroderma. Generalized red erythema and exfoliative scale in this erythrodermic patient.

Surface Change

SCALE, DESQUAMATION (SCALING) A scale is flat plate or flake arising from the outer-most layer of the stratum corneum. Groups of coherent cornified cells packed with filamentous proteins desquamate in scales imperceptibly from the skin's surface under normal circumstances on a regular basis as the epidermis is replaced completely every 27 days. When epidermal differentiation is disordered, accumulation and casting of stratum corneum become apparent as scale which ranges in size from fine dust-like particles to extensive parchment-like sheets. In some cases, scale is observed only after scratching the lesion, a phenomenon known as *latent desquamation*.

Not all scales are similar, and the expert dermatologist with the well-trained eye can obtain diagnostically useful information from close examinations of the type of scale present. Table 4-4 describes the types of scale one may encounter. A clinical example is psoriasis vulgaris (Fig. 4-22; see Chap. 18).

CRUSTS (ENCRUSTED EXUDATES) Crusts are hardened deposits that result when

▲ **FIGURE 4-22** Scale. Brittle silvery scales forming thin platelets in several loose sheets, like mica, on this plaque of psoriasis.

serum, blood, or purulent exudate dries on the surface of the skin. The appearance of crust is frequently heterogeneous and depends on the nature of secretion. The color of crust is a yellow-brown when formed from dried serous secretion; turbid yellowish-green when formed from purulent secretion; and reddish-black when formed from hemorrhagic secretion. Superficial crusts may be thin, delicate, and friable. Crusts may be thick and adherent when involving the entire thickness of the epidermis. Small or punctate crust may result from scratching, whereas larger, honey-colored moist crusts form with impetiginization, a secondary suppuration. Gentle maneuvering of crust may exude secretions from its base. Removal of the crust may reveal an underlying erosion or ulcer. A clinical example is impetigo (Fig. 4-23; see Chap. 177).

EXCORIATIONS Excoriations (Fig. 4-24) are surface excavations of epidermis that result from scratching and are frequent findings in patients experiencing pruritus. Rigorous or uncontrollable scratching may produce long, parallel, sometimes crossing, groups of excoria-

▲ **FIGURE 4-23** Crust. Glistening, honey-colored, delicate crusts under the nose representing impetigo.

▲ **FIGURE 4-24** Excoriation. Linear and punctate excoriations on the back induced by scratching.

tions which may be hemorrhagic when light bleeding is induced.

FISSURE A fissure is a linear loss of continuity of the skin's surface or mucosa that results from excessive tension or decreased elasticity of the involved tissue. Fissures frequently occur on the palms and soles where the thick stratum corneum is least expandable. Transitional areas between skin and mucosa and skin overlying joints are susceptible if elasticity is reduced. A clinical example is fissure on the palm associated with contact dermatitis (Fig. 4-25).

LICHENIFICATION Repeated rubbing of the skin may induce a reactive thickening of the epidermis, with changes in the collagen of the underlying superficial dermis. These changes produce a thickened skin with accentuated markings, which may resemble tree bark. Lichenified plaques may also show signs of scratching, such as excoriations and crusts. A clinical example is lichen simplex chronicus (Fig. 4-26; see Chap. 15).

KERATODERMA Keratoderma is an excessive hyperkeratosis of the stratum corneum that results in a yellowish thickening of the skin, usually on the palms or soles, that may be inherited (abnormal keratin formation) or acquired (mechanical stimulation). A clinical example is plantar keratoderma (Fig. 4-27; see Chap. 48).

▲ **FIGURE 4-25** Fissure. A linear loss of continuity of the skin on the palm representing a fissure.

▲ **FIGURE 4-26** Lichenification. An area of thickened skin with accentuated skin markings induced by repeated rubbing, representing lichenification noted in lichen simplex chronicus.

ESCHAR The presence of an eschar implies tissue necrosis, infarction, deep burns, gangrene, or other ulcerating process. It is a circumscribed, adherent, hard, black crust on the surface of the skin that is moist initially, protein rich, and avascular. This milieu fosters microbial growth. The eschar may slough naturally, or it may be débrided surgically to facilitate re-epithelialization and wound healing. A clinical example is thermal burn (Fig. 4-28; see Chap. 94).

Fluid-Filled Lesions

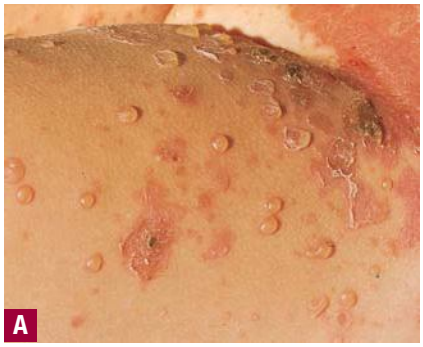
VESICLE AND BULLA A vesicle is a fluid-filled cavity or elevation smaller than or equal to 0.5 cm, whereas a bulla (blister) measures larger than 0.5 cm. The fluid in the cavity exerts equal pressure in all directions to give rise to a spherical shape. Vesicles may be non-palpable in areas of thicker stratum corneum such as the palm, where their presence may be suggested by a circumscribed translucency or

▲ **FIGURE 4-27** Keratoderma. Yellowish thickening of skin on the soles in this patient with an inherited keratoderma.

▲ **FIGURE 4-28** Eschar. Overlying eschars compromising peripheral perfusion in a burn victim.

a residual collarette of scale left behind after rupture. Mucosal vesicles rupture easily and may only be noted as an erosion or white thin plaque. Vesicles and bullae arise from cleavage at various levels of the epidermis (intraepidermal) or of the dermal-epidermal interface (sub-epidermal). The amount of pressure required to collapse the lesion may help predict whether the bulla is intraepidermal or sub-epidermal. Reliable differentiation, however, requires histopathologic examination of the blister cavity edge. Cleavage just beneath the stratum corneum produces a subcorneal vesicle or bulla. Intraepidermal vesiculation may result from spongiosis (widened intercellular spaces due to edema) or acantholysis (loss of cohesion between keratinocytes due to the loss of intercellular attachments). "Ballooning degeneration" (cytoplasmic swelling with loss of keratinocyte attachments) of epidermal cells noted in viral infections also results in epidermal vesiculation.

Because of their size, bullae are easily identifiable as tense or flaccid weepy blisters. Once collapsed or torn, blisters may leave behind erosions. The cavity wall is often thin and translucent enough to allow the visualization of contents, which may be clear, serous, hemorrhagic, or pus filled. Cleavage in tense bullae are commonly located at the dermal-epidermal junction. Sub-epidermal blisters are usually a result of mechanical fragility, or autoimmunity to or genetic alteration of a component of the basement membrane zone. A clinical example of vesicle is toxin-producing



▲ **FIGURE 4-29** Vesicle (**A**) and bulla (**B**). Fragile sub-corneal translucent vesicles representing impetigo caused by a toxin-producing staphylococcus (**A**) and large tense sub-epidermal bullae filled with serous or hemorrhagic fluid in this patient with bullous pemphigoid (**B**).

staphylococcal impetigo (Fig. 4-29A; see Chap. 178). A clinical example of bulla is a bullous pemphigoid (Fig. 4-29B; see Chap. 54).

PUSTULE A pustule is a circumscribed, raised cavity in the epidermis or infundibulum containing pus. The purulent exudate, composed of leukocytes with or without cellular debris, may contain bacteria or may be sterile. A Gram stain and culture of the exudate from pustules should be performed when the potential for infection exists. Depending on its sterility, the exudate may be white, yellow, or greenish-yellow in color. Pustules may vary in size and, in certain situations, may coalesce to form "lakes" of pus. When associated with hair follicles, pustules may appear conical and contain a hair in the center. There may be an erythematous halo surrounding the pustule. Because of

▲ **FIGURE 4-30** Pustule. Two pustules representing superficial pyoderma.

their superficial location, pustules generally heal without scarring. A clinical example is superficial pyoderma (Fig. 4-30; see Chap. 177).

FURUNCLE A furuncle (Fig. 4-31; see Chap. 177) is a deep necrotizing folliculitis with suppuration. It presents as an inflamed follicle-centered nodule usually greater than 1 cm with a central necrotic plug and an overlying pustule. Several furuncles may coalesce to form a carbuncle.

ABSCESS An abscess (Fig. 4-32; see Chap. 179) is a localized accumulation of purulent material so deep in the dermis or subcutaneous tissue that the pus is usually not visible on the surface of the skin. An abscess is a pink erythematous, warm, tender, fluctuant nodule that may be associated with other signs of infection such as fever. It frequently begins as a folliculitis resulting from streptococcal or staphylococcal infection.

Purpura/Vascular Lesions

PURPURA Extravasation of red blood from cutaneous vessels into skin or mu-

▲ **FIGURE 4-31** Furuncle. An inflamed follicular-based nodule with a central necrotic plug that has come loose. There is crusting over the surface.

▲ **FIGURE 4-32** Abscess. A tender red erythematous fluctuant abscess on the leg.

cous membranes results in reddish-purple lesions included under the term *purpura*. The application of pressure with two glass slides or an unbreakable clear lens (diascopy) on a reddish-purple lesion is a simple and reliable method for differentiating redness due to vascular dilatation (erythema) from redness due to extravasated erythrocytes or erythrocyte products (purpura). If the redness is non-blanching under the pressure of the slide, the lesion is purpuric.

Petechiae are small, pinpoint purpuric macules. Ecchymoses are larger, bruise-like purpuric patches. These lesions correspond to a noninflammatory extravasation of blood. As extravasated red blood cells decompose over time, the color of purpuric lesions change from bluish-red to yellowish-brown or green. If a lesion is purpuric and palpable ("palpable purpura"), the suggestion of an inflammatory insult to the vessel wall as a cause of extravasation of blood and inflammatory cells exists. A clinical example is leukocytoclastic vasculitis (Fig. 4-33; see Chap. 164).

TELANGIECTASIA Telangiectasia (Fig. 4-34; see Chap. 173) are persistent dilatations of small capillaries in the superficial dermis that are visible as fine, bright, non-pulsatile red lines or net-like patterns on the skin. Telangiectasia may or may not disappear with diascopy.

INFARCT An infarct is an area of cutaneous necrosis resulting from a bland or inflammatory occlusion of blood vessels in the skin. A cutaneous infarct presents as a tender, irregularly shaped dusky reddish-gray macule or firm plaque that is sometimes depressed slightly below the plane of the skin. The demarcation of an infarct corresponds to the distribution of blood of the affected vessels. A pink zone of hyperemia often surrounds the area of infarction. A clinical example

▲ **FIGURE 4-33** Purpura. Non-blanching red erythematous papules and plaques (palpable purpura) on the legs, representing leukocytoclastic vasculitis.

▲ **FIGURE 4-34** Telangiectasia. Blanching dilated superficial capillaries representing telangiectasia.

▲ **FIGURE 4-35** Infarct. Dusky purple discoloration representing an area of infarction that eventuates in tissue necrosis. This patient had cholesterol emboli lodged in the distal end arteries of the toes.

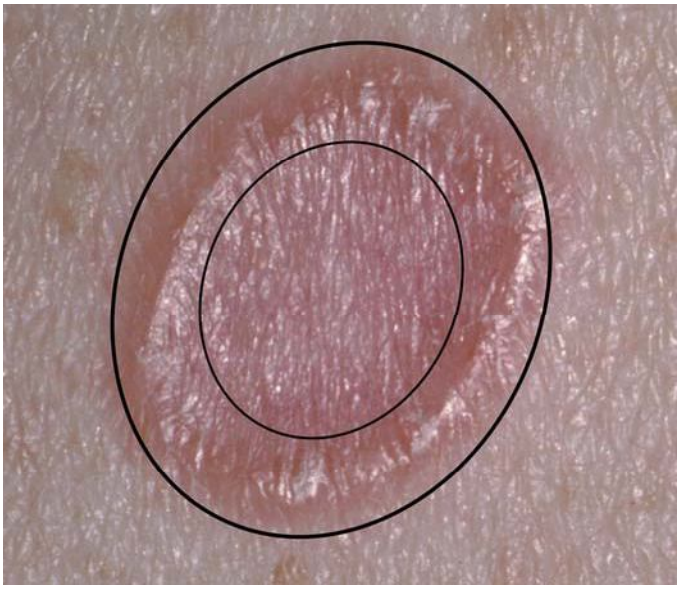
is cholesterol emboli (Fig. 4-35; see Chap. 174).

Shape, Arrangement, and Distribution of Lesions

Once the type or types of lesions have been identified, one needs to describe their shape, arrangement, and pattern of distribution, all useful characteristics in morphologic diagnosis. For example, a single scaly plaque on a patient's trunk may have a broad differential diagnosis, but the same plaques symmetrically distributed on the elbows, knees, and umbilicus would be highly suggestive of psoriasis. The following descriptions of shapes and arrangements of skin lesions may be applied to single or multiple lesions. For example, a single lesion may be linear or multiple lesions may assume a linear pattern.

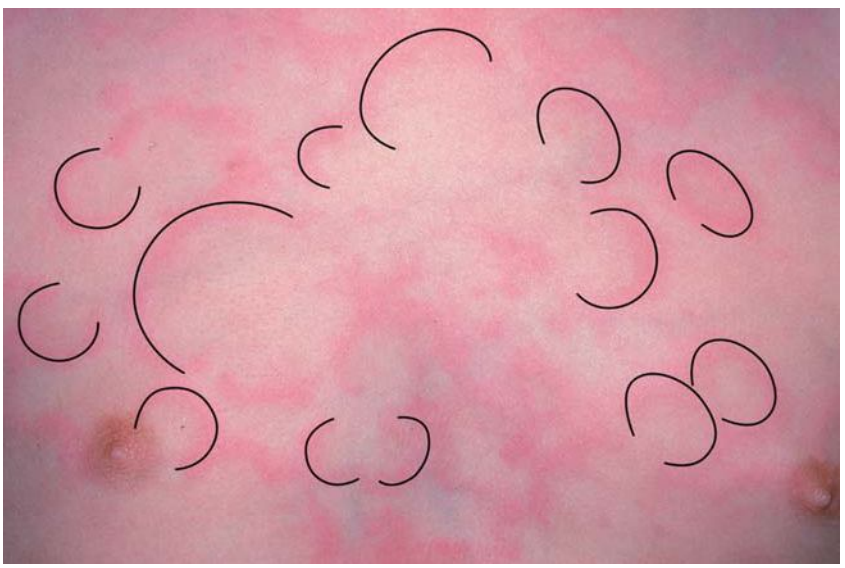
SHAPE OR CONFIGURATION OF SKIN LESIONS

- Annular (Fig. 4-36): ring-shaped; implies that the edge of the lesion differs from the center, either by being raised, scaly, or differing in color (e.g., granuloma annulare, tinea corporis, erythema annulare centrifugum).
- Round/nummular/discoid (Fig. 4-37): coin-shaped; usually a round to oval lesion with uniform morphology from the edges to the center (e.g., nummular eczema, plaque-type psoriasis, discoid lupus).
- Polycyclic (Fig. 4-38): formed from coalescing circles, rings, or incomplete rings (e.g., urticaria, subacute cutaneous lupus erythematosus).
- Arcuate (Fig. 4-39): arc-shaped; often a result of incomplete formation of an annular lesion (e.g., urticaria, subacute cutaneous lupus erythematosus).

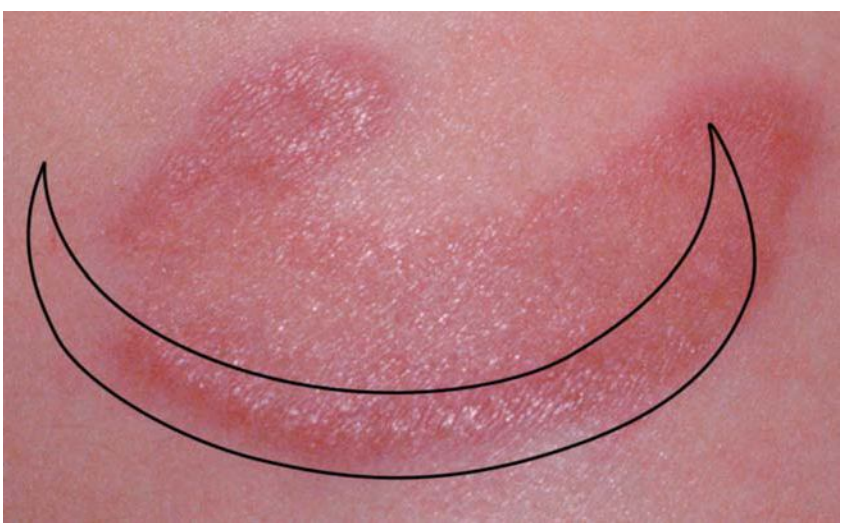


▲ **FIGURE 4-36** Annular lesion. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)

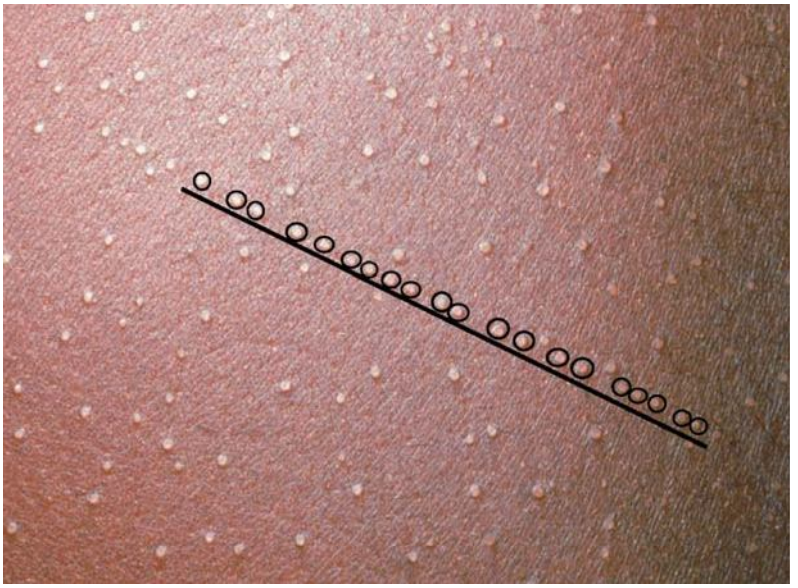
▲ **FIGURE 4-37** Nummular lesion. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)



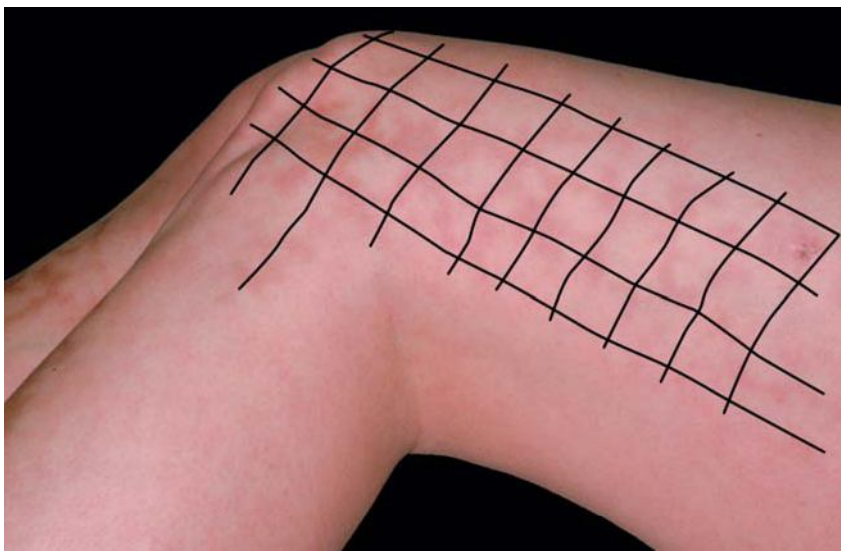
▲ **FIGURE 4-38** Polycyclic lesion. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)



▲ **FIGURE 4-39** Arcuate lesion. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)



▲ **FIGURE 4-40** Linear distribution of lesions. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)



▲ **FIGURE 4-41** Reticular lesion. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)

▲ **FIGURE 4-42** Serpiginous lesion. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)

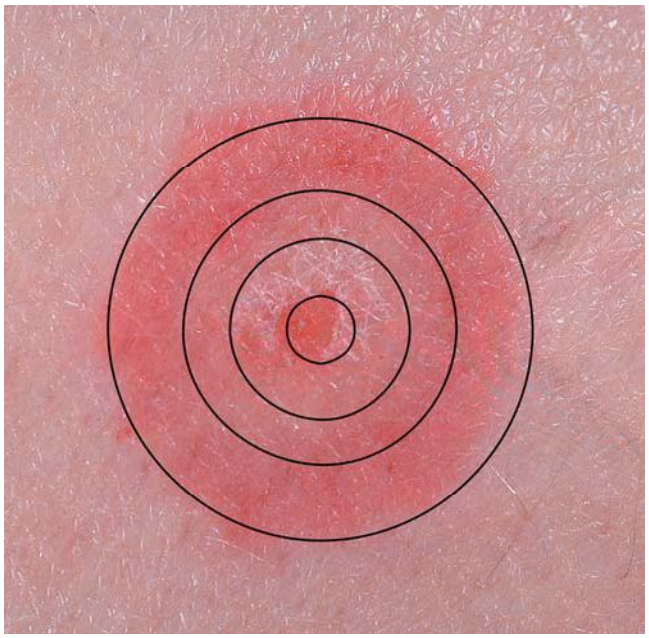
- Linear (Fig. 4-40): resembling a straight line; often implies an external contactant or Koebner phenomenon has occurred in response to scratching; may apply to a single lesion (e.g., a scabies burrow, poison ivy dermatitis, or bleomycin pigmentation) or to the arrangement of multiple lesions (e.g., lichen nitidus or lichen planus).
- Reticular (Fig. 4-41): net-like or lacy in appearance, with somewhat regularly spaced rings or partial rings and sparing of intervening skin (e.g., livedo reticularis, cutis marmorata).
- Serpiginous (Fig. 4-42): serpentine or snake-like (e.g., cutaneous larva migrans, in which the larva migrates this way and that through the skin in a wandering pattern).
- Targetoid (Fig. 4-43): target-like, with at least three distinct zones (e.g., erythema multiforme).
- Whorled (Fig. 4-44): like marble cake, with two distinct colors interspersed in a wavy pattern; usually seen in mosaic disorders in which cells of differing genotypes are interspersed (e.g., incontinentia pigmenti, hypomelanosis of Ito, linear and whorled nevoid hypermelanosis).

Arrangement of Multiple Lesions

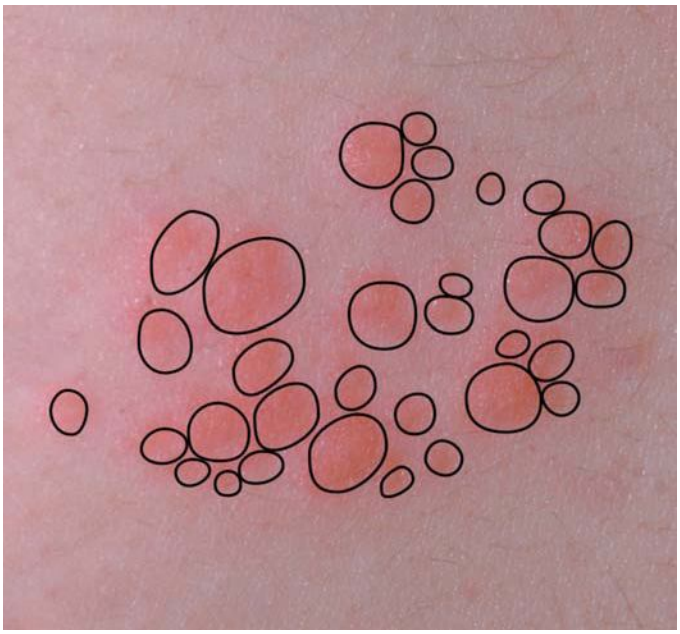
- Grouped/herpetiform (Fig. 4-45): lesions clustered together (e.g., classic example is herpes simplex virus 1 reactivation noted as grouped vesicles on an erythematous base; also seen with certain arthropod bites).
- Scattered (Fig. 4-46): irregularly distributed.

Distributions of Multiple Lesions

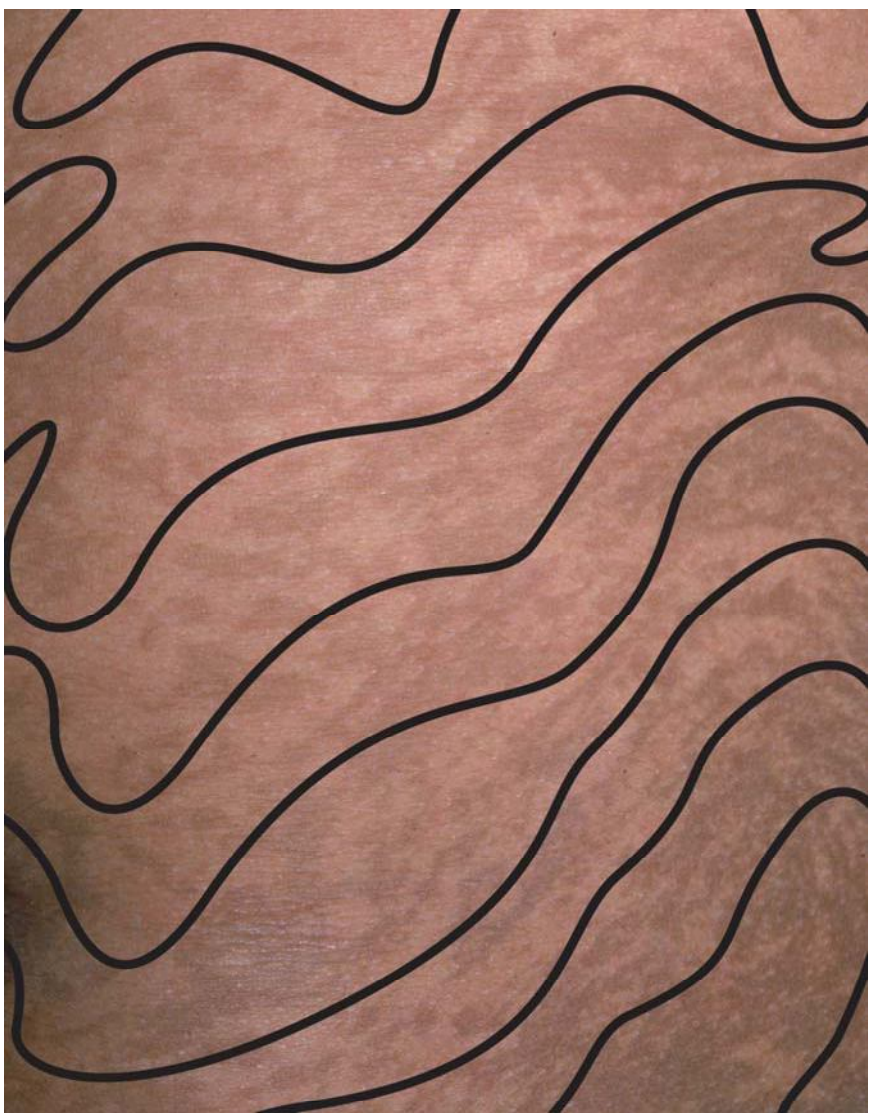
- Dermatomal/zosteriform: unilateral and lying in the distribution of a single spinal afferent nerve root; the classic example is herpes zoster.
- Blaschkoid (Fig. 4-47): following lines of skin cell migration during embryogenesis; generally longitudinally oriented on the limbs and circumferential on the trunk, but not perfectly linear (see also Whorled in Shape and Configuration of Lesions); described by Alfred Blaschko and implies a mosaic disorder (e.g., incontinentia pigmenti, inflammatory linear verrucous epidermal nevus).
- Lymphangitic: lying along the distribution of a lymph vessel; implies an



▲ **FIGURE 4-43** Targetoid lesion. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)



▲ **FIGURE 4-45** Grouped: clustered. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)



▲ **FIGURE 4-44** Whorled: marbled appearance. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)

▲ **FIGURE 4-46** Scattered lesion. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)

▲ **FIGURE 4-47** Lesions in the distribution described by Blaschko for developmental lesions.

infectious agent that is spreading centrally from an acral site, usually a red streak along a limb due to a staphylococcal or streptococcal cellulitis.

- Sun exposed: occurring in areas usually not covered by clothing, namely the face, dorsal hands, and a triangular area corresponding to the opening of a V-neck shirt on the upper chest (e.g., photodermatitis, subacute cutaneous lupus erythematosus, polymorphous light eruption, squamous cell carcinoma).
- Sun protected: occurring in areas usually covered by one or more layers of clothing; usually a dermatosis that is improved by sun exposure (e.g., parapsoriasis, mycosis fungoides).
- Acral: occurring in distal locations, such as on the hands, feet, wrists, and ankles (e.g., palmoplantar pustulosis, chilblains).
- Truncal: occurring on the trunk or central body.
- Extensor: occurring over the dorsal extremities, overlying the extensor muscles, knees, or elbows (e.g., psoriasis).
- Flexor: overlying the flexor muscles of the extremities, the antecubital and popliteal fossae (e.g., atopic dermatitis).
- Intertriginous: occurring in the skin folds, where two skin surfaces are in contact, namely the axillae, inguinal folds, inner thighs, inframammary skin, and under an abdominal pannus; often related to moisture and heat generated in these areas (e.g., candidiasis).
- Localized: confined to a single body location (e.g., cellulitis).
- Generalized: widespread. A generalized eruption consisting of inflammatory (red) lesions is called an *exanthema* (rash). A macular exanthema consists of macules, a papular exanthema of papules, a vesicular exanthema of vesicles, etc. (e.g., viral exanthems, drug eruption).
- Bilateral symmetric: occurring with mirror-image symmetry on both sides of the body (e.g., vitiligo, plaque-type psoriasis).
- Universal: involving the entire cutaneous surface (e.g., erythroderma, alopecia universalis).

Table 4-5 describes some clinically relevant maneuvers and morphologic signs that point to particular integumentary or systemic diseases.

As the late Thomas B. Fitzpatrick often said, "dermatologists are physicians who can diagnose a rash!". They may also be internists, surgeons, biochemists,

TABLE 4-5
Selection of Cutaneous Signs[a]

Cutaneous Sign	Description	Significance
Apple jelly sign	A yellowish hue is produced from pressure on the lesion with a glass slide.	Noted in granulomatous processes.
Asboe-Hansen sign	Lateral extension of a blister with downward pressure.	Noted in blistering disorders in which the pathology is above the basement membrane zone.
Auspitz sign	Pinpoint bleeding at the tops of ruptured capillaries with forcible removal of outer scales from a psoriatic plaque.	Not entirely sensitive or specific for psoriasis.
Butterfly sign	Butterfly-shaped sparing from excoriations of the nonreachable interscapular region.	Noted in disorders associated with pruritus and implies that the physical findings are a consequence of rubbing and scratching.
Buttonhole sign	A flesh-colored, soft papule feels as though it can be pushed through a "buttonhole" into the skin.	Noted in a neurofibroma.
Carpet tack sign	Horny plugs at the undersurface of scale removed from a lesion.	Noted in lesions of chronic cutaneous lupus.
Crowe sign	Axillary freckling.	Noted in neurofibromatosis type I; may be seen as part of lentiginosis profuse.
Darier sign	Urticarial wheal produced in a lesion after it is rubbed with the rounded end of a pen. The wheal, which is strictly confined to the borders of the lesion, may not appear for several minutes.	Noted in urticaria pigmentosa and rarely with cutaneous lymphoma or histiocytosis.
Dermatographism	Firmly stroking unaffected skin produces a wheal along the shape of the stroke within seconds to minutes.	Symptomatic dermatographism represents a physical urticaria.
Pseudo-Darier sign	Transient induration of a lesion or piloerection after rubbing.	Noted in congenital smooth muscle hamartoma.
Fitzpatrick (dimple) sign	Dimpling of the skin with lateral compression of the lesion with the thumb and index finger produces dimpling due to tethering of the epidermis to the dermal lesion.	Characteristic of dermatofibroma.
Gottron sign	Raised or flat pink to violaceous erythema and/or papules of metacarpal or interphalangeal joints, olecranon, patellae, or malleoli.	Classically used in reference to dermatomyositis.
Hair collar	Ring of dark long scalp hair encircling a congenital lesion.	Associated with aplasia cutis, encephalocele, meningocele, or heterotopic brain tissue.
Heliotrope sign	Violaceous erythema over eyelids.	Noted in dermatomyositis.
Hertoghe sign	Thinning or loss of the outer third of the eyebrow.	May be associated with atopic dermatitis, hypothyroidism, systemic sclerosis.
Hutchinson nail sign	Periungual extension of pigment to the proximal and lateral nail folds.	Noted in subungual melanoma.
Hutchinson nose sign	Vesicles on the tip of the nose in a patient with herpes zoster of the face.	Due to the involvement of the nasociliary branch of ophthalmic nerve (V1) and indicates a higher likelihood of ocular disease.
Leser-Trélat sign	Sudden eruption of inflammatory seborrheic keratoses-like lesions.	Associated with systemic malignancy. Also reported with benign neoplasms, eczema, pregnancy, leprosy.
Nikolsky sign	Lateral pressure on unblistered skin with resulting shearing of the epidermis.	Noted in blistering disorders in which the pathology is above the basement membrane zone. Relevant entities include pemphigus vulgaris and toxic epidermal necrolysis.
Oil drop sign	Area of yellowish discoloration resembling an oil drop involving the nail bed distally (but not involving the free edge).	Indicates onycholysis noted in psoriatic nail disease.
Russell sign	Abrasions, lacerations, callosities of metacarpal and proximal interphalangeal joints.	Due to trauma from incisor teeth during self-induced vomiting in bulimia.
Shawl sign	Erythema over upper back and shoulders.	Classically used in reference to dermatomyositis.
Trousseau sign	Recurrent migratory superficial thrombophlebitis of small and large cutaneous veins.	Associated with internal malignancy (usually pancreatic), Behçet disease, rickettsial infections.
Ugly duckling sign	A pigmented lesion, among numerous atypical but clinically benign nevi, that stands out from the rest and may be a melanoma.	Helpful in screening numerous pigmented lesions in a low-risk individual. Once the lesion is distinguished from the others, it may be evaluated further for abnormal clinical features.

[a]Others are discussed in the chapters on diseases in which the signs occur.

TABLE 4-6
Ten Pointers and Pitfalls in Dermatologic Diagnosis

- Approach each and every evaluation with patience and thoroughness.
- Beware of "snap," "curbside," or "doorway" diagnoses.
- Examine the entire mucocutaneous surface, as well as the hair and nails.
- A new or changing mole should be carefully evaluated.
- Do not remove tissue without sending a portion for histologic examination.
- If the dermatopathologic findings are not consistent with the clinical impression, obtain another biopsy.
- If forced to choose between incongruent clinical and pathologic impression, follow clinical lead (cautiously).
- Generalized pruritus of more than 1 month's duration mandates a complete systemic workup.
- Seemingly non-specific rashes may just be camouflaged specific disorders.
- Drug-induced eruptions can mimic most skin conditions.
- Be wary of the "atypical" diagnosis. Atypical "this" may be "typical" that to someone who has seen it before.
- Consider all other reasonable possibilities before making a diagnosis of factitial disorder.

or immunologists; but without competency in dermatologic diagnosis they cannot qualify as dermatologists. This skill, however, is not specific to dermatologists. Any physician who makes the effort to study the skin and learn the dermatologic lexicon can develop a functional appreciation of the fundamentals of diagnosis. The advanced diagnostic eye can only be acquired by endlessly repeated encounters in which the physician is forced not only to look at, but also to observe, the rash while an experienced mentor points the way. The most common error in dermatologic diagnosis is to regard the lesions as non-specific "rashes" rather than as aggregates of specific individual lesions. As in surveying a blood smear, a "general impression" is not enough: The morphologic aspects of each individual cell must be carefully scrutinized and judged to be normal or abnormal. Too often, physicians adopt a speedy, superficial approach to the skin that they would not apply to any other organ that they examine (Table 4-6).

Lewis Thomas has said that "Medicine is no longer the laying on of hands, it is more like the reading of signals from machines." In dermatology, there can be no replacement for the laying on of hands, and the physician is repeatedly gratified by reading signals not from machines, but from people.

CHAPTER 5

Diagnostic Procedures and Devices

Alon Scope
Allan C. Halpern

"Don't just stand there and look: do something"

—Shelley WB and Shelley ED[1]

With a clinically well-trained eye and appropriate patient history, the majority of skin lesions can be diagnosed with simple visual inspection. However, details seen by the naked eye are limited in magnification, depth, and contrast. In this chapter, we discuss procedures and devices that can aid the clinician in making the correct diagnosis. We present the diagnostic aids in an order that escalates in terms of invasiveness, cost, and technical complexity (see eFig. 5-0.1 in on-line edition).

ENHANCE YOUR LOOK: VISUAL AIDS TO INSPECTION

Magnifying Lens

Magnification of surface pathology can be achieved with a hand-held lens. Magnifying instruments with built-in lighting and a magnification of 2- to 10-fold are readily available. Swabbing the skin surface with alcohol or application of a drop of oil before magnification can eliminate dirt particles and enhance the transparency of the stratum corneum.

Diascopy

Diascopy is performed by firmly pressing a transparent, hard, flat object (such as two microscope slides) on the surface of the skin. The user should be careful not to injure the patient's or his or her own skin with the sharp edge of the slide. Diascopy can be useful in distinguishing erythema secondary to vasodilation, which is blanchable with pressure, from erythrocyte extravasation (purpura) which retains its red color. In nevus anemicus, in which the blood vessels in the lesion are vasoconstricted, pressure on the edge of the lesion makes the margins inapparent. Diascopy is also useful in detection of the yellowish-brown ("apple jelly") color in papules or nodules of granulomatous processes, such as sarcoidosis, granuloma annulare, and tuberculosis.

Wood's Light

The Wood's light ("black light"), first described in 1903, is a useful device for the clinical evaluation of varied cutaneous diseases such as pigment disorders, skin infections, and porphyrias. The Wood's

DIAGNOSTIC PROCEDURES AND TECHNIQUES

AT A GLANCE

- Diagnostic procedures and techniques can be ranked as a ladder that escalates in terms of invasiveness, cost, and technical complexity.
- The basis is clinical history and physical examination ("ask, look, manipulate"), but further diagnostic clues can be obtained from visual aids ("enhance your look"), such as Wood's light, digital photography, and dermoscopy.
- There are bedside and office procedures, short of a biopsy, that include microscopic and microbiologic evaluation of blisters, scales, discharged fluids, and hair ("scrape, pull, swab").
- Further laboratory and imaging evaluation may be required to assess for systemic involvement of disease.
- Results of diagnostic procedures, including biopsy, need to be interpreted in the context of the clinical assessment.

light is produced with a high pressure mercury lamp emitting through a "Wood's filter" made of silicate with nickel oxide, which is opaque to all radiation beyond a wavelength between 320 nm and 400 nm [ultraviolet A (UVA)], with peak emission at 365 nm. An examiner using Wood's light should use a completely dark room, allow time for accommodation of vision to see the contrasts clearly, hold the lamp at least 10 cm from the skin, and notify the patient to avoid looking directly at the light source.[2]

Wood's light is strongly absorbed by melanin, making it a useful tool in the evaluation of pigmented lesions.[3] A lesion with an increased concentration of epidermal melanin appears darker than surrounding normal skin, with more contrast than normally discernible by visible light examination. Thus, Wood's lamp can be helpful in determining the subtle clinical borders of a lentigo maligna.

The ability of Wood's light to produce characteristic fluorescence in pathologic conditions extends its application to skin infections and porphyria. The green fluorescence of ectothrix-type tinea capitis, as in *Microsporum* sp. infection, can help make the correct bedside diagnosis; it can also serve as a guide to the scalp site that has a higher likelihood of yielding a positive culture, although not all cases clearly fluoresce.[7] Typical fluorescence may also be seen in erythrasma ("coral red"), tinea versicolor (yellow to orange) and *Pseudomonas aeruginosa* infection in burn patients (green), particularly if the examined area has not been cleansed recently.[4] In porphyria cutanea tarda, Wood's light can be used to screen for pink-orange fluorescence in the urine.

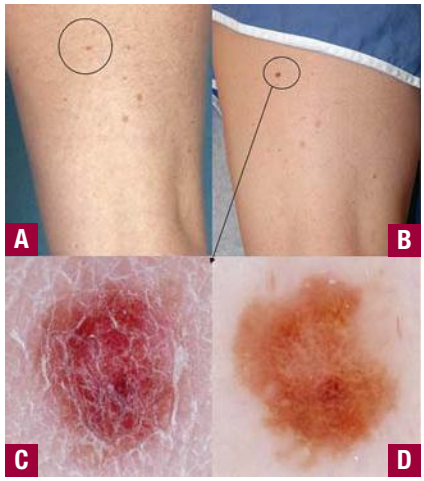
The examiner should be aware of false-positive sources of fluorescence such as scales, ointments, dried soaps, threads of fiber, and scars.

Dermoscopy

Clinicians that use dermoscopy have come to appreciate sub-surface diagnostic cues. Thus enters a new set of primary morphology terms. Dermoscopy (reported in the literature under varied names, including *epiluminescence microscopy*, *dermatoscopy*, *skin surface microscopy*) is a non-invasive technique that uses a hand-held instrument (dermoscope) equipped with a light source and magnifying optics. The application of a liquid interface (usually oil, water, or alcohol) to the surface of the skin decreases light reflection by the epidermis. Thus, the dermoscope immersed in the fluid interface allows for the visualization of subsurface anatomic structures of the epidermis and papillary dermis that are otherwise invisible to the unaided eye (Fig. 5-1). A polarized-light dermoscope allows for comparable sub-surface visualization by absorbing surface backscatter, without the need for skin contact or liquid immersion.

Dermoscopy increases clinical diagnostic accuracy for melanoma diagnosis by approximately 10 percent to 20 percent.[8] Dermoscopy facilitates differentiating melanocytic lesions from other pigmented lesions such as seborrheic keratoses, hemangiomas, and pigmented basal-cell carcinomas.[9] A two-step algorithm has been developed to approach such differentiation.[10,11] In the first step, the observer decides whether the lesion is melanocytic or non-melanocytic by searching for a set of specific structures, such as pigment network and globules which connote melanocytic lesions. These specific dermoscopic structures have been correlated to known histopathologic features.[12] When a lesion is classified as melanocytic, the observer then continues to the second step, which involves assessment (see Chap. 124) of the lesion as benign or malignant. Several dermoscopic algorithms have been developed for the second step, including pattern analysis, the ABCD rule of dermoscopy (see Chap. 124), Menzies method, and the 7-point checklist of dermoscopy.[2] Dermoscopy may also be helpful in the diagnosis of nonmelanoma skin cancer. For example, arborizing (branching) blood vessels are typical of basal cell carcinomas; tortuous, glomerulus-like ("glomeruloid") blood vessels are seen in Bowen disease; and pin-point, dotted vessels in squamous cell carcinoma.

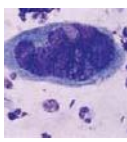
Dermoscopy has also been applied to evaluation of inflammatory lesions. Dermoscopy of the proximal nail folds can be used in place of bulky capillaroscopy to identify tortuous, dilated capillary loops and micro-hemorrhages in autoimmune diseases such as scleroderma and dermatomyositis.[13]



▲ **FIGURE 5-1** Visual aids to diagnosis: comparing baseline digital photography (**A**) to an image taken 3 years later (**B**), shows a lesion (*circles*) has become darker and larger. Clinical close-up image reveals a 7-mm brown-reddish papule not inherently concerning for malignancy (**C**). However, the degree of change along with dermoscopy (**D**) that shows a multi-component pattern with a negative network, irregular globules and regression, prompted an excisional biopsy. The lesion proved to be a malignant melanoma 0.5 in Breslow thickness.

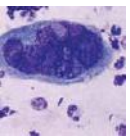
Photography

One of the most important signs of skin cancer is a history of change. Physicians frequently encounter situations in which the clinical diagnosis of a cutaneous lesion is uncertain, and thus, the presence of baseline photographs for comparison can facilitate the decision whether to



perform a biopsy. Those lesions that are new or have significantly changed may need to be biopsied (see Fig. 5-1), whereas if the lesion is found to be stable, the patient can be reassured that the lesion is unlikely to be cancerous.[17] A potential pitfall for photographically assisted follow-up is that reliance on monitoring lesions for change may reduce the sensitivity for diagnosis of skin cancer at the initial visit,[18] which could lead to untoward outcomes in patients who do not comply with the recommended follow-up.[19]

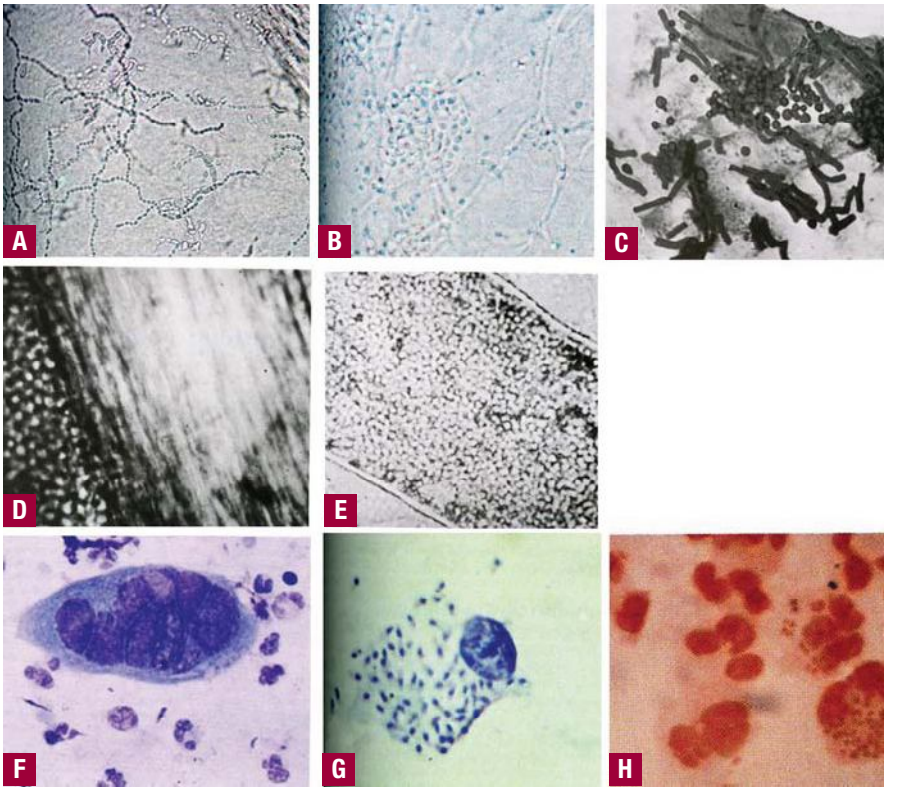
SCRAPE, PULL, SWAB



The scrape, pull, swab step of the diagnostic ladder considers sampling of cutaneous lesions short of performing a biopsy. Hair can be sampled by pulling or plucking for microscopic evaluation of fungal infection and hair disorders. Hair pulling, denoting gentle traction of hairs from the roots, is preferred over the hair plucking method (quick pulling with hand or clamp), because it is less painful and results in less hair shaft distortion.[23] A vesicular lesion can be scraped for Tzanck smear and the fluid sent, if appropriate, for culture or other microbial analysis methods, such as immunofluorescence or polymerase chain reaction. The lesion can be scraped with a scalpel or glass slide to sample scales in suspected fungal infection, burrows in scabies, and the base of an ulcer in genital lesions for direct microscopic identification of pathogens.[24] Mucosal surfaces, such as the nares, oropharynx, and urethra, can be swabbed for microbial cultures. For skin lesions, aspiration of pus/fluid collection and biopsy are better methods for pathogen identification than superficial swab sampling.[25] Fig. 5-2 depicts examples of infectious entities that can be readily diagnosed in the office setting.

BIOPSY THE LESION

Biopsy of the skin is a routine and essential diagnostic technique in dermatologic practice, as the skin is readily accessible to biopsy. The biopsy can be useful to confirm the clinical assessment when a definitive diagnosis is needed, add a diagnostic clue when clinical evidence is inconclusive, and occasionally uncover an unsuspected diagnosis. The biopsy may also be obtained to reassure the patient, and often the physician, that the diagnosis is correct despite suboptimal response to treatment. In case of lesions that are removed for cosmetic purposes, it is often prudent to submit the specimen for pathologic evaluation for medicolegal considerations.



▲ **FIGURE 5-2** What to expect under the microscope: (**A**) septate hyphae in dermatophyte infection, (**B**) budding yeasts in *Candida*, (**C**) pityriasis versicolor demonstrating hyphae and spores ("spaghetti and meatballs"), (**D**) ectothrix-type tinea capitis, (**E**) endothrix-type tinea capitis, (**F**) multinucleated giant cell in herpetic infection (Tzanck smear), (**G**) *Leishmania* tissue amastigotes, and (**H**) diplococci within leukocytes in gonorrhea.

Selecting the appropriate biopsy technique requires an understanding of the sampling extent of each method weighed against the probable diagnosis.[6] In addition, the two opposing vectors in selecting the biopsy method are the wish to minimize scarring, gearing toward a smaller, more superficial biopsy, versus the limitations posed on the histopathologic analysis by inadequate sampling.[28] The flip side of the cosmetic advantage of small biopsies is that an insufficient biopsy may mandate a second procedure that could actually result in an inferior cosmetic outcome than if a proper biopsy had been done in the first place. A biopsy can completely remove the lesion, or in lesions with a large surface area, partially sample it. A shave biopsy usually transects the superficial to mid-dermis and thus is more appropriate to exophytic or warty processes or lesions limited to the epidermis or papillary dermis, such as seborrheic keratosis, solar keratosis, and epidermal nevus. A punch biopsy should be performed if the pathology lies in the dermis or subcutaneous fat. The punch can remove a small lesion in its entirety or sample a core of tissue in larger lesions. It is appropriate for most inflammatory processes, such as cutaneous vasculitis, or dermatoses associated with deposits, such as granuloma annulare. However, a punch biopsy, unless of sufficient bore to encompass the entire lesion, is not the method of choice for removal of most neoplastic processes, because there is a substantial rate of incomplete excision and diagnostic sampling error.

Pathology reports should not be accepted at face value when inconsistent with the clinical impression.[35] Clinical-pathology correlation should be pursued through further sectioning and re-evaluation of the specimen, performing additional biopsies, or by seeking a second pathologist's opinion. Finally, there are reaction patterns with similar histopathologic appearance despite distinct etiology, as is often the case with chronic dermatitis, and thus further evaluation, such as patch testing, is warranted to uncover the specific cause.

INVESTIGATE FURTHER

EVOLVING TECHNOLOGIES

Computer-assisted diagnostic systems are being applied primarily to the evaluation of pigmented lesions. Most systems analyze the dermoscopic image of a lesion, using a multitude of parameters such as dimensions, geometry, number of colors, hue, distribution of structures, texture, and gradient of change from the normal skin. Another strategy is multi-spectral imaging, which applies a range of visible-light and near infrared wavelengths to the lesion, variable in the depth of their skin penetration and their enhancement of tissue chromophores (such as melanin, collagen, and hemoglobin).[36] This provides the computer with a greater set of parameters for analysis than the standard dermoscopic image.

Sub-surface imaging modalities include cutaneous ultrasonography, reflectance confocal microscopy (RCM), and optical coherence tomography (OCT). Rules of thumb that apply to sub-surface imaging are that (1) the deeper one sees into the tissue, the lower the image resolution, and (2) longer wavelengths penetrate deeper. An inherent limitation of imaging is observer dependency.

Ultrasound imaging is based on the fact that tissue components impede and reflect acoustic waves differently.[38] Ultrasound systems produce a two-dimensional image ("B-scan") of the skin by displaying the magnitude of acoustic reflection as degree of brightness. Intermediate frequency ultrasound (7.5 to 10.0 MHz) is used to evaluate subcutaneous masses for size, extent, and consistency (solid versus cystic) and to monitor for the presence of regional lymph-node metastases in melanoma. High-frequency ultrasound (20 MHz) is currently under study as a means to assess tumor thickness preoperatively in melanoma and non-melanoma skin cancer. The hypoechogenicity of tumors compared with the surrounding dermis forms the basis for image contrast.

In contrast, OCT produces a two-dimensional vertical image of the skin that is analogous to the aforementioned B-mode ultrasound imaging, except that it uses light rather than sound waves.[48] Again, melanin produces increased backscatter of light making this modality potentially useful for pigmented lesion evaluation. Currently commercially available OCT systems do not deliver the cellular-detail resolution of RCM, limiting the ability to differentiate benign and malignant lesions, but images deeper into the tissue (up to 1 mm), allowing for assessment of the overall lesion architecture and depth of tumor invasion.[49]

CHAPTER 6

Basic Pathologic Reactions of the Skin

Martin C. Mihm, Jr.
Abdul-Ghani Kibbi
Klaus Wolff

The skin is composed of different tissue compartments that interconnect anatomically and interact functionally. It is difficult to envisage epidermal function without signals from the dermis or passenger leukocytes traveling to and from the skin. On the other hand, epidermis, dermis, and subcutaneous tissue are heterogeneous in nature and an analysis of pathologic processes involving the skin should therefore consider both this heterogeneity and the interactions of the individual cutaneous compartments; only then will it be understood why a few basic reactions lead to a multiplicity of reaction patterns within this tissue.

Pathophysiologically, the skin can be subdivided into three reactive units that extend beyond anatomic boundaries (Fig. 6-1); they overlap and can be divided into different subunits that respond to pathologic stimuli according to their inherent reaction capacities in a coordinated pattern.

The superficial reactive unit comprises the subunits epidermis, the junction zone, the subjacent loose connective tissue of the papillary body and its capillary network, and the superficial venular plexus (see Fig. 6-1, SRU). The reticular layer of the dermis represents another reactive unit and is composed of connective tissue and the deeper dermal vascular plexus (see Fig. 6-1, DRU). The third reactive unit, the subcutaneous tissue, is anatomically and functionally also heterogeneous; septal and lobular compartments may be involved either alone or together (see Fig. 6-1, S). Hair follicles and glands are a separate (fourth) reactive unit embedded in these three basic units.

SUPERFICIAL REACTIVE UNIT

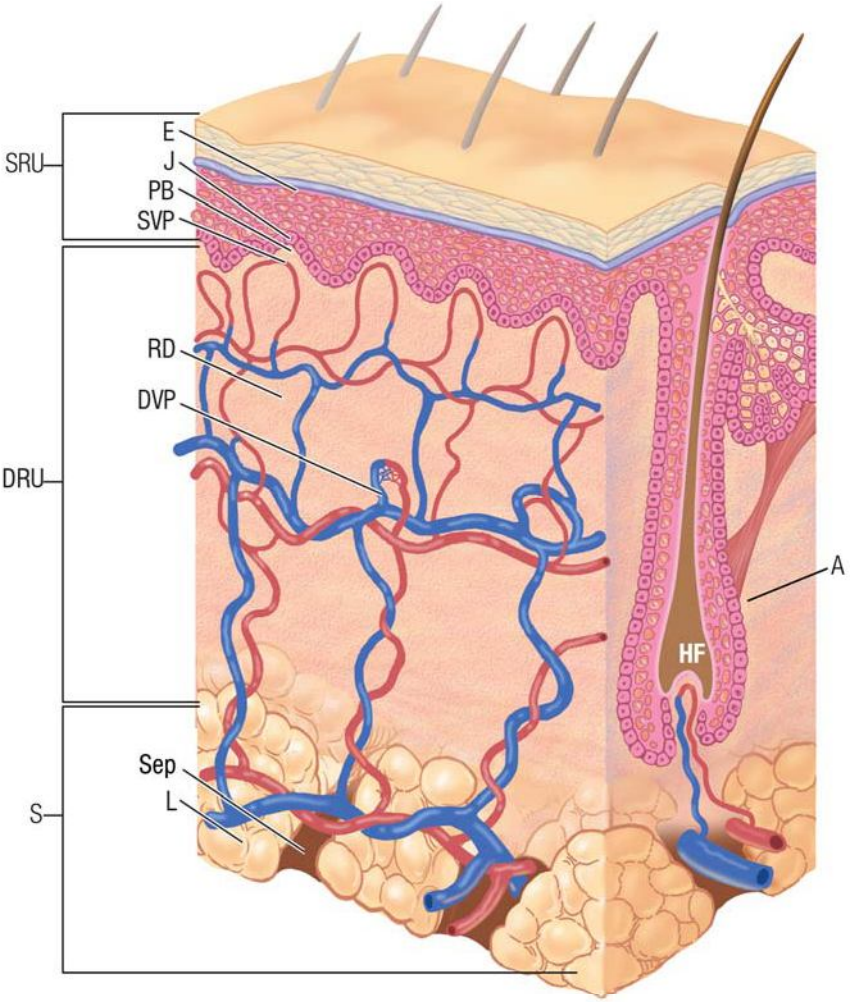
Epidermis (See Fig. 6-1, E)

Keratinocytes, which have the capacity to keratinize, represent the bulk of the epidermis. The epidermis, an ectodermal epithelium, also harbors a number of other cell populations such as melanocytes, Langerhans cells, Merkel cells, and cellular migrants (see Chap. 7). The basal cells of the epidermis undergo proliferation cycles that provide for the renewal of the epidermis and, as they move toward the surface of the skin, undergo a differentiation process that results in keratinization. The epidermis is thus a dynamic tissue in which cells are constantly in nonsynchronized motion; the proliferation kinetics and the

BASIC PATHOLOGIC REACTIONS

AT A GLANCE

- Different tissue compartments interconnect anatomically and interact functionally. These are the reactive units of skin.
- The superficial reactive unit comprises the epidermis, the junction zone, and the papillary body with its vascular system.
- The reticular dermis with the deeper dermal vascular plexus is the second reactive unit.
- The third reactive unit is the subcutaneous tissue with its septal and lobular compartments.
- Hair follicles and glands are a fourth reactive unit embedded into these three units.
- Pathologic processes may involve these reactive units alone or several of them in a concerted fashion.
- The heterogenicity and interaction of these individual cutaneous compartments explain why a few basic pathologic reactions lead to a multiplicity of clinical and pathologic reaction patterns.

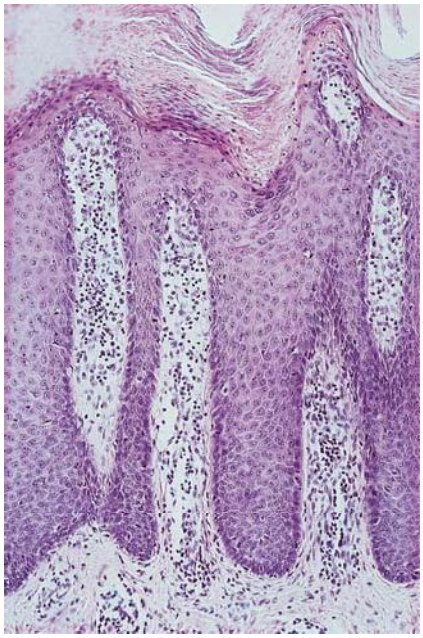


▲ **FIGURE 6-1** Reactive units of skin. The superficial reactive unit (SRU) comprises the epidermis (E), the junction zone (J), and the papillary body (PB) with the superficial microvascular plexus. The dermal reactive unit (DRU) consists of the reticular dermis (RD) and the deep dermal microvascular plexus (DVP). The subcutaneous reactive unit (S) consists of lobules (L) and septae (Sep). A fourth unit is the appendages (A; hair and sebaceous glands are the only appendages shown). HF = hair follicle.

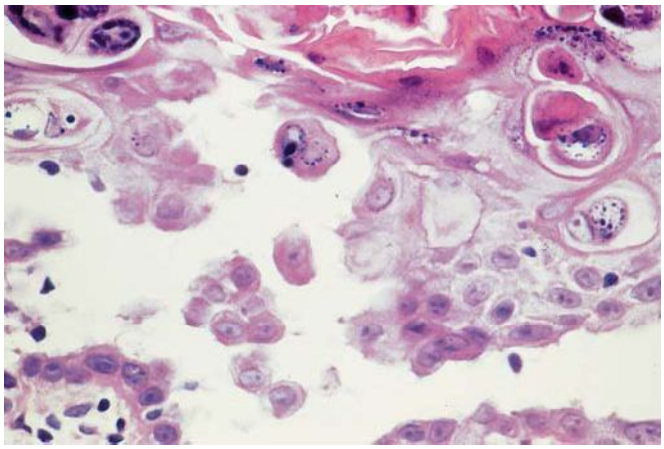
direction and speed of migration of the individual cell populations differ from each other, so that keratinocytes not only pass each other but also pass melanocytes or Langerhans cells as they move toward the surface of the skin. At the same time they are interconnected through forces of cohesion that guarantee the continuity of the epithelium. Stability for this directional cellular flow is provided by the basal membrane complex (see Chap. 51), which anchors the epidermis to the dermis, and the stratum corneum, which encases the epidermis on the outside. It is here that individual cell migration ceases as the keratinizing cells are firmly interconnected by an intercellular cement-like substance (see Chap. 45). These forces of cohesion are finally lost at the surface of the epidermis where the individual cornified cells are desquamated. Pathologic changes within the epidermis may therefore relate to the kinetics of epidermal cells or their differentiation (see Chap. 44) and may involve transepidermal migration and intraepidermal cohesion; they also relate to peripatetic leukocytes and Langerhans cells trafficking to and from the epidermis and adhesion molecules facilitating and directing such cellular movements. For example, unless a Langerhans cell expresses the chemokine CCR6, it cannot migrate from the dermis to the epidermis. Without expression of CCR7, migration to the lymph node is not possible. Furthermore, many pathologic alterations are related to cytokines and hormones generated by keratinocytes, Langerhans cells, melanocytes, and peripatetic leukocytes. They may affect the entire cell population or individual cells, may be primarily targeted on keratinocytes, or may encompass the other epidermal cell populations as well.

DISTURBANCES OF EPIDERMAL CELL KINETICS The mitotic rate of germinative cells, the desquamation rate of corneocytes, and the generation time of epidermal cells determine the homeostasis of the epidermis (see Chap. 44). Under physiologic conditions, there is a balance among proliferation, differentiation, and desquamation. Enhanced cell proliferation accompanied by an enlargement of the germinative cell pool and increased mitotic rates lead to an increase of the epidermal cell population and thus to a broadening of the epidermis (*acanthosis*) (Fig. 6-2). A shift in the ratio of resting to proliferating cell as is the case in psoriasis (see Chap. 18) will lead to both an increase in the turnover of the entire epidermis and to a considerable increase of the volume of germinative cells that have to be accommodated at the dermal-epidermal junction.

This in turn results in an elongation of the rete ridges, which is accompanied by



▲ **FIGURE 6-2** Acanthosis. This sign of increased epidermal kinetics is illustrated in a photomicrograph of psoriasis. Parakeratosis, the retention of nuclei in the horny layer, is evident.



▲ **FIGURE 6-3** The association of dyskeratosis and acantholysis is seen in this high-power view of Darier disease, which also demonstrates the intraepidermal cleft formation resulting from these phenomena.

a compensatory elongation of the connective tissue papillae, resulting in an enlargement of the dermal-epidermal interface and, consequently, in an increased area for dermal-epidermal interactions (see Fig. 6-2).

DISTURBANCES OF EPIDERMAL CELL DIFFERENTIATION A simple example of disturbed epidermal differentiation is parakeratosis, in which faulty and accelerated cornification leads to a retention of pyknotic nuclei of epidermal cells (see Fig. 6-2). A parakeratotic stratum corneum is not a compact sheet of cornified cells but a loose structure with gaps between cells; these gaps lead to a loss of the barrier function of the epidermis.

Parakeratosis can be the result of incomplete differentiation in postmitotic germinative cells. Considering a transit time of 14 days for a postmitotic epidermal cell, a pathologic signal inducing parakeratosis in a cell early in differentiation requires almost 2 weeks to appear histologically in the stratum corneum. Alternatively, parakeratosis can also be the result of reduced transit time, which does not permit epidermal cells to complete the whole differentiation process, as for example in psoriasis. However, "parakeratosis" of cellophane-stripped epidermis becomes microscopically visible as early as 1 hour after trauma; here, parakeratosis does not represent disturbed differentiation; rather, it results from direct cellular injury to a viable epidermis deprived of its protective horny layer. Therefore, the morphologic term *parakeratosis* signifies both a programmed disturbance of differentiation and maturation and direct cellular injury.

Dyskeratosis is a term formerly used for premature cornification of individual cells within the viable layers of the epidermis. It is now understood that dyskeratosis represents the morphologic presentation of apoptosis of keratinocytes. Dyskeratotic cells have an eosinophilic cytoplasm and a pyknotic nucleus and are packed with keratin filaments arranged in perinuclear aggregates. Such a cell will tend to round up and lose its attachments to the surrounding cells. Dyskeratosis is therefore often associated with acantholysis (see Disturbances of Epidermal Cohesion) but not vice versa (Fig. 6-3).

In some diseases, dyskeratosis is the expression of a genetically programmed disturbance of keratinization as is the case in Darier disease (see Chap. 49). Dyskeratosis may occur in actinic keratosis and squamous cell carcinoma. Dyskeratosis may also be caused by direct physical and chemical injury. In the sunburn reaction, eosinophilic, apoptotic cells—so-called sunburn cells—are found within the epidermis within the first 24 hours after irradiation with UVB (see Chap. 89), and similar "dyskeratotic," that is, apoptotic, cells may occur after high dose systemic cytotoxic treatment. Individual cell death within the epidermis is a regular phenomenon in graft-versus-host reactions of the skin (see Chap. 28) and in erythema multiforme (see Chap. 38).

DISTURBANCES OF EPIDERMAL COHESION Epidermal cohesion is the result of a dynamic equilibrium of forming and dissociating intercellular contacts. Specific intercellular attachment devices (desmosomes) and the intercellular substance are responsible for intercellular cohesion. However, epidermal cohesion must permit epidermal cell motion. Desmosomes dissociate and re-form at new sites of intercellular contact as cells migrate through the epidermis. Intercellular cohesion forces are strong enough to guarantee the continuity of the epidermis as an uninterrupted epithelium but, on the other hand, are adaptable enough to permit locomotion, permeability of the intercellular space, and intercellular interactions.

The most common result of disturbed epidermal cohesion is the intraepidermal vesicle, a small cavity filled with fluid. A classification of intraepidermal blistering by anatomic level is shown in Table 6-1.

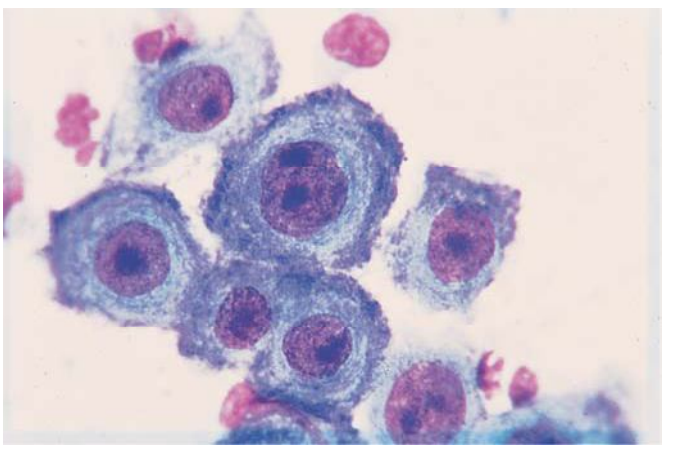
▲ **FIGURE 6-4** Spongiform vesicle resulting from edematous separation of keratinocytes. These are still partially attached to each other by desmosomes and have thus acquired a stellate appearance.

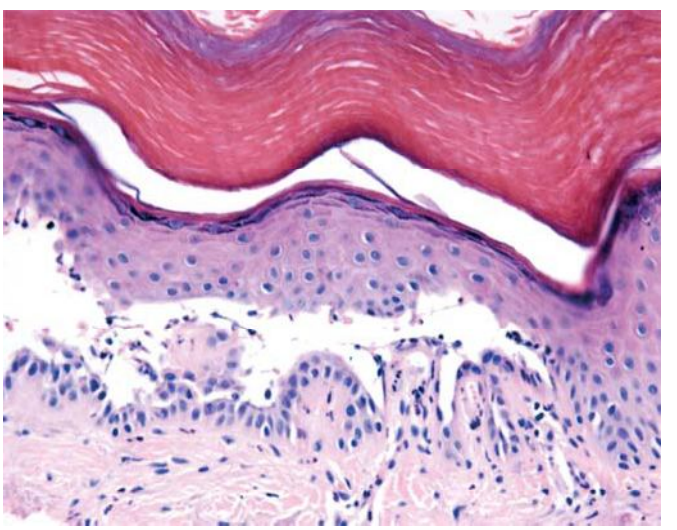
Three basic morphologic patterns of intraepidermal vesicle formation are classically recognized. *Spongiosis* is an example of the secondary loss of cohesion between epidermal cells due to the influx of tissue fluid into the epidermis. Serous exudate may extend from the dermis into the intercellular compartment of the epidermis; as it expands, epidermal cells remain in contact with each other only at the sites of desmosomes, acquiring a stellate appearance and giving the epidermis a spongelike morphology (spongiosis). As the intercellular edema increases, individual cells rupture and lyse, and microcavities (spongiotic vesicles) result (Fig. 6-4). Confluence of such microcavities leads to larger blisters. Epidermal cells may also be separated by leukocytes that disturb intraepidermal coherence; thus, the migration of leukocytes into the epidermis and spongiotic edema are often a combined phenomenon, best illustrated by acute contact dermatitis. The accumulation of polymorphonuclear leukocytes within the epidermis, the resulting separation of epidermal cells, and their subsequent destruction eventually lead to the formation of a spongiform pustule, one of the histopathologic hallmarks of psoriasis.

Acantholysis is a primary loss of cohesion of epidermal cells. This is initially characterized by a separation of the interdesmosomal regions of the cell membranes of keratinocytes, followed by splitting and a disappearance of desmosomes (see Chap. 52). The cells are intact but are no longer attached; they acquire their smallest possible surface and round up (Figs. 6-3 and 6-5). Intercellular gaps and slits result, and the influx of fluid from the dermis leads to a cavity, which may form in a suprabasal (Fig. 6-6), midepidermal, or even subcorneal location. Acantholytic cells can easily be demonstrated in cytologic smears (see Fig. 6-5) and in some conditions have diagnostic significance.

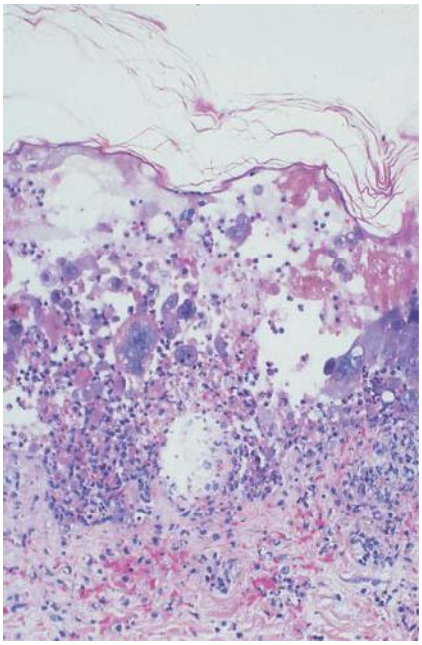
Acantholysis occurs in a number of different pathologic processes that do not have a uniform etiology and pathogenesis. Acantholysis may be a primary event leading to intraepidermal cavitation (primary acantholysis) or a secondary phenomenon in which epidermal cells are shed from the walls of established intraepidermal blisters (secondary acantholysis). Primary acantholysis is a pathogenetically relevant event in diseases of the pemphigus group (see Chap. 52), in which it results from the interaction of autoantibodies and antigenic determinants on the keratinocyte membranes and in the staphylococcal scalded-skin syndrome, where it is caused by a staphylococcal exotoxin (epidermolysin) (see Chap. 178). In familial benign pemphigus, it results from the combination of a genetically determined defect of the keratinocyte cell membrane and exogenous factors



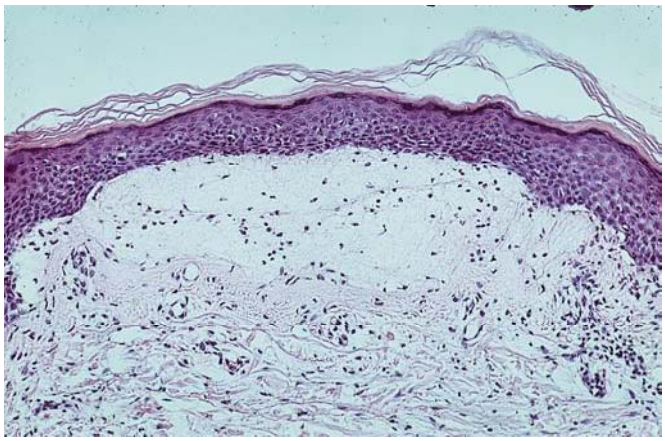
▲ **FIGURE 6-5** Acantholysis. Single as well as clusters of acantholytic cells are seen. The round shapes result from the loss of intercellular connections. Cytologic smear preparation of pemphigus vulgaris.



▲ **FIGURE 6-6** Pemphigus vulgaris. An intraepidermal suprabasal cleft is visible that has resulted from suprabasal acantholysis. It contains acantholytic and inflammatory cells.



▲ **FIGURE 6-7** Herpes simplex infection. The epidermis shows marked ballooning degeneration, cytolysis, and intraepidermal vesiculation. Acantholytic and multinucleated epidermal giant cells are a clue to herpetic infection.



▲ **FIGURE 6-8** Bullous pemphigoid. Subepidermal (junctional) cleft formation and a perivascular and interstitial lymphoeosinophilic infiltrate are characteristic.

(see Chap. 49). A similar phenomenon, albeit more confined to the suprabasal epidermis, occurs in Darier disease, where it is combined with dyskeratosis in the upper epidermal layers (see Fig. 6-3) and a compensatory proliferation of basal cells into the papillary body (see Chap. 49). When acantholysis results from viral infection, it is usually combined with other cellular phenomena such as ballooning giant cells and cytolysis (Fig. 6-7; see Chaps. 193 and 194).

Indeed, a loss of epidermal cohesion can also result from a dissolution of cells (i.e., cytolysis). In the epidermolytic forms of epidermolysis bullosa, basal cells rupture as a result of trauma so that the cleft forms through the basal cell layer independently from preexisting anatomic boundaries (see Chap. 60). Cytolytic phenomena in the stratum granulosum are characteristic for epidermolytic hyperkeratosis, bullous congenital ichthyosiform erythroderma, ichthyosis hystrix, and some forms of hereditary palmoplantar keratoderma (see Chaps. 47 and 48).

Dermal-Epidermal Junction (See Fig. 6-1, J)

Epidermis and dermis are interlocked by means of the epidermal rete ridges and the corresponding dermal papillae and foot-like cytoplasmic microprocesses of basal cells that extend into corresponding indentations of the dermis. Dermal-epidermal attachment is enforced by hemidesmosomes that anchor basal cells on the basal lamina; this, in turn, is attached to the dermis by means of anchoring filaments and microfibrils (see Chap. 51). The basal lamina is not a rigid structure because leukocytes, Langerhans cells, or other migratory cells pass through it without causing a permanent breach in the junction. After being destroyed by pathologic processes, the basal lamina is reconstituted; this represents an important phenomenon in wound healing and other reparative processes. Functionally, the basal lamina is part of a unit that, by light microscopy, appears as the periodic acid-Schiff–positive "basal membrane" and, in fact, represents the entire junction zone. This consists of the lamina lucida, spanned by microfilaments, and subjacent anchoring fibrils, small collagen fibers, and extracellular matrix (see Chap. 51). The junction zone is a functional complex that is primarily affected in a number of pathologic processes.

DISTURBANCES OF DERMAL-EPIDERMAL COHESION The destruction of the junction zone or its components usually manifests as disturbance of dermal-epidermal cohesion and leads to blister formation. These blisters appear to be subepidermal by light microscopy (Fig. 6-8) but in reality may be localized at different levels and result from pathogenetically heterogeneous processes. A classification of blisters at the junction by anatomic level is given in Table 6-2. Subepidermal blister formation occurs in forms of epidermolysis bullosa (see Chap. 60) or can be the result of a complex inflammatory process that involves the entire junction zone, as is the case in lupus erythematosus, erythema multiforme, or lichen planus; therefore, it may be a phenomenon occurring in a group of etiologically and pathogenetically heterogeneous conditions. In bullous pemphigoid (see Fig. 6-8), cleft formation runs through the lamina lucida of the basal membrane and is caused by autoantibodies directed against specific antigens on the cytomembrane of basal cells (*junctional blistering*) (see Fig. 6-8; see Chap. 54). The presence of eosinophil granules that contain major basic protein that is toxic to keratinocytes also causes keratinocyte injury. Junctional blistering also occurs in the junctional forms of epidermolysis bullosa, but here it is due to the impairment or absence of molecules important for epidermal-dermal cohesion (see Chap. 60; see Table 6-2).

In sub-epidermal blistering, the target of the pathologic process is below the basal lamina (dermolytic blistering) (see Table 6-2). Reduced anchoring filaments and increased collagenase production result in dermolytic dermal-epidermal separation in recessive epidermolysis bullosa (see Chap. 60); circulating auto-

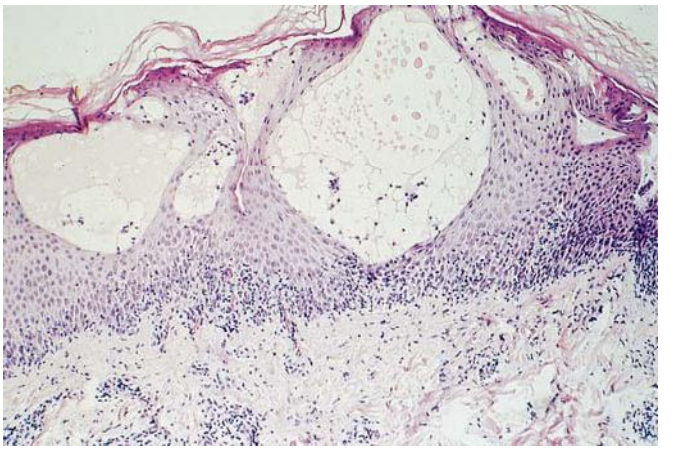
antibodies directed against type VII collagen in anchoring fibrils are the cause of dermolytic blistering in acquired epidermolysis bullosa (see Chap. 58). Other immunologically mediated inflammatory mechanisms result in dermolytic blistering in dermatitis herpetiformis (see Chap. 59), and physical and chemical changes in the junction zone and papillary body are the cause for a dermolytic cleft formation after trauma in porphyria cutanea tarda (see Chap. 132).



▲ **FIGURE 6-10** Contact dermatitis. Intraepidermal spongiotic vesicles and pronounced intercellular edema are present in the epidermis. The dermis contains perivascular aggregates of lymphocytes and histiocytes admixed with occasional eosinophils.

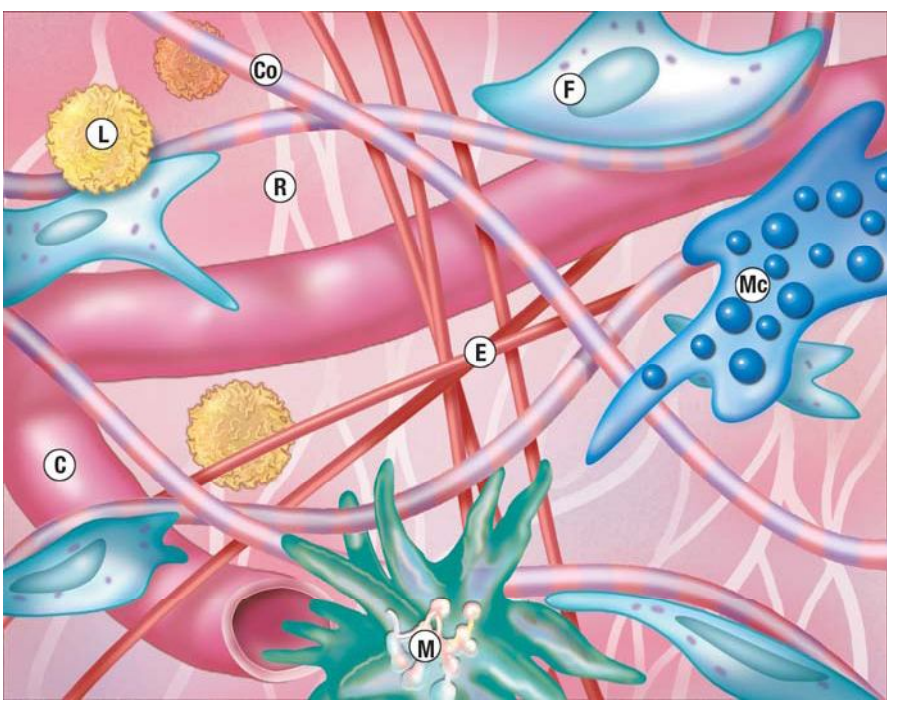
Pathologic Reactions of the Entire Superficial Reactive Unit (See Fig. 6-1, SRU)

Most pathologic reactions of the superficial skin involve the subunits of the superficial reactive unit jointly and thus include the papillary body of the dermis with the superficial microvascular plexus. This is a highly reactive tissue compartment consisting of capillaries, pre- and postcapillary vessels (see Chap. 163), fibroblasts, macrophages, dendritic cells, and peripatetic lymphocytes all embedded in a loose connective tissue and extracellular matrix (Fig. 6-9). The prominence of involvement of one of the components over the others may lead to the development of different clinical pictures. A few examples of such interactions are detailed below.

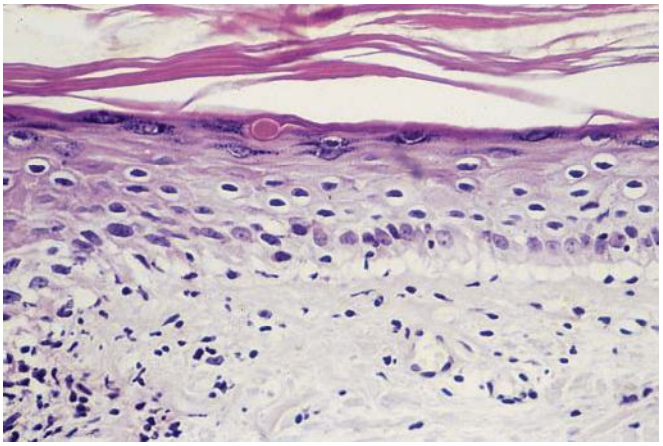
CONTACT DERMATITIS (See Chap. 13) In allergic contact dermatitis, there is an inflammatory reaction of the papillary body and superficial microvascular plexus and spongiosis of the epidermis (see Fig. 6-4) with signs of cellular injury and parakeratosis. Lymphocytes infiltrate the epidermis early in the process and aggregate around Langerhans cells, and this is followed by spongiotic vesiculation (Fig. 6-10). Parakeratosis develops as a consequence of epidermal injury, and the inflammation in the papillary body and around the superficial venular plexus stimulates mitotic processes within the epidermis, which, in turn, result in acanthosis and epidermal hyperplasia in chronic lesions.

PSORIASIS (See Chap. 18) The initial lesion of psoriatic lesions appears to be the perivascular accumulation of lymphocytes and monocytoid elements within the papillary body and superficial venules and focal migration of leukocytes into the epidermis. Acanthosis caused by increased epidermal proliferation, papillomatosis, and edema of the elongated dermal papillae together with vasodilatation of the papillary capillary loops and a denser perivascular infiltrate develop almost simultaneously (see Fig. 6-2); the disturbed differentiation of the epidermal cells results in parakeratosis, and neutrophils infiltrating the epithelium from tortuous capillaries (squirting capillaries) lead to spongiform pustules and, in the parakeratotic stratum corneum, to Munro's abscesses. The stimulus for increased epidermal proliferation follows signals released from T cells that are attracted to the epidermis by the expression of adhesion molecules at the keratinocyte surface and are maintained by cytokines released by keratinocytes (see Chap. 18). The composite picture characteristic of psoriasis, therefore, results from a combined pathology of the papillary body with the superficial venules, the epidermis, and circulating cells.

Psoriasis is a good example of the limited specificity of histopathologic reaction patterns within the skin because psoriasiform histologic features occur in a number of diseases unrelated to psoriasis.



▲ **FIGURE 6-9** The compartment of the papillary body consists of capillaries (C), fibroblasts (F), macrophages and dendritic cells (M), peripatetic lymphocytes (L) and mast cells (Mc) all embedded in a loose connective tissue of extracellular matrix, thin collagen fibers (Co), elastic fibers (E) that are mostly oriented perpendicularly to the skin surface, and branched reticulin fibers (R).



▲ **FIGURE 6-11** Lupus erythematosus. Hyperkeratosis, thinned epidermis devoid of rete ridges, and vacuolization of the basement membrane zone are present.

INTERFACE DERMATITIS Inflammation along the dermal-epidermal junction associated with vacuolation characterizes interface dermatitis. This common type of reaction may lead to papules or plaques in some skin diseases and bullae in others.

ERYTHEMA MULTIFORME (See Chap. 38) Two types of reactions occur. In both there is interface dermatitis characterized by lymphocytes scattered along a vacuolated dermal-epidermal junction.

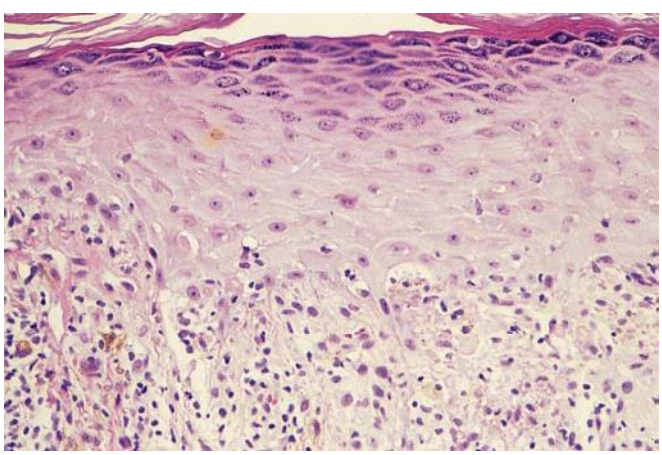
LUPUS ERYTHEMATOSUS (See Chap. 156) Inflammation, edema, and a lymphocytic infiltrate in the papillary body and superficial venular plexus, as well as in the deeper layers of the dermis, are hallmarks of lupus erythematosus. The main target is the dermal-epidermal junction, where scattered lymphocytes appear and immune complex deposition leads to broadening of the PAS-positive basement membrane zone, accompanied by hydropic degeneration and destruction of basal cells and progressive atrophy (Fig. 6-11). Cytoid bodies result from apoptosis of individual epidermal cells that are infiltrated and coated by immunoglobulins. The changes in the junctional zone reflect on epidermal differentiation resulting in increased orthokeratosis and parakeratosis. Lupus erythematosus readily illustrates the heterogeneity, as well as the lack of specificity, of cutaneous reaction patterns: histologically, it is possible to distinguish between acute and chronic lesions but not between cutaneous and systemic lupus erythematosus. In chronic persisting lesions, the changes in the junctional zone initially associated with atrophy secondarily result in hyperplasia, hyperkeratosis, and an increased interdigitation between epidermis and connective tissue, whereas in acute cases, the destruction of the basal cell layer may lead to sub-epidermal blistering.

LICHEN PLANUS (See Chap. 26) This disease also exhibits a primarily junctional reaction pattern with accumulation of a dense lymphocytic infiltrate in the subepidermal tissue and cytoid bodies at the junction (Fig. 6-12). Lymphocytes encroach on the epidermis, destroying the basal cells, but they do not infiltrate the suprabasal layers and blister formation only rarely ensues. These alterations are accompanied by changes of epidermal differentiation—there is a widening of the stratum granulosum (*hypergranulosis*) and hyperkeratosis. Identical changes can be seen in graft-versus-host disease (see Chap. 28). Current thinking imputes a delayed hypersensitivity reaction to a keratinocyte antigen, the nature of which is unclear. The association of $CD8^+$ lymphocytes in apposition to apoptotic keratinocytes supports this view. The expression of Fas/FasL is also in favor of a role for apoptosis in the pathogenesis of these lesions.

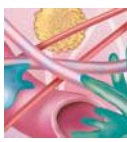
DERMATITIS HERPETIFORMIS (See Chap. 59) This condition is usually included among the classic bullous dermatoses; however, it illustrates that the preponderance of one or several pathologic reaction patterns may obscure the true pathogenesis of the condition. The deposition of immunoglobulin A and complement on fibrillar and nonfibrillar sites within the tips of the dermal papillae, and the activation of the alternative pathway of the complement cascade, lead to an influx of leukocytes, which form small abscesses at the tips of the dermal papillae, as well as inflammation and edema (Fig. 6-13). This explains why the primary clinical lesion in dermatitis herpetiformis is urticarial or papular in nature, because only in the case of massive neutrophil infiltration will there be tissue destruction and cleft formation below the lamina densa that results in clinically visible vesiculation.

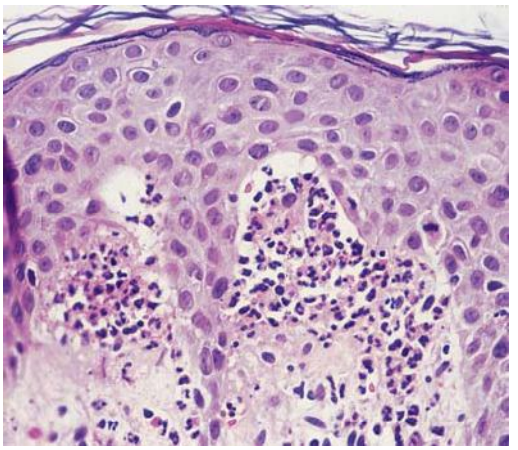
RETICULAR DERMIS (See Fig. 6-1, DRU)

The dermis represents a strong fibroelastic tissue with a network of collagen and elastic fibers embedded in an extracellular matrix with a high water-binding capacity (see Chap. 61). In contrast to the tightly interwoven fibrous components of this reticular layer of the dermis (Fig. 6-14), the previously described fibrous texture of the papillary body and the perifollicular and perivascular compartments is loose (see Fig. 6-9), and the orientation of the collagen bundles here follows the structures they surround.



▲ **FIGURE 6-12** Lichen planus. There is hyperkeratosis, wedge-shaped hypergranulosis, basal cell vacuolization, and a lymphocytic infiltrate at the dermal-epidermal junction. This infiltrate "hugs" the basal cell layer and is associated with many cytoid bodies.

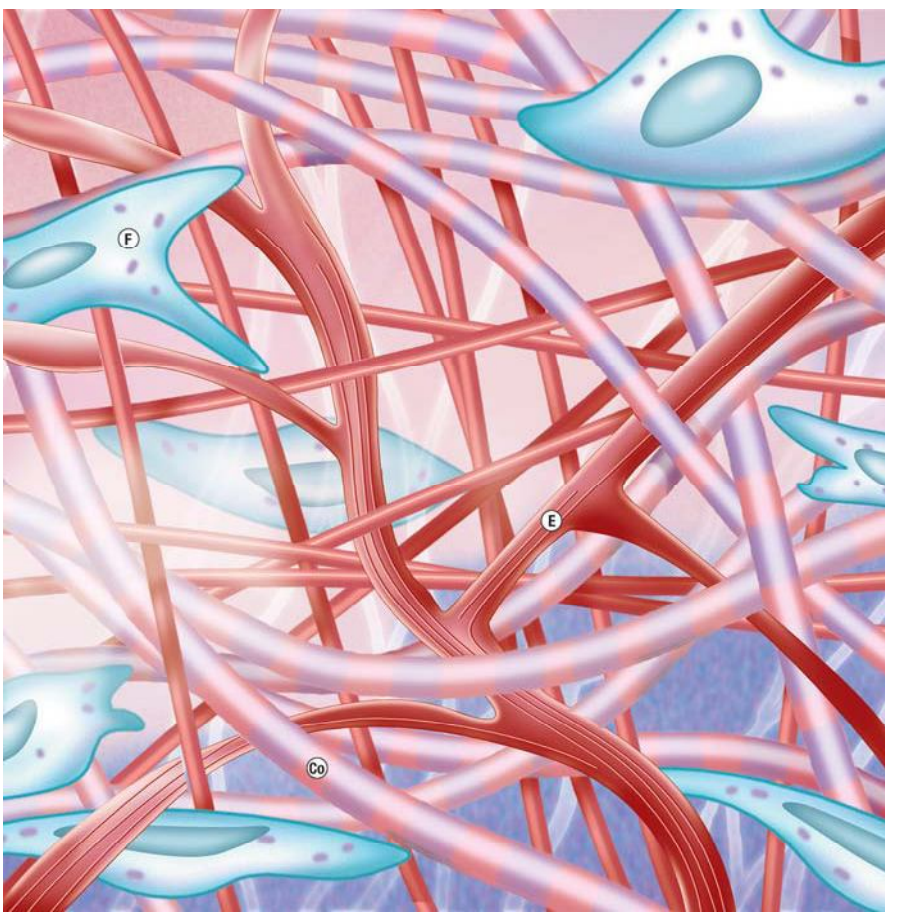




◀ **FIGURE 6-13** Dermatitis herpetiformis. Two papillae show microabscesses composed of neutrophils. Vacuolization and early cleft formation are evident in both papillae.

The dermis contains a superficial and deep vascular network. In the upper dermis, the superficial plexus supplies individual vascular districts consisting of several dermal papillae. Superficial and deep networks are connected so intimately that the entire dermal vascular system represents a single three-dimensional unit (see Chap. 163). On the other hand, there are profound functional differences between superficial and deep dermal vascular networks (see Chap. 163), which explain the differences of homing patterns of inflammatory cells to these sites.

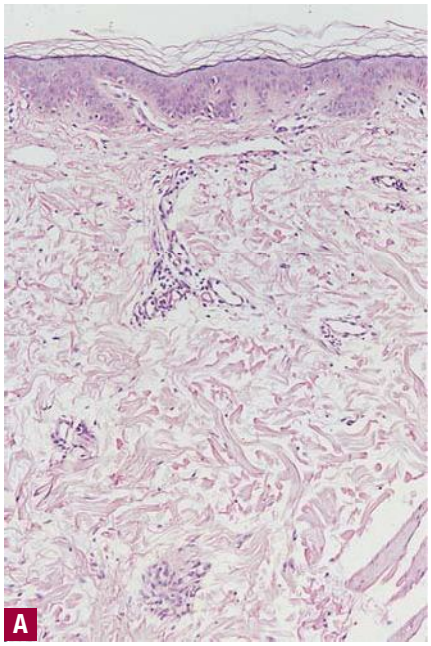
As for the superficial microvascular system, two reaction patterns occur: (1) acute inflammatory processes in which the epidermis and junctional zone are often involved together with the vascular system, and (2) more chronic processes that often remain confined to the perivascular compartment. In this context, it should be noted that the cytologic composition of an inflammatory infiltrate within the skin does not always mirror the acuity of an inflammatory process. Polymorphonuclear leukocytic infiltrates are not always synonymous with an acute process; conversely, chronic processes are not always represented by a lymphohistiocytic infiltrate.

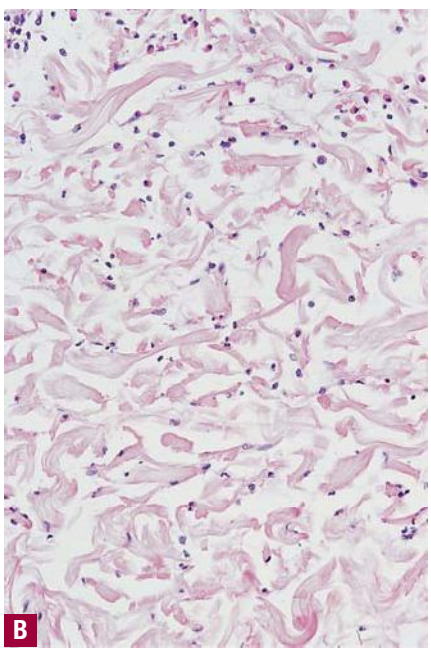


▲ **FIGURE 6-14** The reticular dermis is tightly woven fibroelastic tissue with a network of thick, banded collagen fibers (Co) and elastic (E) fibers embedded in an extracellular matrix. All are produced by fibroblasts (F). This tissue is much denser, relatively acellular, and has fewer capillary vessels than the papillary body (compare with Fig. 6-9).

Inflammation confined to the superficial connective tissue–vascular unit is characterized by endothelial activation, vascular dilatation, increased permeability, edema, a reduction of intravascular blood flow, an accumulation of red blood cells in the capillary loops, and cellular infiltration of the perivascular tissue. Depending on the degree of inflammation, the macroscopic corollary of the histologic changes represents erythematous, urticarial, and infiltrative (papular) lesions. The release of mediators from immunoglobulin E–laden mast cells in type I immune reactions, such as urticaria, is histologically manifested primarily as vasodilatation, edema of the papillary body, and a rather sparse infiltrate of leukocytes and histiocytic elements around the superficial venules (Fig. 6-15). These lesions usually resolve relatively rapidly without any residual pathology. More massive reactions, however, lead to a dense perivascular infiltrate (Fig. 6-16), and this may represent a transition to those processes where edema is less pronounced and where dense lymphocytic infiltrates surround the vessels in a sleevelike fashion, as is the case in cutaneous drug eruptions (see Fig. 6-16). More dramatic alterations occur when the vascular system itself is the target of the inflammatory process resulting in a destruction of at least some of the vessel components, as is the case in necrotizing vasculitis. These exudative changes result in clinical palpable purpura (Fig. 6-17; see Chap. 164).

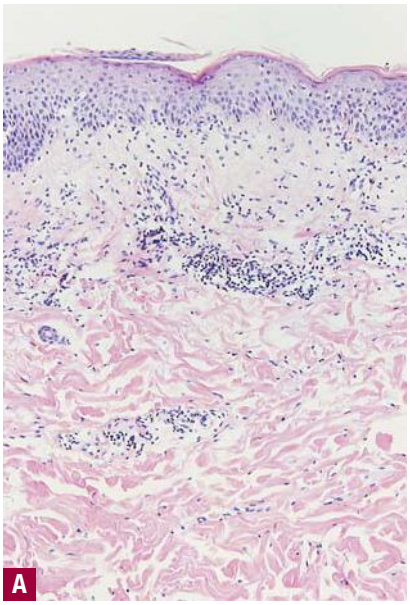
Chronic inflammatory reactions of the superficial microvascular plexus usually reveal lymphocytic infiltrates in close association with the vascular walls clinical manifesting as erythema. In purpura simplex (see Chap. 169), damage to the vessel wall is much less evident than in necrotizing vasculitis, but the integrity of the vessels is also impaired as is evidenced by hemorrhage into the tissue. Lymphocytes and, as a secondary reaction, histiocytic elements partly laden with phagocytosed material including iron constitute the inflammatory infiltrate.

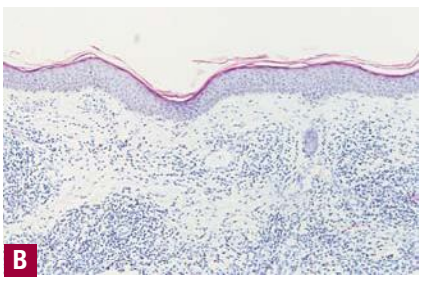




▲ **FIGURE 6-15** Urticaria. **A.** Characteristic of this reaction is a sparse, perivascular lymphocytic infiltrate with few eosinophils. Note the slight edema in the dermis and around the postcapillary venules. **B.** Higher magnification reveals separation of collagen bundles by edema and sparse interstitial inflammatory infiltrate with eosinophils.

The reaction patterns described for the vascular system of the papillary body and the superficial venular plexus also occur in the deep dermis, but there are morphologic and functional differences because here larger vessels are involved. Lymphocytic infiltrates surrounding the vessels in a sleevelike fashion lead to clinical signs only when they are substantial, and then they represent the histopathologic substrate for



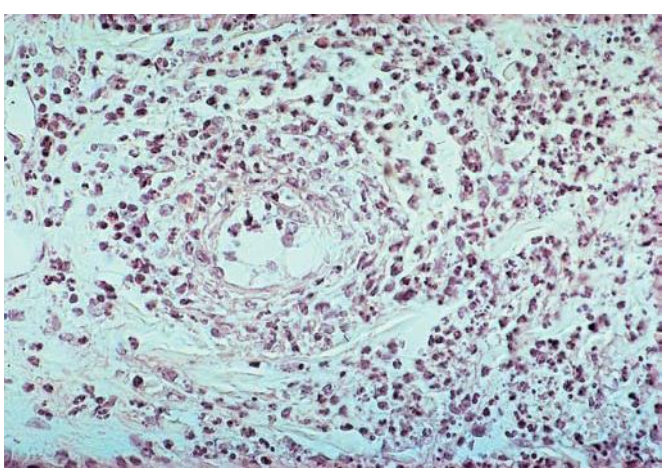


▲ **FIGURE 6-16** Drug eruption. **A.** Throughout the dermis, perivascular sleeves of mononuclear cells, mainly lymphocytes, are present about superficial and deep venules. There is slight edema in the papillary body and minimal interface dermatitis in this reaction to nifedipine. **B.** More pronounced, even nodular, mononuclear cell infiltrates around vessels in a drug reaction to a β blocker.

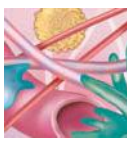
papular or nodular lesions. This is the case with drug eruptions (see Chap. 40; see Fig. 6-16B) and it is also true for deep-seated infiltrates in lupus erythematosus. In the case of necrotizing vasculitis of the medium-sized and larger vessels, there is usually a much more pronounced inflammatory infiltrate, clinically appearing as papular and nodular lesions, and secondary changes due to the interruption of the vascular flow are more pronounced: necrosis, blistering, and ulceration result as is the case in cutaneous panarteritis nodosa of the macroscopic type (see Chap. 165). In contrast to the macroscopic variant, microscopic polyarteritis nodosa affects vessels of varying sizes including venules and arterioles, affects lungs and kidneys, and is perinuclear neutrophil antibodies positive. Granulomatous vasculitis also leads to nodular lesions, whereas the hyalinizing vascular changes and vascular occlusion in livedoid vasculitis result in ischemic necrosis (see Chap. 164).

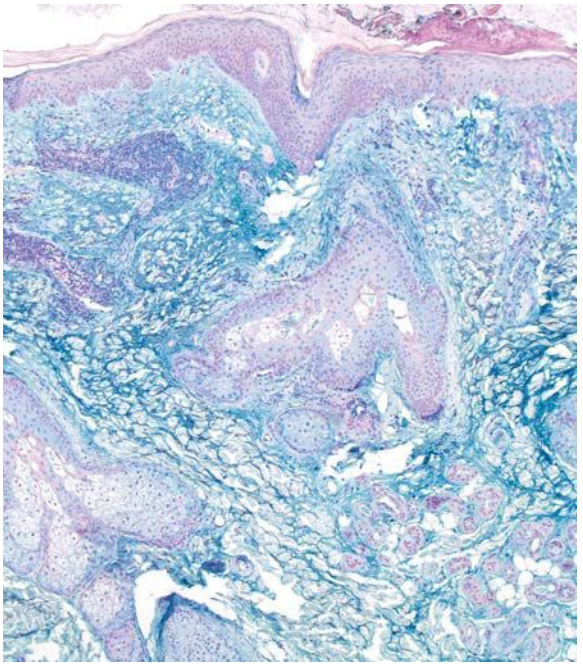
Lymphocytic Infiltrates

Although lymphocytic infiltrates occur in the majority of inflammatory dermatoses, there are a number of pathologic processes in which such infiltrates are the most prominent feature and thus determine the histologic picture. Lymphocytic infiltrates are formed in inflammatory or proliferative conditions and in the latter may represent a benign or malignant process. They may differ in their cytologic appearance and distribution, may be confined to the periadventitial compartments of the vascular system (superficial and deep perivascular dermatitis), or may occur diffusely throughout the collagenous tissue (diffuse dermatitis). They may be confined almost exclusively to the papillary dermis (interface dermatitis) and spare the sub-epidermal compartment or may exhibit pro-



▲ **FIGURE 6-17** Necrotizing vasculitis. An inflammatory infiltrate composed mostly of neutrophils and nuclear dust is present both around and in the wall of a venule where fibrin is also deposited.



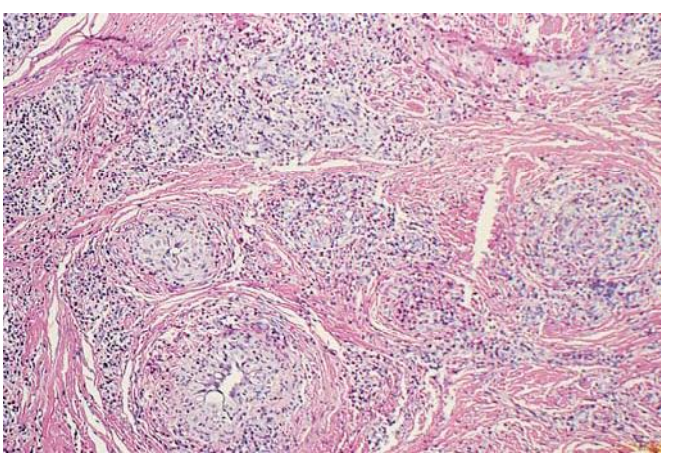


▲ **FIGURE 6-18** Mucinosis in lupus erythematosus. The prominent feature shown here is abundant mucin in the superficial and mid-dermis.

nounced epidermotropism. They may be independent of vessels, sparse (interstitial dermatitis) or nodular (nodular dermatitis). Because lymphocytes are a heterogeneous population of cells, the analysis of such infiltrates should take into account not only the cytomorphology and distribution pattern but histochemical properties and immunologic markers. The analysis of round cell infiltrates by monoclonal antibodies (immunophenotyping) and determination of their clonality are important aspects of dermatopathology (see Chap. 147).

Among the many possible reaction patterns characterized by lymphocytic infiltrates, several typical patterns can be distinguished.

- Superficial perivascular infiltrates are often accompanied by secondary reactions of the epidermis. Lymphoid cells surround the vascular channels in a sleevelike fashion but often extend diffusely to the epidermis, which may reveal focal parakeratosis in these areas. Clinically, these changes are often characterized as palpable figurate erythemas such as erythema annulare centrifugum, but polymorphic light eruption, drug eruptions (see Fig. 6-16A), or insect bites can produce a similar histopathologic picture.
- Lymphocytic cuffing of venules without involvement of the papillary body and the epidermis may occur in figurate erythemas and in drug eruptions (see Fig. 6-16B). The infiltrates of chronic lymphatic leukemia show a similar distribution pattern but are usually more pronounced.
- Perivascular lymphocytic infiltrates with a mucinous infiltration of the nonperivascular connective tissue may be found in lymphocytic infiltration of Jessner-Kanof, reticular erythematous mucinosis (see Chap. 147), or in lupus erythematosus (Fig. 6-18) and dermatomyositis (see Chaps. 156 and 157).
- Nodular lymphocytic infiltrates, which extend throughout the dermis exhibiting focal accumulations of histiocytic cells and thus acquiring the appearance of lymphoid follicles, are typical of lymphocytoma cutis (see Chap. 147). Phagocytosed polychrome bodies in histiocytic cells, mitoses in the center of the lymphoid follicles, and an admixture of eosinophils are characteristic features, as is the fact that the papillary body is usually spared so that a conspicuous grenz zone is found between the infiltrate and the epidermis.
- Non-follicular lymphocytic infiltrates sparing the superficial reactive unit may also occur in benign lymphoid hyperplasias, but in these cases, the differentiation from malignant lymphoma is very difficult. Polymorphic infiltrates showing histiocytes, plasma cells, and occasional eosinophils are usually benign, whereas most malignant non-Hodgkin lymphomas exhibit a more monomorphous picture.
- Nodular accumulations of lymphocytes with an admixture of plasma cells and eosinophils accompanied by vascular hyperplasia are characteristic of angiolymphoid hyperplasia (Fig. 6-19), in which blood vessel walls are thickened and the endothelial cells appear proliferated, swollen, and enlarged.
- Atypical lymphocytic infiltrates involving both the superficial and deeper dermis, and cytologically characterized by pronounced pleomorphism of the cellular infiltrate, are characteristic of lymphomatoid papulosis one of the spectrum of CD30$^+$ lymphoproliferative disorders (see Chap. 147). This condition exemplifies the problems that arise when the histopathology of a lesion is used alone to determine whether a process is benign or malignant. Without knowledge of the clinical features and the



▲ **FIGURE 6-19** Angiolymphoid hyperplasia. Numerous vascular channels are surrounded by aggregates of inflammatory cells made up of lymphocytes and eosinophils. Note the protrusion of endothelial cells into the lamina of these vessels.

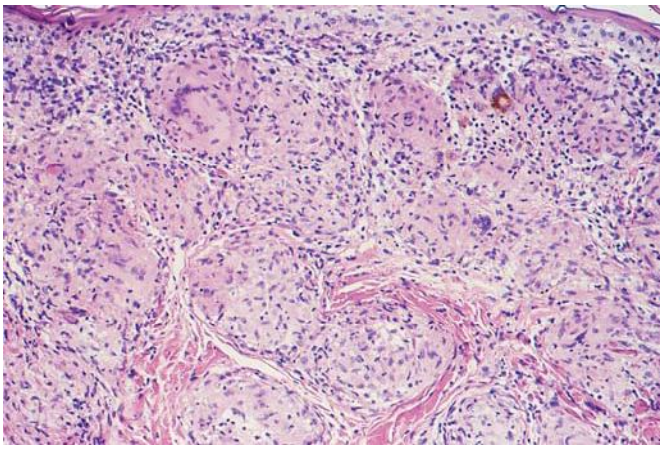
course of disease, a definite diagnosis is extremely difficult.

Polymorphonuclear Leukocytic Infiltrates

Although neutrophils are the classic inflammatory cells of acute bacterial infections, there are diseases in which neutrophils dominate the histopathology, even in the absence of a bacterial cause. In pyoderma gangrenosum, massive neutrophilic infiltration leads to sterile abscesses, breakdown of the tissue, and ulceration (see Chap. 32). In dermatitis herpetiformis, neutrophils accumulate in the tips of dermal papillae and form papillary abscesses (see Fig. 6-13) that precede the dermolytic blister formation described in Disturbances of Dermal-Epidermal Cohesion (see also Chap. 59). In erythema elevatum diutinum, neutrophils are the predominant cells centering around superficial and mid-dermal vessels, which exhibit fibrinoid homogenization of their walls (toxic hyalin) and signs of vasculitis (see Chap. 166). The neutrophil is also the predominant cell in the early stages of the more common necrotizing vasculitis (see Fig. 6-17). Neutrophils also represent the majority of the often massive inflammatory infiltrate in acute febrile neutrophilic dermatosis, which is accompanied by pronounced sub-epidermal edema (see Chap. 31).

Granulomatous Reactions

Skin is an ideal tissue for granuloma formation in which histiocytes play a key role. Although these cells are involved at one time or another in practically all inflammatory processes, it is only the proliferation and focal aggregation of histiocytic cells that may be termed a *granuloma*. When such cells are closely clustered they resemble epithelial tissue, hence the designation *epithelioid cells*. Development of giant cells, storage of phagocytosed material, and the admixture of inflammatory cells, such as lymphocytes, plasma cells, and eosinophils, may render the histologic picture of a granulomatous reaction more complex. To these have to be added vascular changes and alterations in the fibrous structure of the connective tissue. Granulomas almost always lead to destruction of pre-existing tissue, particularly elastic fibers, and in such instances result in atrophy, fibrosis, or scarring. Tissue damage or destruction manifests either as necrobiosis or fibrinoid or caseous necrosis, or it may result from liquefaction and abscess formation or from replacement of pre-existing tissue by fibrohistiocytic infiltrate and fibrosis.

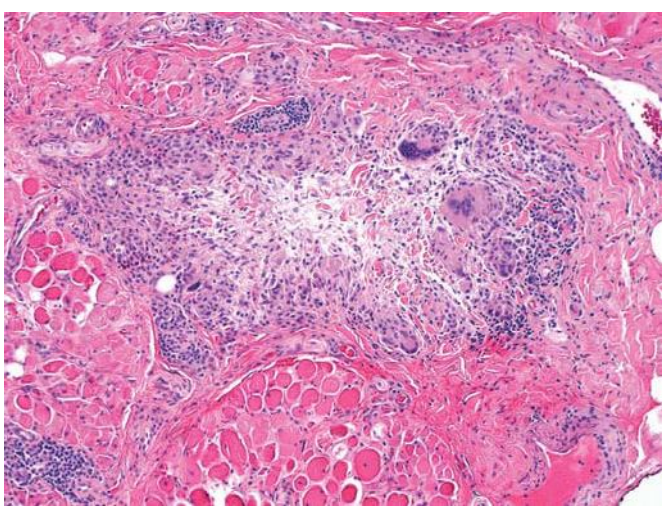


▲ **FIGURE 6-20** Sarcoidal granuloma. In the dermis, numerous "naked" tubercles consisting of epithelioid cells and scant lymphocytes are seen. The overlying epidermis is atrophic.

Sarcoidal granulomas (see Chap. 153) are typically characterized by naked nodules consisting of epithelioid cells, occasional Langhans giant cells, and only a small number of lymphocytes (Fig. 6-20). Silica, zirconium, and beryllium granulomas and a number of foreign-body granulomas may have such histopathologic features.

Granulomatous reactions of the skin comprise a large spectrum of histopathologic features. Palisading granulomas surround necrobiotic areas of the connective tissue with histiocytes in radial alignment (Fig. 6-21). Granuloma annulare, necrobiosis lipoidica, rheumatoid nodules, and the juxta-articular nodules of syphilis belong to this group. These reactions may have significance as signs of systemic disease. For example, when there are prominent neutrophils in the necrobiotic area of granuloma annulare or necrobiosis one may suspect an associated inflammatory bowel disease. Endocrinopathies can also be associated with these disorders, diabetes mellitus is a classic example associated with necrobiosis lipoidica. Of course, rheumatoid nodules can be associated with rheumatoid arthritis but can also occur as a result of trauma in some cutaneous locations. Drugs may also cause these reactions.

Infectious granulomas with a sarcoidal appearance may occur in tuberculosis, syphilis, leishmaniasis, leprosy, or fungal infections. Necrosis can also develop within the granuloma proper, as is the case for fibrinoid necrosis in sarcoidosis, caseation in tuberculosis, or the necrosis developing in mycotic granulomas. Many of the infectious granulomas are associated with epidermal hyperplasia, often exhibiting intraepidermal abscesses in which the causative organism



▲ **FIGURE 6-21** Granuloma annulare. A well-circumscribed palisading granuloma is seen in the dermis. Necrobiotic collagen is surrounded by histiocytes, lymphocytes, and a few scattered multinucleated giant cells.

can be found, often in a multinucleate giant cell. In the dermis there is a mixture of cells, including histocytes, epithelioid cells, eosinophils, neutrophils, and lymphocytes.

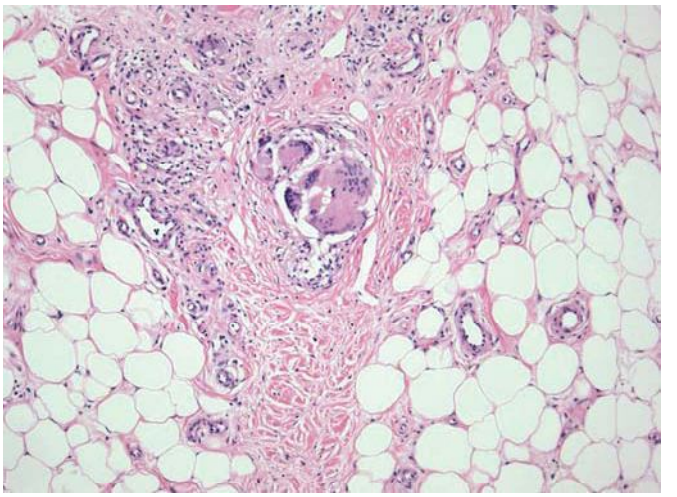
It is often difficult to classify granulomatous reactions within the skin by the histopathology alone, for even completely different etiologic conditions such as immunopathies and some forms of vasculitis may develop granulomas.

A specific form of granulomatous reaction results when the cellular infiltrate consists almost exclusively of the key granuloma cell, the *histiocyte*. One property of this cell is its capacity to store phagocytosed material. In xanthomatous reaction patterns, histiocytes take up and store fat and are thus transformed into foam cells. They are distributed either diffusely, as is the case in diffuse normolipemic xanthomatosis, or as an aggregate infiltrate mimicking a tumor, as in the xanthomas occurring in the hyperlipoproteinemias and xanthelasma (see Chap. 35).

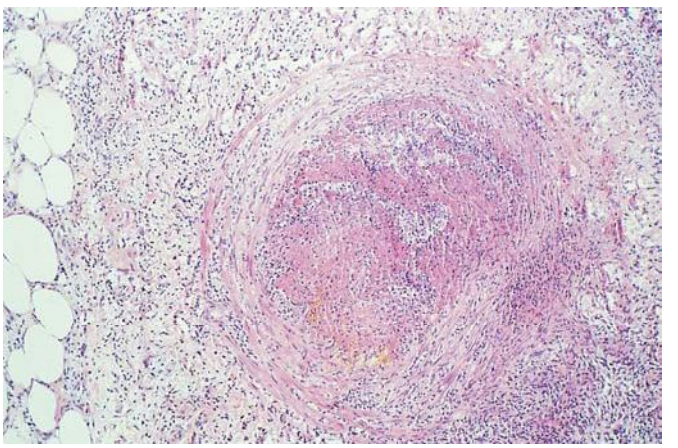
Fibrous Dermis and Extracellular Matrix (See Fig. 6-1, DRU)

Sclerosing processes of the skin involve mainly the connective tissue of the dermis (see Figs. 6-1, DRU, and 6-14) but usually reflect dynamic changes of structure and function that involve practically all compartments of this organ. The hallmark of scleroderma (see Chap. 158) is the homogenization and dense packing of the collagen bundles, a narrowing of the interfascicular clefts within the reticular dermis, and the disappearance of the boundary between this portion of the dermis and the papillary body. There is also a diminution of the small papillary and subpapillary vessels, which appear narrowed, and, in the early stages, a perivascular lymphocytic infiltrate and edema. The impressive thickening of the dermis not only results from an increase of its fibrous components but is also caused by the fibrosis of the superficial layers of the subcutaneous fat that follows lymphocytic infiltration and a histiocytic reaction.

Sclerodermoid changes may be found in the toxic oil syndrome and L-tryptophan disease, eosinophilic fasciitis (see Chap. 35), and mixed connective tissue disease; they also occur in pachydermoperiostosis, where an increase of fibroblasts and ground substance accompany the sclerotic changes, and in porphyria cutanea tarda, which shows



▲ **FIGURE 6-22** Erythema nodosum. A chronic granulomatous inflammatory infiltrate with giant cells extends along the thickened septum into the adjacent fat lobule.



▲ **FIGURE 6-23** Nodular vasculitis. The characteristic features illustrated are severe vasculitis with necrosis of the large vessel wall and occlusion of the lumen. Necrosis of the fat lobules is present, as well as an acute and chronic inflammatory cell infiltrate.

typical hyalinization of the papillary vessels. In lichen sclerosus, there is a massive edema of the papillary body and a dense lymphocytic infiltrate that initially hugs the epidermis and later separates the edematous papillary body from the reticular dermis (see Chap. 63). As sclerosis sets in, there is also a disappearance of elastic tissue from the papillary body; the concomitant involvement of the epidermis includes hydropic degeneration of basal cells, atrophy, and, at the same time, hyperkeratosis. Changes in the junctional zone in this condition may occasionally lead to a separation of the epidermis from the dermis and thus to blister formation.

Faulty synthesis or cross-linking of collagen results in a number of well-defined diseases or syndromes but leads to relatively few characteristic histopathologic changes. In the different types of the Ehlers-Danlos syndrome (see Chap. 139), the faulty collagen cannot be recognized histopathologically, and only the relative increase of elastic tissue may indicate that something abnormal has occurred in the dermis. In generalized elastolysis, a fragmentation of elastic fibers is the histopathologic substrate of the clinical appearance of cutis laxa, and the fragmentation and curled and clumped appearance of elastic fibers are similarly diagnostic in pseudoxanthoma elasticum (see Chap. 139). On the other hand, in actinic elastosis, the histologic substrate of dermatoheliosis, all components of the superficial connective tissue are involved (see Chap. 89). Except for a narrow grenz zone below the epidermis, the papillary body and the superficial layers of the reticular dermis are filled with clumped and curled fibers that progressively become homogenized and basophilic. They are stained by dyes that have an affinity for

elastic tissue and thus histochemically behave similar to elastic fibers.

Such profound changes of dermal architecture become clinically apparent: The taut and firm connective tissue in scleroderma reflects the sclerotic texture and homogenization of the collagen bundles seen histologically; the loose folds of cutis laxa are a result of the fragmentation of elastic fibers; the cobblestone-like papules in pseudoxanthoma elasticum correspond to the focal aggregation of the pathologically altered elastic material; and the coarseness of skin lines and surface profile in dermatoheliosis are the clinical manifestations of the focal aggregation of elastotic material.

SUBCUTANEOUS FAT (See Fig. 6-1, S)

Inflammatory processes in the subcutaneous adipose tissue take a slightly different course than in the connective tissue of the dermis because of the specific anatomy of the subcutis (see Chaps. 7 and 68). Inflammation of subcutaneous fat reflects either an inflammatory process of the adipose tissue proper or the fat lobules (see Fig. 6-1, L) or a process arising in the septa (see Fig. 6-1, Sep); it can involve small venules and capillaries or arise from the larger muscular vessels. The histopathologic manifestations may vary accordingly. Small-vessel pathology is usually manifested locally, involving the neighboring fat lobules, whereas the destruction or occlusion of a larger vessel influences the entire tissue segment. Destruction of fat, be it of a traumatic or inflammatory nature, leads to the release of fatty acids that by themselves are strong inflammatory stimuli, attracting neutrophils and scavenger histiocytes and macrophages; phagocytosis of destroyed fat usually results in lipogranuloma formation.

Septal processes that follow inflammatory changes of the trabecular vessels are usually accompanied by edema, infiltration of inflammatory cells, and a histiocytic reaction. This is the classic appearance in erythema nodosum (Fig. 6-22; see Chap. 68). Recurring septal inflammation may lead to a broadening of the interlobular septa, fibrosis, the accumulation of histiocytes and giant cells, and may result in vascular proliferation. By contrast, in nodular vasculitis (Fig. 6-23), large-vessel vasculitis in the septal area is accompanied by necrosis of the fat, followed by histiocytic reactions, epithelioid cell granulomas within the fat lobules, and a fibrotic reaction sclerosing the entire subcutaneous fat. On the other hand, lobular panniculitis results from the necrosis of fat lobules as the primary event, as is the case in idiopathic nodular panniculitis (see Chap. 68), followed by an accumulation of neutrophils and leukocytoclasia. The lipid material derived from necrotic adipocytes contains free and esterified cholesterol, neutral fats, soaps, and free fatty acids, which, in turn, exert an inflammatory stimulus. Histiocytic cells migrate into the inflamed fat, and phagocytosis leads to foam cell formation. Epithelioid granulomas with giant cells may also result, and all types of fibrosis may develop. Fat necrosis is, therefore, the primary, and inflammation the secondary, event in this type of panniculitis.

The inherent capacity of the adipose tissue to respond to pathologic stimuli also holds true for disease conditions that affect the subcutaneous tissue only secondarily or result from exogenous factors. Traumatic panniculitis leads to necrosis of fat lobules and a reactive inflammatory and granulomatous tissue response. After the injection of oils or silicone, large cystic cavities may be formed, whereas after the injection of pentazocine, for instance, fibrosis and sclerosis dominate the histopathologic picture. Oily substances may remain within the adipose tissue for long periods without causing a significant tissue reaction; oil cysts evolve that are surrounded by multiple layers of residual connective tissue, so that the tissue acquires a "Swiss cheese" appearance. Animal or vegetable oils often lead to tuberculoid or lipophagic granulomas with massive histiocytic reactions, foam cells, and secondary fibrosis.

Panniculitis also occurs as a result of infectious agents (cocci, mycobacteria, and other bacterial and fungal organisms) or a specific disease process. In sarcoidosis, fat is gradually replaced by epithelioid cell nodules and, in lymphoma, by specific lymphomatous infiltrates. In lupus panniculitis, a dense lymphocytic infiltrate of the septal and lobular tissue determines the histopathologic picture, as does involvement of vessels manifesting as vasculitis. However, destruction of fat, liquefaction, and lipogranuloma may be so pronounced that the vascular component can hardly be recognized, and the histopathologic picture may resemble idiopathic nodular panniculitis.

SECTION 3

OVERVIEW OF BIOLOGY, DEVELOPMENT, AND STRUCTURE OF SKIN

CHAPTER 7

Development and Structure of Skin

David H. Chu

SKIN: AN OVERVIEW

Skin is a complex organ that protects its host from its environment, at the same time allowing interaction with the environment. It is much more than a static, impenetrable shield against external insults. Rather, the skin is a dynamic, complex, integrated arrangement of cells, tissues, and matrix elements that mediates a diverse array of functions: skin provides a physical permeability barrier, protection from infectious agents, thermoregulation, sensation, ultraviolet (UV) protection, wound repair and regeneration, and outward physical appearance (Table 7-1). These various functions of skin are mediated by one or more of its major regions—the epidermis, dermis, and hypodermis (Fig. 7-1; see also Fig. 6-1, Chap. 6). These divisions are interdependent, functional units; each region of skin relies upon and is connected with its surrounding tissue for regulation and modulation of normal structure and function at molecular, cellular, and tissue levels of organization (see Chap. 6).

Whereas the epidermis and its outer stratum corneum provide a large part of the physical barrier provided by skin, the structural integrity of the skin as a whole is provided primarily by the dermis and hypodermis. Antimicrobial activities are provided by the innate immune system and antigen-presenting dendritic cells of the epidermis, circulating immune cells that migrate from the dermis, and antigen-presenting cells of the dermis (see Chap. 10). Protection from UV irradiation is provided in great measure by the most superficial cells of the epidermis. Inflammation begins with the keratinocytes of the epidermis or immune cells of the dermis, and sensory apparatus emanates from nerves that initially traverse the hypodermis to the dermis and epidermis, ending in specialized receptive organs or free nerve endings. The largest blood vessels of the skin are found in the hypodermis, which serve to transport nutrients and immigrant cells (see Fig. 6-1, Chap. 6). The cutaneous lymphatics course through the dermis and hypodermis, serving to filter debris and regulate tissue hydration. Epidermal appendages provide special protective or sensory functions. Skin also determines a person's physical appearance, influenced by pigmentation provided by melanocytes, with body contours, appearance of age, and actinic damage influenced by the epidermis, dermis, and hypodermis. The skin begins to be organized during embryogenesis, where intercellular and intracellular signals, as well as reciprocal crosstalk between different tissue layers, are instrumental in regulating the eventual maturation of the different components of skin.

What follows is an integrated description of the major structural features of the skin and how these structures allow the skin to achieve its major functions, followed by a review of their embryologic origins. Also highlighted are illustrative cutaneous diseases that manifest when these functions are defective. Understanding the genetic and molecular basis of skin disease has confirmed, and in some cases revealed, the many factors and regulatory elements that play critical roles in skin function.

STRUCTURE AND FUNCTION OF SKIN AT A GLANCE

- Three Major Layers—Epidermis, Dermis, Hypodermis:
  - Epidermis: major permeability barrier, innate immune function, adhesion, ultraviolet protection.
  - Dermis: major structural element, three types of components—cellular, fibrous matrix, diffuse and filamentous matrix. Also site of vascular, lymphatic, and nerve networks.
  - Hypodermis (subcutis): insulation, mechanical integrity, containing the larger source vessels and nerves.

EPIDERMIS

One of the most fundamental and visible features of skin is the stratified, cornified epidermis (Fig. 7-2). The epidermis is a continually renewing structure that gives rise to derivative structures called appendages (pilosebaceous units, nails, and sweat glands). The epidermis ranges in thickness from 0.4 to 1.5 mm, as compared with the 1.5- to 4.0-mm full-thickness skin. The majority of cells in the epidermis are keratinocytes that are organized into four layers, named for either their position or a structural property of the cells. These cells progressively differentiate from

TABLE 7-1
Functions of Skin

Function	Tissue Layer	Some Associated Diseases
Permeability barrier	Epidermis	Atopic dermatitis
		Ectodermal dysplasias
		Ichthyoses
		Keratodermas
		Exfoliative dermatitis
		Bullous diseases
Protection from pathogens	Epidermis	Verruca vulgaris
	Dermis	Ecthyma
		Cellulitis
		Leishmaniasis
		Human immunodeficiency virus
		Tinea pedis/corporis
Thermoregulation	Epidermis	Ectodermal dysplasias
	Dermis	Raynaud
	Hypodermis	Hyperthermia
Sensation	Epidermis	Diabetic neuropathy
	Dermis	Leprosy
	Hypodermis	Pruritus
		Postherpetic neuralgia
Ultraviolet protection	Epidermis	Xeroderma pigmentosum
		Oculocutaneous albinism
Wound repair/regeneration	Epidermis	Keloid
	Dermis	Venous stasis ulcer
		Pyoderma gangrenosum
Physical appearance	Epidermis	Melasma
	Dermis	Vitiligo
	Hypodermis	Scleroderma
		Lipodystrophy

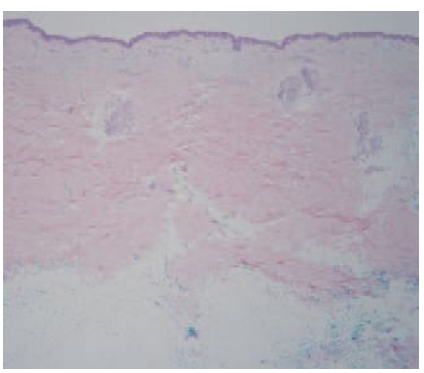
proliferative basal cells, attached to the epidermal basement membrane, to the terminally differentiated, keratinized stratum corneum, the outermost layer and barrier of skin (see Chap. 45). Intercalated among the keratinocytes at various levels are the immigrant resident cells—melanocytes, Langerhans cells, and Merkel cells. Other cells, such as lymphocytes, are transient inhabitants of the epidermis and are extremely sparse in normal skin. There are many regional differences in the epidermis and its appendages. Some of these differences are apparent grossly, such as thickness (e.g., palmoplantar skin vs. truncal skin, Fig. 7-3); other differences are microscopic.

Pathologic changes in the epidermis can occur as a result of a number of different stimuli: repetitive mechanical trauma (as in lichen simplex chronicus), inflammation (as in atopic dermatitis and lichen planus), infection (as in verruca vulgaris), immune system activity and cytokine abnormalities (as in psoriasis, Fig. 7-4), autoantibodies (as in pemphigus vulgaris and bullous pemphigoid), or genetic defects that influence differentiation or structural proteins [as in epidermolysis bullosa (EB) simplex, epidermolytic hyperkeratosis, the ichthyoses, and Darier disease].

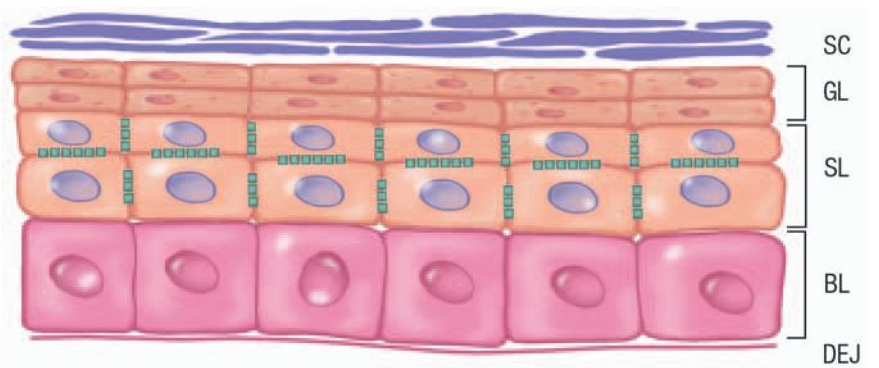
Layers of the Epidermis

BASAL LAYER The keratinocyte is an ectodermally derived cell and is the primary cell type in the epidermis, accounting for at least 80 percent of the total cells. The ultimate fate of these cells is to contribute the components for the epidermal barrier as the stratum corneum. Thus, much of the function of the epidermis can be gleaned from the study of the structure and development of the keratinocyte.

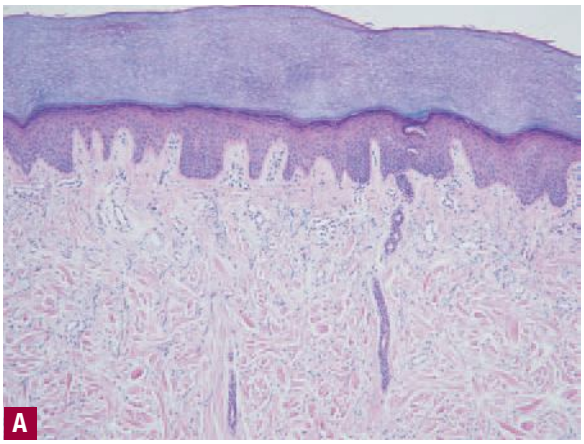
Keratinocyte differentiation (keratinization) is a genetically programmed, carefully regulated, complex series of morphologic changes and metabolic events whose endpoint is a terminally differentiated, dead keratinocyte (corneocyte) that contains keratin filaments, matrix protein, and a protein-reinforced

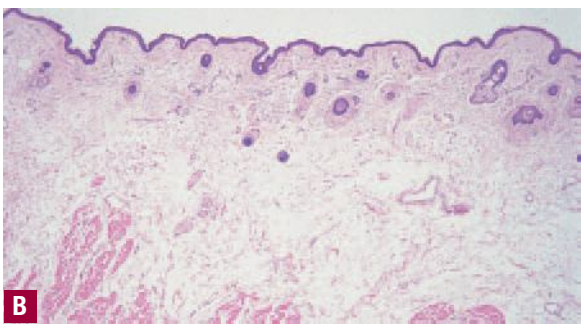


▲ **FIGURE 7-1** The major regions of skin. Skin is composed of three layers: (1) epidermis, (2) dermis, and (3) hypodermis. The outermost epidermis is separated from the dermis by a basement membrane zone, the dermal-epidermal junction. Below the dermis lies the subcutaneous fat (hypodermis). Epidermal appendages, such as hair follicles and eccrine and apocrine sweat glands, begin in the epidermis but course through the dermis and/or the epidermis. Blood vessels, lymphatics, and nerves course through the subcutaneous fat and emerge into the dermis. (Used with permission from O. Kovich, MD.)

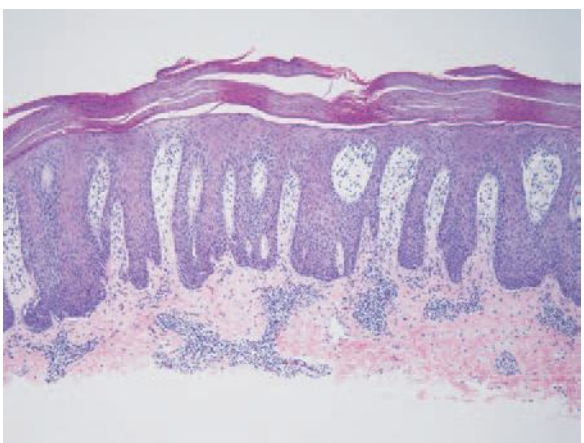


▲ **FIGURE 7-2** Schematic of epidermis. The epidermis is a stratified, cornified epithelium. The deepest layer consists of basal cells (BL) that rest upon the basement membrane of the dermal-epidermal junction (DEJ). These cells differentiate into the cells of the spinous layer (SL), characterized by abundant desmosomal spines. Spinous cells eventually become granular layer cells (GL), producing many of the components of the cornified envelope. Ultimately, the terminally differentiated keratinocytes shed their nuclei and become the stratum corneum (SC), a cross-linked network of protein and glycolipids.





► **FIGURE 7-3** Anatomic variation in epidermal thickness. **A.** Acral skin. **B.** Eyelid skin. Note that the epidermis is considerably thicker in (**A**) than (**B**), including the compact layers of the stratum corneum, as well as the deeper epidermal layers. (Used with permission from O. Kovich, MD.)



►**FIGURE 7-4** Epidermal hyperplasia. Hyperproliferation of the epidermis can occur due to a number of causes, as manifested in diseases such as psoriasis (pictured), as well as lichen simplex chronicus, atopic dermatitis, lichen planus, and verruca vulgaris. (Used with permission from O. Kovich, MD.)

plasma membrane with surface-associated lipids (see Chap. 44).

Keratins are a family of intermediate filaments and are the hallmark of all epithelial cells, including keratinocytes (reviewed in refs. 1 and 2). They serve a predominantly structural role in the cells. Fifty-four different functional keratin genes have been identified in humans—34 epithelial keratins and 17 hair keratins.[3] The co-expression of specific keratin pairs is dependent on cell type, tissue type, developmental stage, differentiation stage, and disease condition (Table 7-2). Furthermore, the critical role of these molecules is underscored by the numerous manifestations of disease that arise because of mutations in these genes (see Table 7-2). Thus, knowledge of keratin expression, regulation, and structure provides insight into epidermal differentiation and structure.

The basal layer (stratum germinativum) contains mitotically active, columnar-shaped keratinocytes that attach via keratin filaments (K5 and K14) to the basement membrane zone at hemidesmosomes (see Chap. 51), attach to other surrounding cells through desmosomes, and that give rise to cells of the more superficial, differentiated epidermal layers. Ultrastructural analysis reveals the presence of membrane-bound vacuoles that contain pigmented melanosomes transferred from melanocytes by phagocytosis.[4] The pigment within melanosomes contributes to the overall skin pigmentation perceived macroscopically.[5] The basal layer is the primary location of mitotically active cells of the epidermis. Cell kinetic studies suggest that the basal layer cells exhibit different proliferative potentials (stem cells, transit amplifying cells, and postmitotic cells), and in vivo and in vitro studies suggest that there exist long-lived epidermal stem cells[6] (see Chap. 44). Because basal cells can be expanded in tissue culture and used to reconstitute sufficient epidermis to cover the entire skin surface of burn patients,[7,8] such a starting population is presumed to contain long-lived stem cells with extensive proliferative potential.

A large amount of data supports the existence of multipotent epidermal stem cells within the bulge region of the hair follicle based on these traits.[9–17] Cells from this region are able to contribute to the formation not only of the entire pilosebaceous unit, but to the interfollicular epidermis as well.[14–17]

The existence of an additional progenitor population of cells, within the surface epidermal basal layer, is also supported by a number of lines of evidence, both in vitro and in vivo. These putative basal stem cells appear to be clonogenic, progress rapidly through S-phase of the cell cycle, and divide infrequently during stable self-renewal (retaining radiolabeled nucleotide label over long periods). Additionally, they are capable of cell division in response to exogenous and endogenous agents. Early lineage tracing experiments in the epidermis identified that keratinocytes are organized into vertical columns of progressively differentiating cells, termed *epidermal proliferating units*.[18–21]

The second type of cell, the transit amplifying cells of the basal layer, arises as a subset of daughter cells produced by the infrequent division of stem cells. These cells provide the bulk of the cell divisions needed for stable self-renewal and are the most common cells in the basal compartment. After undergoing several cell divisions, these cells give rise to the third class of epidermal basal cells, the postmitotic cells that undergo terminal differentiation. Although long believed to detach from the basal lamina to migrate to a more superficial (suprabasal) position in the epidermis, recent evidence has suggested that asymmetric division of basal cells relative to the basement membrane can directly give rise to a suprabasal differentiating daughter cell.[30] In humans, the normal transit time for a basal cell, from the time it loses contact with the basal layer to the time it enters the stratum corneum, is at least 14 days. Transit through the stra-

TABLE 7-2
Expression Patterns of Keratin Genes and Keratin-Associated Diseases

Basic	Acidic	Tissue Expression	Disease Association
1	10	Suprabasal keratinocytes	Bullous congenital ichthyosiform erythroderma; diffuse nonepidermolytic PPK (keratin 1)
1	9	Suprabasal keratinocytes (palmoplantar skin)	Epidermolytic PPK (epidermolytic hyperkeratosis)
2	10	Upper spinous and granular layers	Ichthyosis bullosa of Siemens
3	12	Cornea	Meesmann's corneal dystrophy

8	18	Simple epithelium	Cryptogenic cirrhosis

PPK = palmoplantar keratoderma.

tum corneum and subsequent desquamation require another 14 days. These periods of time can be altered in hyperproliferative or growth-arrested states.

SPINOUS LAYER The shape, structure, and subcellular properties of spinous cells correlate with their position within the mid-epidermis. They are named for the spine-like appearance of the cell margins in histologic sections. Suprabasal spinous cells are polyhedral in shape with a rounded nucleus. As these cells differentiate and move upward through the epidermis, they become progressively flatter and develop organelles known as *lamellar granules* (see Granular Layer). Spinous cells also contain large bundles of keratin filaments, organized around the nucleus and inserted into desmosomes peripherally.

Spinous cells retain the stable K5/K14 keratins that are produced in the basal layer but do not synthesize new messenger RNA (mRNA) for these proteins, except in hyperproliferative disorders. Instead, new synthesis of the K1/K10 keratin pair occurs in this epidermal layer. These keratins are characteristic of an epidermal pattern of differentiation and thus are referred to as the *differentiation-specific* or *keratinization-specific keratins*. This normal pattern of differentiation is switched to an alternative pathway in hyperproliferative states, however. In conditions such as psoriasis, actinic keratoses, and wound healing, synthesis of K1 and K10 mRNA and protein is downregulated, and the synthesis and translation of messages for K6 and K16 are favored. Correlated with this change in keratin expression is a disruption of normal differentiation in the subsequent granular and cornified epidermal layers (see Granular Layer and Stratum Corneum). mRNA for K6 and K16 are present throughout the epidermis normally, but the message is only translated on stimulation of proliferation.

The "spines" of spinous cells are abundant desmosomes, calcium-dependent cell surface modifications that promote adhesion of epidermal cells and resistance to mechanical stress (reviewed in ref. 31; see also Chaps. 44 and 51). Within each cell is a desmosomal plaque, which contains the polypeptides plakoglobin, desmoplakins I and II, keratocalmin, desmoyokin, and plakophilin. Transmembrane glycoproteins—desmogleins 1 and 3 and desmocollins I and II, members of the cadherin family—provide the adhesive properties of the extracellular portion of the desmosomes, known as the *core*. Whereas the extracellular domains of the cadherins form part of the core, the intracellular domains insert into the plaque, linking them to the intermediate filament (keratin) cytoskeleton. Although desmosomes are related to adherens junctions, the latter associate with actin microfilaments at cell–cell interfaces, via a distinct set of cadherins (e.g., E-cadherin) and intracellular catenin adapter molecules.

That the desmosomes are integral mediators of intercellular adhesion is clearly demonstrated in diseases in which these structures are disrupted (Table 7-3).[32] The autoimmune bullous diseases pemphigus vulgaris and pemphigus foliaceus (see Chap. 52) are caused by antibodies that target the desmoglein proteins within the desmosomes. Loss of desmosomal adhesion results in the characteristic rounding and separation of keratinocytes (acantholysis), ultimately forming a blister within the epidermis. Strikingly, the clinical presentation of these diseases reflects the relative expression in the tissue of the desmoglein 1 and 3 proteins

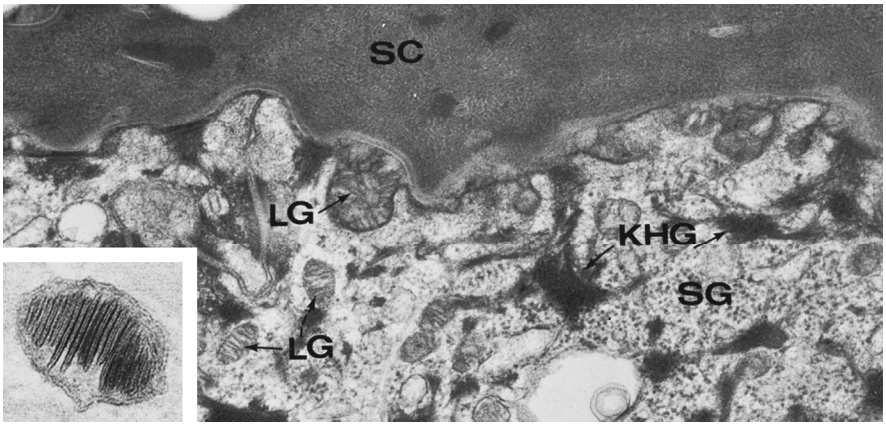
TABLE 7-3
Disease Resulting from Disruption of Desmosomal Proteins

Protein	Diseases
Desmoglein 1	Pemphigus foliaceus Striate palmoplantar keratoderma Staphylococcal scalded-skin syndrome Bullous impetigo
Desmoglein 3	Pemphigus vulgaris
Desmoglein 4	Autosomal recessive hypotrichosis
Plakoglobin	Palmoplantar keratoderma with wooly hair and arrhythmogenic right ventricular cardiomyopathy (Naxos disease)
Plakophilin 1	Ectodermal dysplasia/skin fragility syndrome (skin erosions, dystrophic nails, sparse hair, and painful palmoplantar keratoderma)
Plakophilin 2	Arrhythmogenic right ventricular cardiomyopathy
Desmoplakin	Lethal acantholytic epidermolysis bullosa Striate palmoplantar keratoderma, type I Palmoplantar keratoderma with left ventricular cardiomyopathy and wooly hair Autosomal dominant arrhythmogenic right ventricular cardiomyopathy

(see Chaps. 51 and 52). Pemphigus vulgaris results from autoantibodies directed against desmoglein 3 and results in disruption of the epidermis between the basal and suprabasal layers (reviewed in ref. 33). On the other hand, desmoglein 1 is expressed in the upper epidermal layers, and antibodies to this protein in patients with pemphigus foliaceus result in blisters in the more superficial granular layer. Other diseases that target the same desmoglein 1 protein but by a different mechanism are staphylococcal scalded skin syndrome (see Chap. 178) and bullous impetigo, in which a bacterial protease cleaves and inactivates desmoglein 1, resulting in the same superficial blistering seen in pemphigus foliaceus.[34] Genetic mutations in other desmosomal components also reveal a role for these proteins in adhesion as well as cell signaling (see Table 7-3).[32]

The importance of calcium as a mediator of adhesion is well illustrated in the cases of two conditions that exhibit characteristic epidermal dyscohesion, Darier disease (keratosis follicularis) and Hailey-Hailey disease (benign chronic pemphigus) (see Chap. 49).[35,36] Both of these diseases are caused by mutations in genes that regulate calcium transport, SERCA2 (sarco/endoplasmic reticulum Ca^{2+}-ATPase type 2 isoform) in the case of Darier disease, and ATP2C1 (ATPase, Ca^{2+} transporting, type 2C, member 1, a regulator of cytoplasmic calcium concentration) in the case of Hailey-Hailey disease.

Lamellar granules are also formed in this layer of epidermal cells (Fig. 7-5). These secretory organelles deliver precursors of stratum corneum lipids into the intercellular space. Lamellar granules contain glycoproteins, glycolipids, phospholipids, free sterols, and a number of acid hydrolases, including lipases, proteases, acid phosphatases, and glycosidases. Glucosylceramides, the precursors to ceramides and the dominant component of the stratum corneum lipids, are also found within these structures (see Chap. 45). Genetic diseases demonstrate the importance of steroid and lipid metabolism for sloughing of cornified cells—in recessive X-linked ichthyosis, for example, mutation of steroid sulfatase results in a retention hyperkeratosis (see Chap. 47).[37,38]



▲ **FIGURE 7-5** Junction of the stratum granulosum (SG) and stratum corneum (SC). Lamellar granules (LG) are in the intercellular space and cytoplasm of the granular cell. Keratohyalin granules (KHG) are also evident. *Inset:* Lamellar granule, ×28,750. (From Holbrook K: Structure and development of the skin, in *Pathophysiology of Dermatologic Disease*, 2nd ed., edited by Soter NA, Baden HP. New York, McGraw-Hill, 1991, p 7, with permission. Inset used with permission from EC Wolff-Schreiner, MD.)

GRANULAR LAYER Named for the basophilic keratohyalin granules that are prominent within cells at this level of the epidermis, the granular layer is the site of generation of a number of the structural components that will form the epidermal barrier, as well as a number of proteins that process these components (see Fig. 7-2) (reviewed in refs. 39 and 40). Keratohyalin granules (see Fig. 7-5) are composed primarily of profilaggrin, keratin filaments, and loricrin. It is in this layer that the cornified cell envelope begins to form. Release of profilaggrin from keratohyalin granules results in the calcium-dependent cleavage of the profilaggrin polymeric protein into filaggrin monomers. These filaggrin monomers aggregate with keratin to form macrofilaments. Eventually, filaggrin is degraded into molecules, including urocanic acid and pyrrolidone carboxylic acid, which contribute to hydration of the stratum corneum and help filter UV radiation. Loricrin is a cysteine-rich protein that forms the major protein component of the cornified envelope, accounting for more than 70 percent of its mass. Upon its release from keratohyalin granules, loricrin binds to desmosomal structures. Loricrin, along with involucrin, cystatin A, small proline-rich proteins (SPR1, SPR2, and cornifin), elafin, and envoplakin are all subsequently cross-linked to the plasma membrane by tissue transglutaminases (TGMs, primarily TGMs 3 and 1), forming the cornified cell envelope.

Mutations in the TGM1 gene have been shown to be the basis of some cases of lamellar ichthyosis, an autosomal recessive condition characterized by large scales and a disruption in the uppermost differentiating layers of the epidermis.[41,42] Another form of ichthyosis, ichthyosis vulgaris, is caused by mutations in the gene encoding filaggrin.[43,44] Loricrin abnormalities result in a form of Vohwinkel syndrome with ichthyosis and pseudoainhum, as well as the disease progressive symmetric keratodermia.[45–47] These findings emphasize the importance of proper formation of the cornified envelope in normal epidermal keratinization.

The final stage of granular cell differentiation involves the cell's own programmed destruction. During this process, in which the granular cell becomes a terminally differentiated corneocyte, an apoptotic mechanism results in the destruction of the nucleus and almost all cellular contents, with the exception of the keratin filaments and filaggrin matrix.

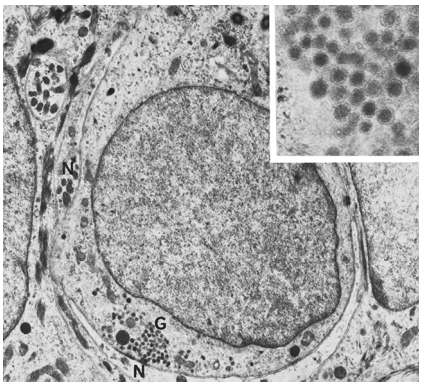
STRATUM CORNEUM (See Chap. 45) Complete differentiation of granular cells results in stacked layers of anucleate, flattened cornified cells that form the stratum corneum. It is this layer that provides mechanical protection to the skin and a barrier to water loss and permeation of soluble substances from the environment (reviewed in refs. 39 and 48). The stratum corneum barrier is formed by a two-compartment system of lipid-depleted, protein-enriched corneocytes surrounded by a continuous extracellular lipid matrix. These two compartments provide somewhat segregated but complementary functions that together account for the "barrier activity" of the epidermis. Regulation of permeability, desquamation, antimicrobial peptide activity, toxin exclusion, and selective chemical absorption are all primarily functions of the extracellular lipid matrix. On the other hand, mechanical reinforcement, hydration, cyto-

kine-mediated initiation of inflammation, and protection from UV damage are all provided by the corneocytes.

Nonkeratinocytes of the Epidermis

Melanocytes are neural crest-derived, pigment-synthesizing dendritic cells that reside primarily in the basal layer (see Chap. 70).[49] By light microscopy, these cells are recognized by their pale-staining cytoplasm, ovoid nucleus, and color of the pigment-containing melanosomes, the distinctive organelle of the melanocyte. The function of melanocytes has been highlighted by disorders in melanocyte number or function. The classic dermatologic disease, vitiligo, is caused by the autoimmune depletion of melanocytes.[50] Causes of other disorders of pigmentation are found in various defects in melanogenesis, including melanin synthesis, melanosome production, and melanosome transport and transfer to keratinocytes (see Chaps. 70 and 73). Regulation of melanocyte proliferation and homeostasis is under intensive study as well as a means to understanding melanoma (see Chap. 124).[4] Keratinocyte–melanocyte interactions are critical for melanocyte homeostasis and differentiation, influencing proliferation, dentricity, and melanization.

Merkel cells are slow-adapting type I mechanoreceptors located in sites of high-tactile sensitivity (see Chap. 120).[51] They are present among basal keratinocytes in particular regions of the body, including hairy skin and in the glabrous skin of the digits, lips, regions of the oral cavity, and the outer root sheath of the hair follicle. Like other nonkeratinocytes, Merkel cells have a pale-staining cytoplasm. Immunohistochemical markers of the Merkel cell include K8, K18, K19, and K20 keratin peptides. K20 is restricted to Merkel cells in the skin and thus may be the most reliable marker. Ultrastructurally, Merkel cells are easily identified by the membrane-bounded, dense-core granules that collect opposite the Golgi and proximal to an unmyelinated neurite (Fig. 7-6). These granules are similar to neurosecretory granules in neurons and contain neurotransmitter-like substances and markers of neuroendocrine cells, including metenkephalin, vasoactive intestinal peptide, neuron-specific enolase, and synaptophysin. Although increasingly more is being learned about the normal function of Merkel cells, they are of particular clinical note because Merkel cell-derived neoplasms are particularly aggressive and difficult to treat (see Chap. 120).



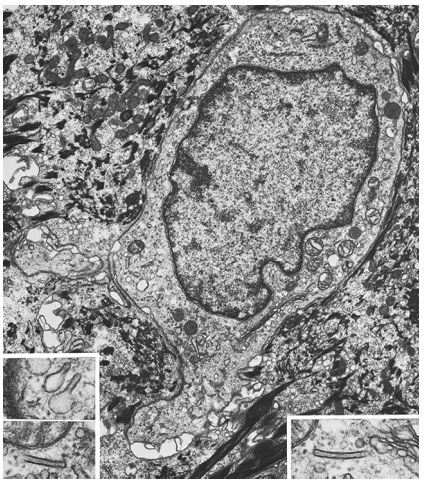
▲ **FIGURE 7-6** Merkel cells from the finger of a 130-mm CR (crown-rump) 21-week human fetus. Note nerve (N) in direct contact with the lateral and basal surfaces of the cell and dense core cytoplasmic granules (G). ×13,925. *Inset:* Merkel cell granules, ×61,450.

Langerhans cells are dendritic antigen-processing and -presenting cells in the epidermis (see Chap. 10).[52] Although they are not unique to the epidermis, they form 2 percent to 8 percent of the total epidermal cell population. They are mostly found in a suprabasal position but are distributed throughout the basal, spinous, and granular layers. In histologic preparations, Langerhans cells are pale-staining and have convoluted nuclei. The cytoplasm of the Langerhans cells contains characteristic small rod- or racket-shaped structures called *Langerhans cell granules* or *Birbeck granules* (Fig. 7-7). They principally function to sample and present antigens to T cells of the epidermis. Because of these functions, they are implicated in the pathologic mechanisms underlying allergic contact dermatitis, cutaneous leishmaniasis, and human immunodeficiency virus infection. Langerhans cells are reduced in the epidermis of patients with certain conditions, such as psoriasis, sarcoidosis, and contact dermatitis; they are functionally impaired by UV radiation, especially UVB.

Because of their effectiveness in antigen presentation and lymphocyte stimulation, dendritic cells and Langerhans cells have become prospective vehicles for tumor therapy and tumor vaccines. These cells are loaded with tumor-specific antigens, which will then stimulate the host immune response to mount an antigen-specific, and therefore tumor-specific, response.

DERMAL-EPIDERMAL JUNCTION

The dermal-epidermal junction (DEJ) is a basement membrane zone that forms the interface between the epidermis and dermis (see Chap. 51).[53,54] The major functions of the DEJ are to attach the epidermis and dermis to each other and to provide resistance against external shearing forces. It serves as a support for the epidermis, determines the polarity of growth, directs the organization of the cytoskeleton in basal cells, provides developmental signals, and serves as a semipermeable barrier.



▲ **FIGURE 7-7** Langerhans cell. Note indented nucleus, lysosomes, as well as rod- and racket-shaped cytoplasmic granules (Birbeck granules), and the absence of keratin filaments. ×13,200. *Inset:* Birbeck granules ×88,000. (Used with permission from N. Romani, MD.)

The DEJ can be subdivided into three supramolecular networks: the hemidesmosome-anchoring filament complex, the basement membrane itself, and the anchoring fibrils. The critical role of this region in maintaining skin structural integrity is revealed by the large number of mutations in DEJ components that cause blistering diseases of varying severity, covered in detail in Chap. 60. These bullous diseases are grouped according to the level of the cleavage within the DEJ—the most superficial, EB simplex, involves basal keratinocyte cleavage. Junctional EB occurs within the lamina lucida and lamina densa regions. Dystrophic EB is the deepest level of blistering, within the sublamina densa/anchoring filaments. Chap. 51 provides a detailed discussion of the DEJ networks.

DERMIS

The dermis is an integrated system of fibrous, filamentous, diffuse, and cellular connective tissue elements that accommodates nerve and vascular networks, epidermally derived appendages, and contains many resident cell types, in-

cluding fibroblasts, macrophages, mast cells, and transient circulating cells of the immune system (see Figs. 6-9 and 6-14). The dermis makes up the majority of the skin and provides its pliability, elasticity, and tensile strength. It protects the body from mechanical injury, binds water, aids in thermal regulation, and includes receptors of sensory stimuli. The dermis interacts with the epidermis in maintaining the properties of both tissues, collaborates during development in the morphogenesis of the DEJ and epidermal appendages (see Development of Skin Appendages), and interacts in repairing and remodeling skin after wounding.

The dermis is arranged into two major regions, the upper papillary dermis and the deeper reticular dermis. These two regions are readily identifiable on histologic section, and they differ in their connective tissue organization, cell density, and nerve and vascular patterns. The papillary dermis abuts the epidermis, molds to its contours, and is usually no more that twice its thickness (see Fig. 6-9). The reticular dermis forms the bulk of the dermal tissue. It is composed primarily of large-diameter collagen fibrils, organized into large, interwoven fiber bundles, with branching elastic fibers surrounding the bundles (see Fig. 6-14). In normal individuals, the elastic fibers and collagen bundles increase in size progressively toward the hypodermis. The subpapillary plexus, a horizontal plane of vessels, marks the boundary between the papillary and reticular dermis. The lowest boundary of the reticular dermis is defined by the transition of fibrous connective tissue to adipose connective tissue of the hypodermis.

Fibrous Matrix of the Dermis

The connective tissue matrix of the dermis is comprised primarily of collagenous and elastic fibrous tissue.[55,56] These are combined with other, nonfibrous connective tissue molecules, including finely filamentous glycoproteins, proteoglycans (PGs), and glycosaminoglycans (GAGs) of the "ground substance."[57]

In terms of acellular components, collagen forms the bulk of the dermis, accounting for approximately 75 percent of the dry weight of skin, and providing both tensile strength and elasticity. (For details regarding the polypeptide structure and distribution of collagens, see Chap. 61.) The periodically banded, interstitial collagens account for the greatest proportion of collagen in adult dermis (type I, 80 percent to 90 percent; III, 8 percent to 12 percent; and V, < 5 percent). Although type V collagen accounts for a relatively small proportion of total collagen, it codistributes with both types I and III collagen to assist in regulating fibril diameter. It is located primarily in the papillary dermis and the matrix surrounding the basement membranes of vessels, nerves, and epidermal appendages, and at the DEJ. Type VI collagen is associated with fibril and in the interfibrillar spaces. Type IV collagen is confined to the basal lamina of the DEJ, vessels, and epidermal appendages. Type VII collagen forms anchoring fibrils at the DEJ.

Elastic connective tissue (see Chap. 61) is complex molecular mesh, assembled into a continuous network that extends from the lamina densa of the DEJ throughout the dermis and into the connective tissue of the hypodermis.[56] Elastic fibers return the skin to its normal configuration after being stretched or deformed. Elastic fibers are also present in the walls of cutaneous blood vessels and lymphatics and in the sheaths of hair follicles. By dry weight, elastic connective tissue accounts for approximately four percent of the dermal matrix protein. The components of elastic fibers include fibrillin-1, a 350-kd molecule, mutations in which cause Marfan syndrome (see Chap. 139). Elastin is the elastic fiber matrix component, and mutations in this protein cause the disease cutis laxa (see Chap. 139). Oxytalan fibers extend from the DEJ to the papillary/reticular dermal junction, where they merge with elaunin fibers. Elaunin fibers, in turn, evolve into mature elastic fibers of the reticular dermis. These fibers are normally located between bundles of collagen fibers, although in certain pathologic conditions, such as Buschke-Ollendorff syndrome, both elastic and collagen fibers become assembled within the same bundle. The importance of this elastic fiber network is clearly seen in the number of multisystem diseases that arise because of mutations in components of this network. Recently, the defect underlying pseudoxanthoma elasticum (PXE) was found to be mutation in ABCC6, a member of the large adenosine triphosphate-dependent transmembrane transporter family. Thus, this disease that is characterized by loss of skin elasticity and calcified elastic fibers is unlikely a primary defect in elastic tissue, but rather a metabolic disorder with secondary involvement of elastic fibers.[58–60] In addition to genetic mutations, solar radiation and aging also contribute to elastic fiber damage.[61]

Filamentous and Diffuse Matrix Components of the Dermis (See Chap. 61)

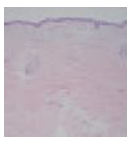
The fibrous and cellular matrix elements are embedded within more amorphous matrix components, which also are found in basement membranes.[62–64] PGs and GAGs surround and embed the fibrous components. PGs are large molecules consisting of a core protein that determines which GAGs will be incorporated into the molecule. The PG/GAG complex can bind water up to 1000 times its own volume and have roles in regulation of water-binding and compressibility of the dermis, as well as increasing local concentrations of growth factors through binding (e.g., basic fibroblast growth factor). They also link cells with the fibrillar and filamentous matrix, influencing proliferation, differentiation, tissue repair, and morphogenesis.

The major PGs in the adult dermis are chondroitin sulfates/dermatan sulfate, including biglycan, decorin, and versican; heparan/heparan sulfate PGs, including perlecan and syndecan; and chondroitin-6 sulfate PGs, which are components of the DEJ (see Chap. 61). The relative amounts of these different PGs change with age, as adult dermis after age 40 years generally has increases in dermatan sulfate, but decreases in chondroitin-6 sulfate and chondroitin sulfate.

Glycoproteins that are found in the dermis include fibronectin, thrombospondin, laminin, vitronectin, and tenascin. Like the PGs/GAGs, they interact with other matrix components via integrin receptors. These molecules facilitate processes of migration, cell adhesion, morphogenesis, and differentiation. Fibronectin is synthesized by both epithelial and mesenchymal cells, and it covers collagen bundles and the elastic network. Vitronectin is present on all elastic fibers except for oxytalan. Tenascin expression is found around the smooth muscle of blood vessels, arrector pili muscles, and appendages such as sweat glands.

Cellular Components of the Dermis

Fibroblasts, macrophages, and mast cells are the regular residents of the dermis,



mostly found around the papillary region and surrounding vessels of the subpapillary plexus (see Fig. 6-20). They also occur in the reticular dermis in the interstices between collagen fiber bundles. The fibroblast is a mesenchymally derived cell that migrates through the tissue and is responsible for the synthesis and degradation of fibrous and nonfibrous connective tissue matrix proteins and a number of soluble factors. Fibroblasts provide a structural extracellular matrix framework as well as promote interaction between epidermis and dermis by synthesis of soluble mediators. Studies of human fibroblasts indicate that even within a single tissue, phenotypically distinct populations exist, some of which relate to regional anatomical differences.[65,66] They are also instrumental in wound healing and scarring, increasing their proliferative and synthetic activity during these processes.

The monocytes, macrophages, and dermal dendrocytes constitute the mononuclear phagocytic system of cells in the skin. Macrophages are derived from precursors in the bone marrow, differentiate into circulating monocytes, then migrate into the dermis to differentiate. These cells are phagocytic; process and present antigen to immunocompetent lymphoid cells; are microbicidal (producing lysozyme, peroxide, and superoxide), tumoricidal, secretory (growth factors, cytokines, and other immunomodulatory molecules), and hematopoietic (see Chap. 10); and are involved in coagulation, atherogenesis, wound healing, and tissue remodeling.

Mast cells (see Chap. 150) are specialized secretory cells that, in skin, are present in greatest density in the papillary dermis, near the DEJ, in sheaths of epidermal appendages, and around blood vessels and nerves of the subpapillary plexus. They are also common in the subcutaneous fat. Mast cells are identified histologically by a round or oval nucleus and abundant, darkly staining cytoplasmic granules. The surface of dermal mast cells is coated with fibronectin, which probably assists in securing cells within the connective tissue matrix. Mast cells can become hyperplastic and hyperproliferative in mastocytosis (see Chap. 150). Mast cells are secretory cells that are responsible for immediate-type hypersensitivity reaction in the skin and are involved in the production of subacute and chronic inflammatory disease. They synthesize secretory granules composed of histamine, heparin, tryptase, chymase, carboxypeptidase, neutrophil chemotactic factor, and eosinophilic chemotactic factor of anaphylaxis, which are mediators in these processes.

The dermal dendrocyte is a stellate, dendritic, or sometimes spindle-shaped, highly phagocytic fixed connective tissue cell in the dermis of normal skin. They are a subset of antigen-presenting macrophages or a distinct lineage that originates in the bone marrow. Similar to many other bone marrow-derived cells, dermal dendrocytes express factor XIIIa and CD45, and they lack typical markers of fibroblasts (e.g., Te-7). These cells are particularly abundant in the papillary dermis and upper reticular dermis, frequently in the proximity of vessels of the subpapillary plexus. Dermal dendrocytes function in the afferent limb of an immune response (see Chap. 10). They are also likely the cell of origin of a number of benign fibrotic proliferative conditions in the skin, such as dermatofibromas and fibroxanthomas (see Chap. 64).

CUTANEOUS VASCULATURE

Blood Vessels (See Chap. 163)

The blood vessels of the skin provide nutrition for the tissue, but in addition, they are involved in temperature and blood pressure regulation, wound repair, and numerous immunologic events.[67] The microcirculatory beds in skin progress from arterioles to precapillary sphincters. Extending from the sphincters are arterial and venous capillaries, which become postcapillary venules, and finally, collecting venules. When compared with vasculature of other organs, the vessels of skin are adapted to shearing forces, as they have thick walls supported by connective tissue and smooth muscle cells. Special cells, known as *veil cells*, surround the cutaneous microcirculation, defining a domain for the vessels within the dermis while remaining separate from the vessel walls.

The rich vascular network of the skin is located at boundaries within the dermis and supplies the epidermal appendages (see Fig. 163-2). The vessels that supply the dermis branch from musculocutaneous arteries that penetrate the subcutaneous fat and enter the deep reticular dermis. At this point, they are organized into a horizontal arteriolar plexus. From this plexus, ascending arterioles extend toward the epidermis. These arterioles contain two layers of smooth muscle cells, as well as pericytes, a second type of contractile cell of the vessel wall. At the junction between the papillary and reticular dermis, terminal arterioles form the subpapillary plexus. The arterioles at this level have only a single layer of smooth muscle cells, organized in a manner to suggest that they function as precapillary sphincters. Capillary loops then extend from the terminal arterioles of the plexus into the papillary dermis. At the apex of each capillary loop is the thinnest portion, in which both the endothelium and basal lamina of the vessels are attenuated, allowing for transport of material out of the capillary. The extrapapillary descending limbs of capillary loops are venous capillaries that drain into venous channels of the subpapillary plexus that lies above and below the arteriolar vascular plexus. The postcapillary venules of the subpapillary plexus are physiologically important components of the microcirculation. They are responsive to mediators such as histamine, developing gaps between adjacent endothelial cells that allow for the extravasation of fluid and cells, and are therefore often the sites of inflammatory cells during these responses.

Certain regions of the skin, such as the palms and soles, contain direct connections between arterial and venous circulation as potential shunts around congested capillary beds. These sites consist of an ascending arteriole (a glomus body), which is modified by three to six layers of smooth muscle cells and has associated sympathetic nerve fibers. The glomus can close completely when the blood pressure is below a critical level.

In the adult, the cutaneous vasculature normally remains quiescent, with the exception of certain hair cycle–dependent angiogenesis during anagen. Quiescence of vessels is in part due to inhibition of angiogenesis in the dermal matrix by factors such as thrombospondin. Pathogenic stimuli sometimes result in secondary angiogenesis, from tumors or during wounding. One of the key mediators of such angiogenesis is vascular endothelial growth factor (VEGF), often secreted by tumors or by keratinocytes (see Chap. 163).[68,69]

Numerous disorders can manifest themselves within the cutaneous vasculature. Leukocytoclastic vasculitis (cutaneous necrotizing venulitis) occurs within the venules in response to a number of potential pathogenic mechanisms (see Chap. 164). Stasis dermatitis,

urticaria, polyarteritis nodosa, thrombosis, and thrombophlebitis all affect vessels in the skin, of different sizes, some by occlusion of vessels (vasculopathy) and others by inflammation of the vessels (vasculitis).

Lymphatics

The lymph channels of the skin are important in regulating pressure of the interstitial fluid by resorption of fluid released from vessels and in clearing the tissues of cells, proteins, lipids, bacteria, and degraded substances.[70,71] The vessels begin in blind-ending initial lymphatics (also known as *lymphatic capillaries*, *prelymphatic tubules*, and *terminal* or *peripheral lymphatics*) in the papillary dermis. They drain into a horizontal plexus of larger lymph vessels located deep to the subpapillary venous plexus. A vertical system of lymphatics then carries fluid and debris through the reticular dermis to another deeper collecting plexus at the reticular dermis–hypodermis border.

Lymph flow within the skin depends on movements of the tissue caused by arterial pulsations and larger-scale muscle contractions and movement of the body, with backflow prevented by bicuspid-like valves within the vessels.

Although lymphatic vessels are only seen with difficulty on histologic section, because they are often collapsed in skin, they are composed of a large lumen and a thinner wall than blood vessels, with endothelium, discontinuous basal lamina, and elastic fibers. Molecular characterization of these vessels has identified Prox1, VEGFR-3, and LYVE-1 as specific markers of lymphatic character, and one of the most heavily-studied lymphangiogenic molecules is VEGF-C (see Chap. 163).

Certain pathologic conditions involve or highlight the lymphatic vessels, such as lymphedema, lymphangioma circumscriptum, and stasis dermatitis. The importance of lymphatics in the progression and spread of cancer is also becoming more clear, as melanoma cells destroy endothelial cells of the initial lymphatics to gain entry to the lymph circulation, and recent studies have shown that tumors themselves can promote lymphangiogenesis as part of their early program on the way to metastasis.[68] The discovery of the molecular defects in hereditary lymphedemas [type I Milroy disease VEGFR-3,[72–74] type II lymphedema praecox, lymphedema distichiasis, lymphedema and yellow nails, and lymphedema and ptosis MFH1 (forkhead transcription factor, FoxC2)[75]] has implicated the VEGFR-3 and FoxC2 in lymphatic development.

CUTANEOUS NERVES AND RECEPTORS

(See Chaps. 101 and 102) The nerve networks of the skin contain somatic sensory and sympathetic autonomic fibers.[76] The sensory fibers alone (free nerve endings) or in conjunction with specialized structures (corpuscular receptors) function as receptors of touch, pain, temperature, itch, and mechanical stimuli. The density and types of receptors are regionally variable, accounting for the variation in acuity at different sites of the body. Receptors are particularly dense in hairless areas such as the areola, labia, and glans penis. Sympathetic motor fibers are codistributed with the sensory nerves in the dermis until they branch to innervate the sweat glands, vascular smooth muscle, the arrector pili muscle of hair follicles, and sebaceous glands.

The nerves of skin branch from musculocutaneous nerves that arise segmentally from spinal nerves. The pattern of nerve fibers in skin is similar to the vascular patterns. That is, nerve fibers form a deep plexus, then ascend to a superficial, subpapillary plexus.

Free nerve endings include the penicillate and papillary nerve fibers and are the most widespread and important sensory receptors of the body. In humans, they are ensheathed by Schwann cells and a basal lamina. Free nerve endings are particularly common in the papillary dermis; the basal lamina of the fiber may merge with the lamina densa of the basement membrane zone.

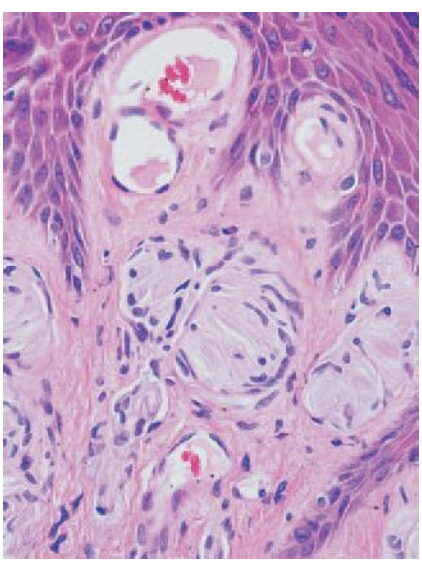
The penicillate fibers are the primary nerve fibers found sub-epidermally in haired skin. These are rapidly adapting receptors that function in the perception of touch, temperature, pain, and itch. Because of overlapping innervation, discrimination tends to be generalized in these regions. On the other hand, free nerve endings present in non-haired, ridged skin, such as the palms and soles, project individually without overlapping distribution. These receptors are thought to function in fine discrimination.

Papillary nerve endings are found at the orifice of a follicle. These branches from nerves that innervate the deeper levels of the follicle are thought to be particularly receptive to cold sensation. Hair follicles also contain other receptors, from myelinated stem axons in the deep dermal plexus, thought to be slow-adapting receptors that respond to the bending or movement of hairs. Cholinergic sympathetic fibers en route to the eccrine sweat gland and adrenergic and cholinergic fibers en route to the arrector pili muscle are carried along with the sensory fibers in the hair basket.

Free nerve endings are also associated with individual Merkel cells. Merkel cell–nerve complexes are described by a variety of names (*touch domes*, *hederiform endings*, *Iggo's capsule*, *Pinkus corpuscles*, *Haarscheibe*), depending on their composition and location. In haired skin, touch domes are associated with hair follicles. In palmoplantar skin, these complexes are found at the site where the eccrine sweat duct penetrates a glandular epidermal papilla.

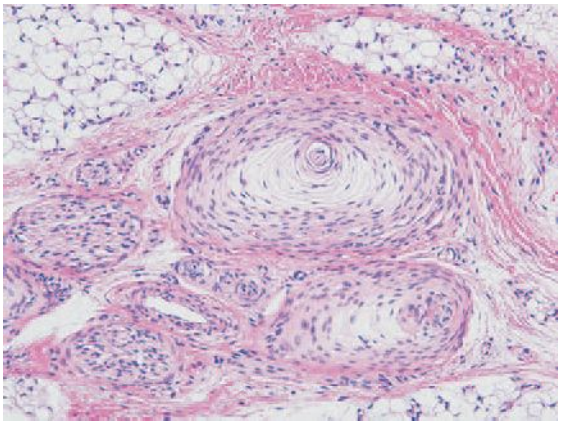
Corpuscular receptors, both Meissner's and Pacinian, contain a capsule and inner core and are composed of both neural and non-neural components. The capsule is a continuation of the perineurium, and the core includes the nerve fiber surrounded by lamellated wrappings of Schwann cells. Meissner's corpuscles are elongated or ovoid mechanoreceptors located in the dermal papillae of digital skin and oriented vertically toward the epidermal surface (Fig. 7-8). One to six axons enter the corpuscle, ramify extensively, and terminate in bulboid endings that are surrounded by lamellae.

The Pacinian corpuscle lies in the deep dermis and subcutaneous tissue of



▲ **FIGURE 7-8** Meissner's corpuscle. Note the capsule and inner core located in the dermal papillae. These collections of cells serve as mechanoreceptors. (Used with permission from O. Kovich, MD.)

skin that covers weight-bearing surfaces of the body. It has a characteristic capsule and lamellar wrappings (Fig. 7-9). The perineural capsule is organized into 30 or more concentric layers of cells and fibrous connective tissue. The middle subcapsular zone is composed of collagen and fibroblasts, and the inner core consists of Schwann cell-derived hemilamellae: flattened semicircles that alternate with those of the opposite side. Pacinian corpuscles serve as rapidly adapting mechanoreceptors that respond to vibrational stimuli.



◀ **FIGURE 7-9** Pacinian corpuscle. Note the characteristic perineural capsule, likened to the appearance of an "onion-skin." Pacinian corpuscles serve as rapidly adapting mechanoreceptors that respond to vibrational stimuli. (Used with permission from O. Kovich, MD.)

HYPODERMIS (SUBCUTIS)

The tissue of the hypodermis insulates the body, serves as a reserve energy supply, cushions and protects the skin, and allows for its mobility over underlying structures. It has a cosmetic effect in molding body contours. The boundary between the deep reticular dermis and the hypodermis is an abrupt transition from a predominantly fibrous dermal connective tissue to a primarily adipose subcutaneous one (see Fig. 6-1, Chap. 6). Despite this clear distinction anatomically, the two regions are still structurally and functionally integrated through networks of nerves and vessels and through the continuity of epidermal appendages. Actively growing hair follicles span the dermis and extend into the subcutaneous fat, and the apocrine and eccrine sweat glands are normally confined to this depth of the skin.

Adipocytes form the bulk of the cells in the hypodermis.[77,78] They are organized into lobules defined by septa of fibrous connective tissue. Nerves, vessels, and lymphatics are located within the septa and supply the region. The synthesis and storage of fat continues throughout life by enhanced accumulation of lipid within fat cells, proliferation of existing adipocytes, or by recruitment of new cells from undifferentiated mesenchyme. The hormone leptin, secreted by adipocytes, provides a long-term feedback signal regulating fat mass. Leptin levels are higher in subcutaneous than omental adipose, suggesting a role for leptin in control of adipose distribution as well.

The importance of the subcutaneous tissue is apparent in patients with Werner syndrome (see Chap. 139), in which subcutaneous fat is absent in lesion areas over bone, or with scleroderma (see Chap. 158), where the subcutaneous fat is replaced with dense fibrous connective tissue. Such regions in Werner patients ulcerate and heal poorly. The skin of patients with scleroderma is taut and painful. In the hereditary and acquired lipodystrophies, loss of subcutaneous fat disrupts glucose, triglyceride, and cholesterol regulation, and causes significant cosmetic alteration, increasing the interest in possible hormonal therapy for these disorders (see Chap. 69).[79] The subcutaneous tissue is involved in different inflammatory conditions, and these are discussed in Chap. 68.

DEVELOPMENT OF SKIN

Significant advances in the understanding of the molecular processes responsible for the development of the skin have been made over the last several years. Such advances increase the understanding of clinicopathologic correlation among some inherited disorders of the skin and allow for the early diagnosis of such diseases.[80,81] The developmental progression of various components of the skin is well documented, and a time line indicating the events that occur during embryonic and fetal development is provided (Table 7-4).[82,83] Of note, the estimated gestational age (EGA) is used throughout this chapter; this system refers to the age of the fetus, with fertilization occurring on day 1. To avoid confusion, it should be pointed out that obstetricians and most clinicians define day 1 as the first day of the last menstrual period (menstrual age), in which fertilization occurs on approximately day 14. Thus, the two dating systems differ by approximately 2 weeks, such that a woman who is 14 weeks pregnant (menstrual age) is carrying a 12-week-old fetus (EGA).

Conceptually, fetal skin development can be divided into three distinct but temporally overlapping stages, those of specification, morphogenesis, and differentiation. These stages roughly correspond to the embryonic period (0 to 60 days), the early fetal period (2 to 5 months), and the late fetal period (5 to 9 months) of development. The earliest stage, specification, refers to the process by which the ectoderm lateral to the neural plate is committed to become epidermis, and subsets of mesenchymal and neural crest cells are committed to form the dermis. It is at this time that patterning of the future layers and specialized structures of the skin occurs, often via a combination of gradients of

proteins and cell–cell signals. The second stage, morphogenesis, is the process by which these committed tissues begin to form their specialized structures, including epidermal stratification, epidermal appendage formation, subdivision between the dermis and subcutis, and vascular formation. The last stage, differentiation, denotes the process by which these newly specialized tissues further develop and assume their mature forms. Table 7-5 integrates specification, morphogenesis, and differentiation with skin morphology and genetic diseases.

For simplification and greater clarity, the stages of development of the epidermis—dermis and hypodermis, dermal–epidermal junction, and epidermal appendages—are presented sequentially.

Epidermis

EMBRYONIC DEVELOPMENT During the third week after fertilization, the human embryo undergoes gastrulation, a complex process of involution and cell redistribution that results in the formation of the three primary embryonic germ layers: ectoderm, mesoderm, and endoderm. Shortly after gastrulation, ectoderm further subdivides into neuroectoderm and presumptive epidermis. The specification of the presumptive epidermis is believed to be mediated by the bone morphogenetic proteins (BMPs). Later during this period, BMPs again appear to play a critical role, along with Engrailed-1 (En1), in specifying the volar versus interfollicular skin.[84–86] By 6 weeks EGA, the ectoderm that covers the body consists of basal cells and superficial periderm cells.

The basal cells of the embryonic epidermis differ from those of later developmental stages. Embryonic basal cells are more columnar than fetal basal cells, and they have not yet formed hemidesmosomes. Although certain integrins (e.g., $\alpha 6\beta 4$) are expressed in these cells, they are not yet localized to the basal pole of the cells. Before the formation of hemidesmosomes and desmosomes, intercellular attachment between individual basal cells appears to be mediated by adhesion molecules such as E- and P-cadherin, which have been detected on basal cells as early as 6 weeks EGA. Keratins K5 and K14, proteins restricted to definitive stratified epithelia, are expressed even at these early stages of epidermal formation.

At this stage, periderm cells form a "pavement epithelium." These cells are

AEC = ankyloblepharon-ectodermal dysplasia-clefting; BCIE = bullous congenital ichthyosiform erythroderma; BMPs = bone morphogenetic proteins; BPAG = bullous pemphigoid antigen; EB = epidermolysis bullosa; EEC = ectrodactyly-ectodermal dysplasia-clefting; GABEB = generalized atrophic benign epidermolysis bullosa; HHT = hereditary hemorrhagic telangiectasia; K = keratin; KID = keratitis-ichthyosis-deafness; MD = multiple dystrophy; NCIE = non-bullous congenital ichthyosiform erythroderma; NGFR = nerve growth factor receptor; PA = pyloric atresia; PXE = pseudoxanthoma elasticum.
Protein names are indicated in **boldface**. Associated diseases/genodermatoses are listed in parentheses. Multiple names for the same protein or syndrome are separated by /. Genes and associated diseases can be found in Online Mendelian Inheritance in Man (OMIM) at http://www.ncbi.nlm.nih.gov/omim.

embryonic epidermal cells that are larger and flatter than the underlying basal cells. Apical surfaces contact the amniotic fluid and are studded with microvilli. Connections between periderm cells are sealed with tight junctions rather than desmosomes. By the end of the second trimester, these cells are sloughed and eventually form part of the vernix caseosa. Like stratified epithelial cells, periderm cells express K5 and K14, but they also express simple epithelial keratins K8, K18, and K19.

Aplasia cutis (see Chap. 106) may reflect focal defects in either epidermal specification or development caused by somatic mosaicism, or mutations that occur postzygotically. The molecular defect for this disorder is not known, however. The fact that few genetic diseases have been described in which epidermal specification or morphogenesis are defective likely reflects the fact that such defects would be incompatible with survival.

EARLY FETAL DEVELOPMENT (MORPHOGENESIS) By the end of 8 weeks of gestation, hematopoiesis has switched from the extraembryonic yolk sac to the bone marrow, the classical division between embryonic and fetal development. By this time, the epidermis begins its stratification and formation of an intermediate layer between the two pre-existing cell layers. The cells in this new layer are similar to the cells of the spinous layer in mature epidermis. Like spinous cells, they express keratins K1/K10 and the desmosomal protein desmoglein-3. The cells are still highly proliferative and, during this period of development, they evolve into a multilayer structure that will eventually replace the degenerating periderm.

Expression of the p63 gene plays a critical role in the proliferation and maintenance of the basal layer cells. Epidermal stratification does not occur in mice deficient for p63.[87–89] In humans, although no null mutations have been isolated, partial loss of p63 function mutations have been identified in ankyloblepharon, ectodermal dysplasia, and cleft lip/palate syndrome (Hay-Wells syndrome) as well as ectrodactyly, ectodermal dysplasia, and cleft lip/palate syndrome (see Chap. 143).[90–92] The pre-existing basal cell layer also undergoes morphologic changes at this time, becoming more cuboidal and expressing new keratin genes, K6, K8, K19, and K6/K16, that are usually expressed in hyperproliferative tissues. The basal layer also begins to elaborate proteins that will ultimately anchor them to the developing basal lamina (see Dermal-Epidermal Junction), including hemidesmosomal proteins BPAG1, BPAG2, and collagens V and VII (see Chaps. 51, 54, and 60).

Embryonic lines of ectodermal formation are revealed in mosaic disorders that follow the lines of Blaschko, including congenital, nevoid, and acquired conditions.[93–95] Molecular demonstration of genetic mosaicism has been reported for a number of X-linked disorders (reviewed in ref. 94), as well as epidermal nevi in epidermolytic hyperkeratosis.[96]

LATE FETAL DEVELOPMENT (DIFFERENTIATION) Late fetal development reveals the further specialization and differentiation of keratinocytes in the epidermis. It is at this time that the granular and stratum corneal layers are formed, and the rudimentary periderm is sloughed. Keratinization of the surface epidermis is a process of keratinocyte terminal differentiation which begins at 15 weeks EGA. The granular layer becomes prominent, and important structural proteins are elaborated in the basal layer cells. The hemidesmosomal proteins plectin and $\alpha 6\beta 4$ integrin are expressed and correctly localized at this time. Mutations in these genes result in various bullous genodermatoses (reviewed in Chap. 60). The more superficial cells undergo further terminal differentiation, and the keratin-aggregating protein filaggrin is expressed at this time.

The formation of the cornified envelope is a late feature of differentiating keratinocytes, and it relies on a number of different modifications to create an impermeable barrier. Enzymes such as transglutaminase, LEKTI (encoded by the gene SPINK-5), phytanoyl coenzyme A reductase, fatty aldehyde dehydrogenase, and steroid sulfatase are all important in the elaboration of the cornified envelope and mature lipid barrier, and defects in these enzymes can lead to abnormal epidermal barrier formation (see Chap. 47).

SPECIALIZED CELLS WITHIN THE EPIDERMIS The three major nonepidermal cell types—melanocytes, Langerhans cells, and Merkel cells—can be detected within the epidermis by the end of the embryonic period. Melanocytes are derived from the neural crest, a subset of neuroectoderm cells. Pigment mosaicism (formerly called *hypomelanosis of Ito* and *linear and whorled hypermelanosis*) (see Chap. 73) following the lines of Blaschko may reflect the migratory paths of melanoblasts, or alternatively, mosaic defects in pigment transfer from melanocytes to keratinocytes. The founders of each melanoblast clone originate at distinct points along the dorsal midline, traversing ventrally and distally to take up residence in the epidermis.

Melanocytes are first seen within the epidermis at 50 days EGA. Melanocytes express integrin receptors in vivo and in vitro and may use these to migrate to the epidermis during embryonic development. Migration, colonization, proliferation, and survival of melanocytes in developing skin depend on the cell surface tyrosine kinase receptor, *c-kit*, and its ligand, stem cell factor.[97,98] Melanin becomes detectable between 3 and 4 months EGA, and by 5 months, melanosomes begin to transfer pigment to keratinocytes. Many genetic disorders of pigmentation have been characterized and are presented in detail in Chaps. 71, 73, and 144. In the adult, a pool of melanocyte precursor cells resides in the upper permanent portion of the hair follicle, capable of producing mature melanocytes.[97,99,100]

Langerhans cells, another immigrant population, are detectable by 40 days EGA. They begin to express CD1 on their surface and to produce their characteristic Birbeck granules by the embryonic–fetal transition. By the third trimester, most of the adult numbers of Langerhans cells will have been produced.

Merkel cells, as described earlier in the chapter (see Nonkeratinocytes of the Epidermis), reside in the epidermis. They are first detectable in the volar epidermis of the 11- to 12-week EGA human fetus. The embryonic derivation of this population of cells is controversial. Evidence for in situ differentiation of Merkel cells from epidermal ectoderm versus immigration of Merkel cells from neural crest is supported by studies in which 8- and 11-week EGA fetal volar skin that lacked Merkel cells was transplanted to the nude mouse. Tissue harvested 8 weeks later contained an abundance of human K18-positive Merkel cells within the epidermis, suggesting that the cells differentiated within the grafted tissue.[101] On the other hand, more recent lineage tracing studies using a neural-crest specific label have suggested that Merkel cells indeed have a neural crest origin.[51]

Dermal and Subcutaneous Development

The origin of the dermis and subcutaneous tissue is more diverse than that of

the epidermis, which is exclusively ectodermally derived. The embryonic tissue that forms the dermis depends on the specific body site.[102,103] Dermal mesenchyme of the face and anterior scalp is derived from neural crest ectoderm. The limb and ventral body wall mesenchyme is derived from the lateral plate mesoderm. The dorsal body wall mesenchyme derives from the dermomyotomes of the embryonic somite. LIM homeobox transcription factor 1 beta (Lmx1B) and Wnt7a are important in the specification of the dorsal limb.[104–106] En1 and BMPs, on the other hand, specify the volar (ventral) limb mesenchyme (see Table 7-5).[88,105]

The embryonic dermis, in contrast to the mature dermis, is cellular and amorphous, with few organized fibers. The mature dermis contains a complex mesh of collagen and elastic fibers embedded in a matrix of PGs, whereas the embryonic mesenchyme contains a large variety of pluripotent cells in a hydrated gel that is rich in hyaluronic acid. These mesenchymal cells are thought to be the progenitors of cartilage-producing cells, adipose tissue, dermal fibroblasts, and intramembranous bone. Dermal fibers exist as fine filaments but not thick fibers. The protein components of the future elastin and collagen fibers are synthesized during this period but not assembled. At this point, there is no obvious separation between cells that will become musculoskeletal elements and those that will give rise to the skin dermis.

Although there is no known inherited disorder of dermal development, certain conditions, such focal dermal hypoplasia (Goltz syndrome) and Proteus syndrome, exhibit focal defects, probably a result of genetic mosaicism affecting genes important in this process (see Chap. 139). Mutations causing a global defect in this process would likely be incompatible with life.

The superficial mesenchyme becomes distinct from the underlying tissue by the embryonic–fetal transition (about 60 days EGA). By 12 to 15 weeks, the reticular dermis begins to take on its characteristic fibrillar appearance in contrast to the papillary dermis, which is more finely woven. Large collagen fibers continue to accumulate in the reticular dermis, as well as elastin fibers, beginning around mid-gestation and continuing until birth. By the end of the second trimester, the dermis has changed from a non-scarring tissue to one that is capable of forming scars. As the dermis matures, it also becomes thicker and well organized, such that at birth, it resembles the dermis of the adult, although it is still more cellular.

Many well-known clinical syndromes and molecules have been discovered that affect this final stage of dermal differentiation. These diseases include dystrophic EB (a collagen VII defect) (see Chap. 60), Marfan syndrome (a defect in fibrillin), Ehlers-Danlos syndrome (collagen V), cutis laxa (elastin), PXE, hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome), and osteogenesis imperfecta (see Chap. 139). In many of these cases, the specific genetic defect helps to define the many different manifestations of these diseases, although in certain cases (e.g., PXE), the identity of the gene does not readily explain the mechanism of disease (see Chap. 139).

SPECIALIZED COMPONENTS OF THE DERMIS ***Blood Vessels and Nerves.*** Cutaneous nerves and vessels begin to form early during gestation, but they do not evolve into those of the adult until a few months after birth. The process of vasculogenesis requires the in situ differentiation of the endothelial cells at the endoderm–mesoderm interface. Originally, horizontal plexuses are formed within the subpapillary and deep reticular dermis, which are interconnected by groups of vertical vessels. This lattice of vessels is in place by 45 to 50 days EGA.

At 9 weeks EGA, blood vessels are seen at the dermal–hypodermal junction. By 3 months, the distinct networks of horizontal and vertical vessels have formed. By the fifth month, further changes in the vasculature derive from budding and migration of endothelium from pre-existing vessels, the process of angiogenesis. Depending on the body region, gestational age, and presence of hair follicles and glands, this pattern can vary with blood supply requirements.

Defects in vascular development have been described, as in the Klippel-Trénaunay and Sturge-Weber syndromes (see Chap. 173). In the Klippel-Trénaunay syndrome, unilateral cutaneous vascular malformations develop, with associated venous varicosities, edema, and hypertrophy of associated soft tissue and bone. In Sturge-Weber syndrome, many cutaneous capillary malformations are seen in the lips, tongue, nasal, and buccal mucosae. Some familial defects in vascular formation result from mutations in the gene encoding Tie-2 receptor tyrosine kinase. Capillary malformations seen in hereditary hemorrhagic telangiectasia have been linked to mutations in transforming growth factor-β–binding proteins, endoglin, and activin receptor-like kinase 1.

Lymphatics. Accumulating evidence suggests that lymphatics originate from endothelial cells that bud off from veins. The pattern of embryonic lymphatic vessel development parallels that of blood vessels. Detailed molecular studies into the development of lymphatics during embryogenesis and fetal development have long been hampered by the lack of lymphatic-specific markers. However, recent studies have identified new genes that appear to be specific for some of the earliest lymphatic precursors. LYVE-1 and Prox-1 are genes considered to be critical for earliest lymphatic specification, whereas VEGF-R3 and SLC may be important in later lymphatic differentiation.[107]

Nerves. The development of cutaneous nerves parallels that of the vascular system in terms of patterning, maturation, and organization. Nerves of the skin consist of somatic sensory and sympathetic autonomic fibers, which are predominantly small and unmyelinated. As these nerves develop, they become myelinated, with associated decrease in the number of axons. This process may continue as long as puberty.

Subcutis

As mentioned in Specialized Components of the Dermis, by 50 to 60 days EGA, the hypodermis is separated from the overlying dermis by a plane of thin-walled vessels. Toward the end of the first trimester, the matrix of the hypodermis can be distinguished from the more fibrous matrix of the dermis. By the second trimester, adipocyte precursors begin to differentiate and accumulate lipids. By the third trimester, fat lobules and fibrous septae are found to separate the mature adipocytes. The molecular pathways that define this process are currently an area of intense investigation. Although few regulators important in embryonic adipose specification and development have been identified, several factors critical for preadipocyte differentiation have been demonstrated, including leptin, a hormone important in fat regulation, and the peroxisome proliferator–activated receptor family of transcription factors.[77,108]

Dermal–Epidermal Junction

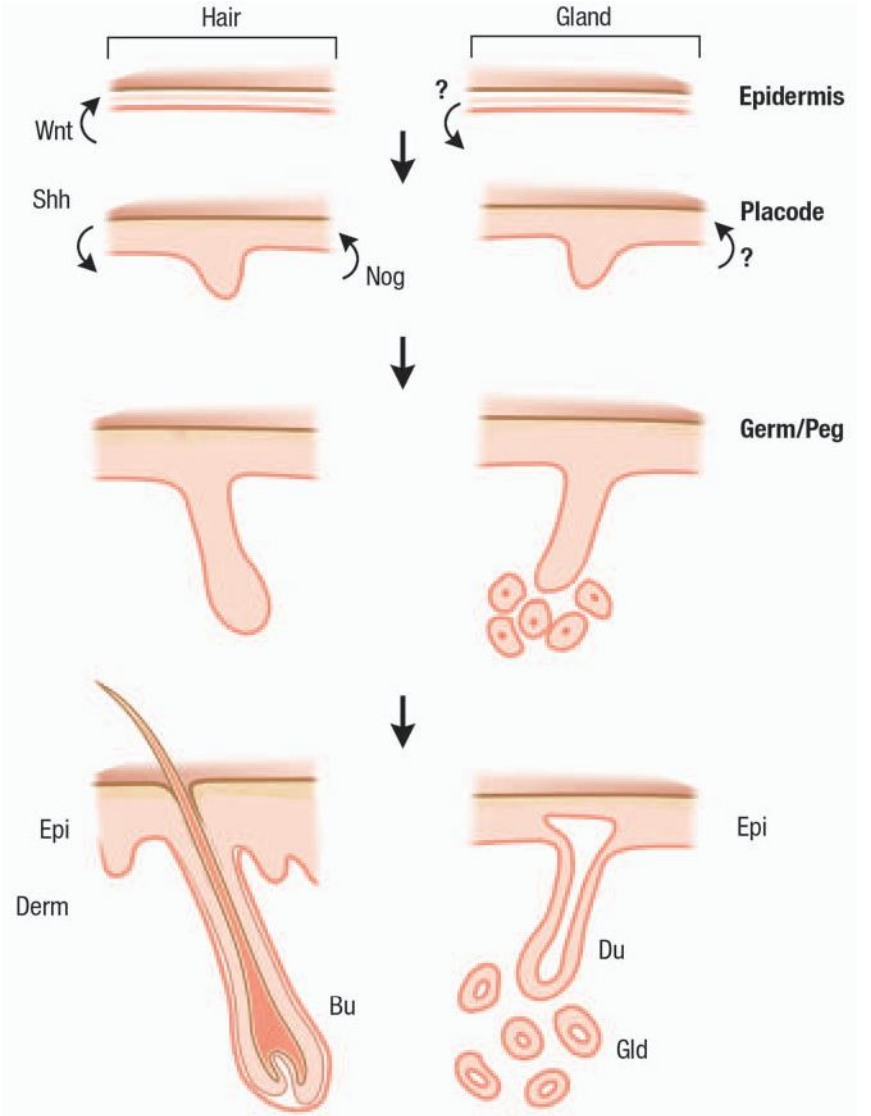
The dermal–epidermal junction is an interface where many inductive interactions occur that result in the specification or differentiation of the characteristics of the dermis and epidermis. This zone includes specialized basement membrane, basal cell extracellular matrix, the basalmost portion of the basal cells, and the superficial-most fibrillar structures of the papillary dermis. Both the epidermis and dermis contribute to this region.

As early as 8 weeks EGA, a simple basement membrane separates the dermis from the epidermis and contains many of the major protein elements common to all basement membranes, including laminin 1, collagen IV, heparin sulfate, and PGs. Components specific to the cutaneous basement membrane zone, such as proteins of the hemidesmosome and anchoring filaments, are first detected at the embryonic–fetal transition. By the end of the first trimester, or around the time of late embryonic development, all basement membrane proteins are in place. The α6 and β4 integrin subunits are expressed earlier than most of the other basement membrane components. However, they are not localized to the basal surface until 9.5 weeks EGA, coincident with the time that the hemidesmosomal proteins are expressed and hemidesmosomes are first observed. At the same time, anchoring filaments (laminin-332) and anchoring fibrils (collagen VII) begin to be assembled. The actual synthesis of collagen VII can be detected slightly earlier, at 8 weeks EGA.

Many congenital blistering disorders have been demonstrated to be a result of defects in proteins of the DEJ (for details, see Chaps. 51 and 60). The severity of the disease, plane of tissue separation, and involvement of non-cutaneous tissues depend on the proteins involved and the specific mutations. These genes are important candidates for prenatal testing.

DEVELOPMENT OF SKIN APPENDAGES

Skin appendages, which include hair, nails, and sweat and mammary glands, are composed of two distinct components: an epidermal portion, which produces the differentiated product, and the dermal component, which regulates differentiation of the appendage. During embryonic development, dermal–epidermal interactions are critical for the induction and differentiation of these structures (Fig. 7-10). Disruption of these signals often has profound influences on development of skin appendages. This discussion focuses on hair differentiation as a paradigm for appendageal development, because it is the appendage that has been studied most intensely.[6,109,110]



▲ **FIGURE 7-10** Appendageal morphogenesis. Through a series of reciprocal epithelial (epidermal)–mesenchymal (dermal) signals, including Wnt, sonic hedgehog (Shh), and Noggin (Nog), appendages such as the hair follicle and eccrine gland begin as epidermal invaginations (placodes), which signal the organization of specialized dermis (dermal condensate). This dermal condensate subsequently signals the differentiation of the epidermal downgrowth into the germ, peg, and mature appendageal structure. Bu = bulge; Derm = dermis; Du = duct; Epi = epidermis; Gld = gland.

Hair (See Chap. 84)

Dermal signals are initially responsible for instructing the basal cells of the epidermis to begin to crowd at regularly spaced intervals, starting between days 75 and 80 on the scalp. This initial grouping is known as the *follicular placode* or *Anlage*. Based on molecular localization of β-catenin, it has been implicated as a candidate for one of the effectors of this "dermal signal."

From the scalp, follicular placode formation spreads ventrally and caudally, eventually covering the skin. The placodes then signal back to the underlying dermis to form a "dermal condensate," which occurs at 12 to 14 weeks EGA. This process is thought to be a balance of placode promoters and placode inhibitors.[6,109,110] Wnt family signaling molecules are proposed to mediate placode promoting effects via the molecules LEF and β-catenin, as well as fibroblast growth factor, transforming growth factor-α, Msx1 and -2, ectodysplasin A (EDA), and EDAR (EDA receptor). BMP family molecules, on the other hand, act

as inhibitors of follicle formation. In model systems, ectopic expression of this family of molecules tends to suppress the formation of follicles. In mice, EDAR and β-catenin expression are required for expression of BMP4 and Sonic hedgehog (Shh), implicating these molecules in early follicular morphogenesis. Furthermore, EDAR may be important for lateral inhibition of cells surrounding the follicles.

Formation of the dermal papilla is thought to be initiated by the "first epithelial signal" that is transmitted from the follicle epithelium to the underlying mesenchyme. Molecules proposed to be involved in this signaling process include platelet-derived growth factor α polypeptide and Shh. After the follicular differentiation process begins, the dermis sends another signal to the epithelial placode cells to proliferate and invade the dermis. The dermal cells associated with the follicle then develop into the dermal papilla. The epithelial cells go on to form the inner root sheath and hair shaft of the mature hair follicle.

In addition to the widened bulge at the base, two other bulges form along the length of the developing follicle, termed the *bulbous hair peg*. The uppermost bulge is the presumptive sebaceous gland, whereas the middle bulge serves as the site for insertion of the arrector pili muscle. This middle bulge is also the location of the multipotent hair stem cells, which are capable of differentiating into any of the cells of the hair follicle, and also have the potential to replenish the entire epidermis, as has seen in cases of extensive surface wounds or burns.

By 19 to 21 weeks EGA, the hair canal has completely formed and the hairs on the scalp are visible above the surface of the fetal epidermis. They continue to lengthen until 24 to 28 weeks, at which time they shift from the active growth (anagen) phase to the degenerative phase (catagen), then to the resting phase (telogen) (see Chap. 84). This completes the first hair cycle. With subsequent hair cycles, hairs increase in diameter and coarseness. During adolescence, vellus hairs of androgen-sensitive areas mature to terminal-type hair follicles.

Sebaceous Glands (See Chap. 77)

Sebaceous glands mature during the course of follicular differentiation. This process begins between 13 and 16 weeks EGA, at which point the presumptive sebaceous gland is first visible as the most superficial bulge of the maturing hair follicle. The outer proliferative cells of the gland give rise to the differentiated cells that accumulate lipid and sebum. After they terminally differentiate, these cells disintegrate and release their products into the upper portion of the hair canal. Sebum production is accelerated in the second and third trimesters, during which time maternal steroids cause stimulation of the sebaceous glands. Hormonal activity is once again thought to influence the production of increased sebum during adolescence, resulting in the increased incidence in acne at this age.

Nail Development (See Chap. 87)

Presumptive nail structures begin to appear on the dorsal digit tip at 8 to 10 weeks EGA, slightly earlier than the initiation of hair follicle development. The first sign is the delineation of the flat surface of the future nail bed. A portion of ectoderm buds inward at the proximal boundary of the early nail field, and gives rise to the proximal nail fold. The presumptive nail matrix cells, which differentiate to become the nail plate, are present on the ventral side of the proximal invagination. At 11 weeks, the dorsal nail bed surface begins to keratinize. By the fourth month of gestation, the nail plate grows out from the proximal nail fold, completely covering the nail bed by the fifth month. Mutations in p63 affect nail development in syndromes such as ankyloblepharon, ectodermal dysplasia, and cleft lip/palate syndrome, as well as ectrodactyly, ectodermal dysplasia, and cleft lip/palate syndrome. Functional p63 is required for the formation and maintenance of the apical ectodermal ridge, an embryonic signaling center essential for limb outgrowth and hand plate formation. Wnt7a is thought to be important for dorsal limb patterning, and thus nail formation. In contrast to follicular development, Shh is not required for nail plate formation. Also similar to follicular differentiation, LMX1b and MSX1 are important for nail specification; LMX1b and MSX1 are mutated in nail-patella syndrome and Witkop syndrome, respectively.[111–113] Hoxc13 appears to be an important homeodomain-containing gene for both follicular and nail appendages, at least in murine models.[114]

Eccrine and Apocrine Sweat Gland Development (See Chap. 81)

Eccrine glands begin to develop on the volar surfaces of the hands and feet, beginning as mesenchymal pads between 55 and 65 days EGA. By 12 to 14 weeks EGA, parallel ectodermal ridges are induced, which overly these pads. The eccrine glands arise from the ectodermal ridge. By 16 weeks EGA, the secretory portion of the gland becomes detectable. The dermal duct begins around week 16, but the epidermal portion of the duct and opening are not complete until 2 weeks EGA.

Interfollicular eccrine and apocrine glands, in contrast, do not begin to bud until the fifth month of gestation. Apocrine sweat glands usually bud from the upper portion of the hair follicle. By 7 months EGA, the cells of the apocrine glands become distinguishable.

Although not much is known with regard to the molecular signals responsible for the differentiation of these structures, the EDA, EDAR, En1, and Wnt10b genes have been implicated. Hypohidrotic ectodermal dysplasia results from mutations in EDA or the EDAR (see Chap. 143).

CHAPTER 8

Genetics in Relation to the Skin

John A. McGrath
W. H. Irwin McLean

THE HUMAN GENOME IN DERMATOLOGY

In the 30 years since the first human gene, placental lactogen, was cloned in 1977, huge investments in time, money, and effort have gone into disclosing the innermost workings of the human genome. The Human Genome Project, which began in 1990, has led to sequence information on more than 3 billion base pairs (bp) of DNA, with identification of most of the estimated 25,000 genes in the entire human genome.[1] Although a few relatively small gaps remain, the near completion of the entire sequence of the human genome is having a huge impact on both the clinical practice of genetics and on the strategies used to identify disease-associated genes. Laborious positional cloning approaches and traditional functional studies are gradually being transformed by the emergence of new genomic and proteomic databases.[2] Some of the exciting challenges that clinicians and geneticists now face are determining the function of these genes and defining disease associations, and, with relevance to patients, correlating genotype with phenotype. Nevertheless, many discoveries are already influencing how clinical genetics is practiced throughout the world, particularly for patients and families with rare, monogenic inherited disorders. The key benefits of dissection of the genome thus far have been the documentation of new information about disease causation, improving the accuracy of diagnosis and genetic counseling, and making DNA-based prenatal testing feasible.[3] Indeed, the genetic basis of more than 2000 inherited single gene disorders has now been determined, of which about 25 percent have a skin phenotype. These discoveries, therefore, have direct relevance to dermatologists and their patients. Recently, studies in rare inherited skin disorders have also led to new insight into the pathophysiology of more common complex trait skin disorders.[4] This new information is expected to have significant implications for the development of new therapies and management strategies for patients. For the dermatologist, therefore, understanding the basic language and principles of clinical and molecular genetics has become a vital part of day-to-day practice. The aim of this chapter is to provide an overview of key terminology in genetics that is clinically relevant to the dermatologist.

THE HUMAN GENOME

Normal human beings have a large complex genome packaged in the form of 46 chromosomes. These consist of 22 pairs of autosomes, numbered in descending order of size from the largest (chromosome 1) to the smallest (chromosome 22), in addition to two sex chromosomes, X and Y. Females possess two copies of the X chromosome, whereas males carry one X and one Y chromosome. The haploid genome consists of about 3.3 billion bp of DNA. Of this, only about 1.5 percent corresponds to protein-encoding exons of genes. Apart from genes and regulatory sequences, perhaps as much as 97 percent of the genome is of unknown function, often referred to as "junk" DNA. Caution should be exercised in labeling the non-coding genome as "junk," however, because other unknown functions may reside in these regions. Much of the non-coding DNA is in the form of repetitive sequences, pseudogenes ("dead" copies of genes lost in recent evolution) and transposable elements of uncertain relevance. Although initial estimates for the number of human genes was in the order of 100,000, current predictions, based on the essentially complete genome sequence, are in the range of 20,000 to 25,000.[1] Surprisingly, therefore, the human genome is comparable in size and complexity to primitive organisms such as the fruit fly. It is thought, however, that the generation of multiple protein isoforms from a single gene via alternate splicing of exons, each with a discrete function, is what contributes to increased complexity in higher organisms, including humans. In addition to protein-encoding genes, there are also many genes encoding untranslated RNA molecules, including transfer RNA, ribosomal RNA, and, as recently described, micro-RNA genes. Micro-RNA is thought to be involved in the control of a large number of other genes through the RNA inhibition pathway.

The draft sequence of the human genome was completed in 2003. Subsequently, small gaps have been filled, and the sequence has now been extensively annotated in terms of genes, repetitive elements, regulatory sequences, polymorphisms, and many other features recognizable by in silico data mining methods informed, wherever possible, by functional analysis. This annotation process will continue for some time as more features are uncovered. The human genome data, and that for an increasing number of other species, is freely available on websites (Table 8-1). Some regions of the genome, particularly near the centromeres, consist of long stretches of highly repetitive sequences that are difficult or impossible to clone and/or sequence. These heterochromatic regions of the genome are unlikely to be sequenced and are thought to be structural in nature, mediating the chromosomal architecture required for cell division, rather than contributing to heritable characteristics.

GENETIC AND GENOMIC DATABASES

Given the size and complexity of the human genome and other genomes now available, analysis of these enormous datasets in any kind of meaningful way is heavily reliant on computers. Even storage and retrieval of the sequence data associated with mammalian genome require considerable computer power, and memory and even the assembly of the raw sequence of any mammalian genome would have been unfeasible without computers. Many

Online Mendelian Inheritance in Man	http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=omim

web browsers for accessing genome data are available and the most useful of these are listed in Table 8-1. Each of these interfaces, which are the ones which the authors find most useful and user-friendly, contains a wide variety of tools for analysis and searching of sequences according to keyword, gene name, protein name, and homology to DNA or protein sequence data.

The main source of historical, clinical, molecular, and biochemical data relating to human genetic diseases is the Online Mendelian Inheritance in Man (OMIM) (see Table 8-1). All recognized genetic diseases and non-pathogenic heritable traits, including common diseases with a genetic component, as well as all known genes and proteins, are listed and reviewed by OMIM number with links to PubMed.

CHROMOSOME AND GENE STRUCTURE

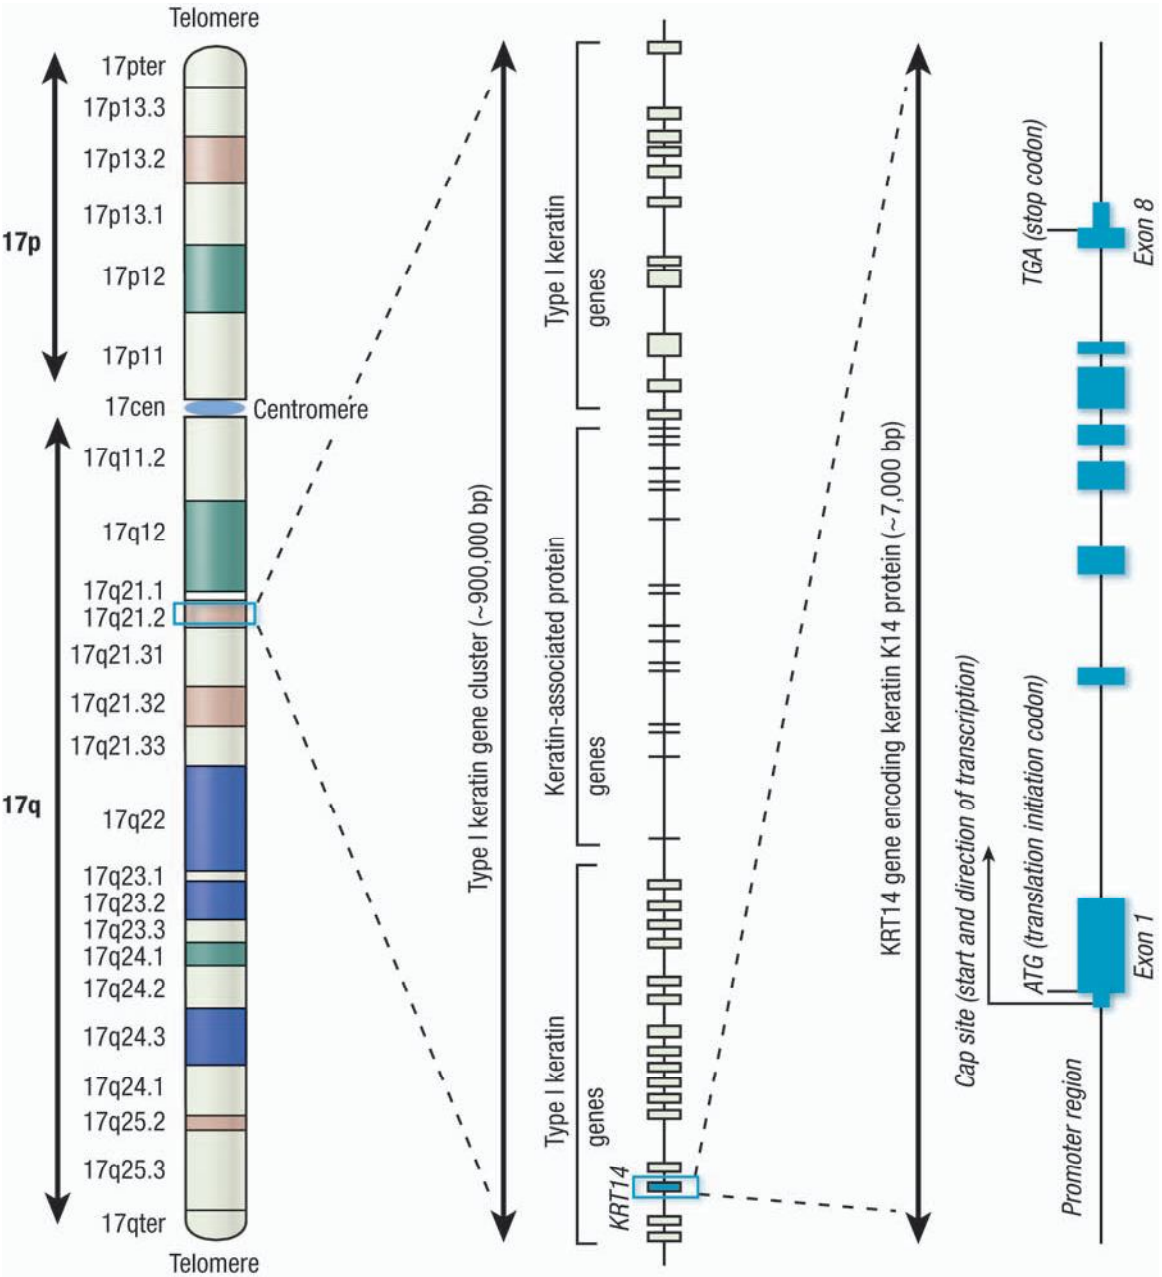
Human chromosomes share common structural features (Fig. 8-1). All consist of two chromosomal arms, designated as "p" and "q." If the arms are of unequal length, the short arm is always designated as the "p" arm. Chromosomal maps to seek abnormalities are based on the stained, banded appearance of condensed chromosomes during metaphase of mitosis. During interphase, the uncondensed chromosomes are not discernible by normal microscopy techniques. Genes can now be located with absolute precision in terms of the range of bp that they span within the DNA sequence for a given chromosome. The bands are numbered from the centromere outwards using a system that has evolved as increasingly discriminating chromosome stains, as well as higher resolution light microscopes, became available. A typical cytogenetic chromosome band is 17q21.2, within which the type I keratin genes reside (see Fig. 8-1).

The ends of the chromosomal arms are known as *telomeres*, and these consist of multiple tandem repeats of short DNA sequences. In germ cells and certain other cellular contexts, additional repeats are added to telomeres by a protein-RNA enzyme complex known as *telomerase*. During each round of cell division in somatic cells, one of the telomere repeats is trimmed off as a consequence of the DNA replication mechanism. By measuring the length of telomeres, the "age" of somatic cells, in terms of the number of times they have divided during the lifetime of the organism, can be determined. Once the telomere length falls below a certain threshold, the cell undergoes senescence. Thus, telomeres contribute to an important biological clock function that removes somatic cells that have gone through too many rounds of replication and are at a high risk of accumulating mutations that could lead to tumorigenesis or other functional aberration.[5]

The chromosome arms are separated by the centromere, which is a large stretch of highly repetitious DNA sequence. The centromere has important functions in terms of the movement and interactions of chromosomes. The centromeres of sister chromatids are where the double chromosomes align and attach during the prophase and anaphase stages of mitosis (and meiosis). The centromeres of sister chromatids are also the site of kinetochore formation. The latter is a multi-protein complex to which microtubules attach, allowing mitotic spindle formation, which ultimately results in pulling apart of the chromatids during anaphase of the cell division cycle.

The majority of chromosomal DNA contains genes interspersed with non-coding stretches of DNA of varying sizes. The density of genes varies widely across the chromosomes so that there are gene-dense regions or, alternately, large areas almost devoid of functional genes. An example of a comparatively gene-rich region of particular relevance to inherited skin diseases is the type I keratin gene cluster on chromosome band 17q21.2 (see Fig. 8-1). This diagram also gives an idea of the sizes in bp of DNA of a typical chromosome and a typical gene located within it. This gene cluster spans about 900,000 bp of DNA and contains 27 functional type I keratin genes, several genes encoding keratin-associated proteins, and a number of pseudogenes (not shown). Because chromosome 17 is one of the smaller chromosomes, Fig. 8-1 starts to give some idea of the overall complexity and organization of the genome.

Protein-encoding genes normally consist of several exons, which collectively code for the amino acid sequence of the protein (or open reading frame). These are separated by non-coding introns. In human genes, few exons are much greater than 1000 bp in size, and introns vary from less than 100 bp up to more than 1 million bp. A typical exon might be 100 to 300 bp in size. The *KRT14* gene encoding keratin 14 or K14 protein is one of the genes in which mutations lead to epidermolysis bullosa (EB) simplex (see Chap. 60) and is illustrated in Fig. 8-1. *KRT14* is contained within about 7000 bp of DNA and consists of eight modestly sized exons interspersed by seven small introns. Although all genes are present in all human cells that contain a nucleus, not every gene is expressed in all cells of tissues. For example, the *KRT14* gene is only active in basal keratinocytes of the epidermis and other stratified epithelial tissues and is essentially silent in all other tissues. When a protein-encoding gene is expressed, the RNA polymerase II enzyme transcribes the coding strand of the gene, starting from the cap site and continuing to the end of the final exon, where various signals lead to termination of transcription. The initial RNA transcript, known as *heteronuclear RNA*, contains intronic as well as exonic sequences. This primary transcript undergoes splicing to remove the introns, resulting in the messenger RNA (mRNA) molecule.[6] In addition, the bases at the 5′ end (start) of the mRNA are chemically modified (capping) and a large number of adenosine bases are added at the 3′ end, known as the *poly-A tail*. These post-transcriptional modifications stabilize the mRNA and facilitate its transport within the cell. The mature mRNA undergoes a test round of translation which, if successful, leads to the transport of the mRNA to the cytoplasm, where it undergoes multiple rounds of translation by the ribosomes, leading to accumulation of the encoded protein. If the mRNA contains a nonsense mutation, otherwise known as a *premature termination codon mutation*, the



▲ **FIGURE 8-1** Illustration of the complexity of the human genome. On the left, the short (p) and long (q) arms of human chromosome 17 are depicted with their cytogenetic chromosome bands. One of these band regions, 17q21.2, is then highlighted to show that it is made up of approximately 900,000 base pairs (bp) and contains several genes, including 27 functional type I keratin genes. Part of this region is then further amplified to show one keratin gene, *KRT14*, encoding keratin 14, which is composed of 8 exons.

test round of translation fails, and the cell degrades this mRNA via the nonsense-mediated mRNA pathway.[7] This is a mechanism that the cell has evolved to remove aberrant transcripts, and it may also contribute to gene regulation, particularly when very low levels of a particular protein are required within a given cell.

Splicing out of introns is a complex process. The genes of prokaryotes, such as bacteria, do not contain introns, and so mRNA splicing is a process that is specific to higher organisms. In some more primitive eukaryotes, RNA molecules contain catalytic sequences known as *ribozymes*, which mediate the self-splicing out of introns without any requirement for additional factors. In mammals, splicing involves a large number of protein and RNA factors encoded by several genes. This allows another level of control over gene expression and also facilitates alternative splicing of exons, so that a single gene can encode several functionally distinct variants of a protein. These isoforms are often differentially expressed in different tissues. In terms of the gene sequences important for splicing, a few bp at the beginning and at the end of an intron, known as the 5′ splice site (or splice donor site) and the 3′ splice site (or splice acceptor site) are crucial. A few other bp within the intron, such as the branch point site located 18 to 100 bp away from the 3′ end, are also critical. Mutations affecting any of the invariant residues of these splice sites lead to aberrant splicing and either complete loss of protein expression or generation of a highly abnormal protein.

The mRNA also contains two untranslated regions, the 5′UTR upstream of the initiating ATG codon and the 3′UTR downstream of the terminator (or stop codon, which can be TGA, TAA or TAG). The 5′UTR can and often does possess introns, whereas the 3′UTR of more than 99 percent of mammalian genes does not contain introns. The nonsense-mediated mRNA decay pathway identifies mutant transcripts by means of assessing where the termination codon occurs in relation to introns. The natural stop codon is always followed immediately by the 3′UTR, which in turn does not normally possess any introns. If a stop codon occurs in an mRNA upstream of a site where an intron has been excised, this message is targeted for nonsense-mediated decay. The only genes that contain introns within their 3′UTR sequences are expressed at extremely low levels. This is one of the ways in which the cell can determine how much protein is made from a particular gene.

Gene complexity is widely variable and not necessarily related to the size of the protein encoded. Some genes consist of only a single small exon, such as those encoding the connexin family of gap junction proteins. Such single exon genes are rapid and inexpensive to analyze routinely. In contrast, the type VII collagen gene, *COL7A1*, in which mutations lead to the dystrophic forms of EB (see Chap. 60), has 118 exons, meaning that 118 different parts of the gene need to be isolated and analyzed for molecular diagnosis of each dystrophic EB patient. The filaggrin gene (*FLG*) on chromosome 1, recently shown to be the causative gene for ichthyosis vulgaris (see Chap. 47) and a susceptibility gene for atopic dermatitis (see Chap. 14), has only three exons. However, the third exon of *FLG* is more than 12,000 bp in size; is made up of repeats of a 1000-bp sequence; and varies in size from 12,000 to 14,000 bp between different individuals in the population. This unusual gene structure makes routine sequencing of genes such as *COL7A1* or *FLG* difficult, time consuming, and expensive.

GENE EXPRESSION

Each specific gene is generally only actively transcribed in a subset of cells or tissues within the body. Gene expression is largely determined by the promoter elements of the gene. In general, the most important region of the promoter is the stretch of sequence immediately upstream of the cap site. This proximal promoter region contains consensus binding sites for a variety of transcription factors, some of which are general in nature and required for all gene expression, others are specific to particular tissue or cell lineage, and some are absolutely specific for a given cell type and/or stage of development or differentiation. The size of the promoter can vary widely according to gene family or between the individual genes themselves. For example, the keratin genes are tightly spaced within two gene clusters on chromosomes 12q and 17q, but these are exquisitely tissue specific in two different ways. First, these genes are only expressed in epithelial cells, and therefore their promoters must possess regulatory sequences that determine epithelial expression. These regulatory elements are therefore specific for cells of ectodermal origin. Second, these genes are expressed in very specific subsets of epithelial cells, and so there must be a second level of control that specifies which epithelial cell layers express specific keratin genes. This is best illustrated in the hair follicle, where there are many different epithelial cell layers, each with a specific pattern of keratin gene expression (see Chap. 84).[8]

Transcription factors are proteins that either bind to DNA directly or indirectly by associating with other DNA-binding proteins. Binding of these factors to the promoter region of a gene leads to activation of the transcription machinery and transcription of the gene by RNA polymerase II. The transcription factor proteins are encoded by genes that are in turn controlled by promoters that are regulated by other transcription factors encoded by other genes. Thus, there are several tiers of control over gene expression in a given cell type, and the intricacies of this can be difficult to fully unravel experimentally. Nevertheless, by isolation of promoter sequences from genes of interest and placing these in front of reporter genes that can be assayed biochemically, such as firefly luciferase that can be assayed by light emission, the activity of promoters can be reproduced in cultured cells that normally express the gene. Combining such a reporter gene system with site-directed mutagenesis to make deletions or alter small numbers of bp within the promoter can help define the extent of the promoter and the important sequences within it that are required for gene expression. A variety of biochemical techniques, such as DNA footprinting, ribonuclease protection, electrophoretic mobility shift assays, or chromatin immunoprecipitation, can be used to determine which transcription factors bind to a particular promoter and help delineate the specific promoter sequences bound. Expression of reporter genes under the control of a cloned promoter in transgenic mice also helps shed light on the important sequences that are required to recapitulate the endogenous expression of the gene under study. Keratin promoters are unusual in that, generally, a small fragment of only 2000 to 3000 bp upstream of the gene can confer most of the tissue specificity. For this reason, keratin promoters are widely used in the dermatology field to drive exogenous transgene expression in the various specific cellular compartments of the epidermis and its appendages for a wide variety of experiments aimed at determining gene, cell, or tissue function.[9]

Some promoter or enhancer sequences act over very long distances. In some cases, sequences located millions of bp distant, with several other genes in the intervening region, somehow influence expression of a target gene. In some genetic diseases, mutations affecting such long-range promoter elements are now emerging. These types of mutations appear to be rare in the genetics field as a whole, but since they occur so very far away from the target gene and are therefore very difficult to find, this class of mutation may, in fact, be more common than is immediately obvious. In general, relatively few disease-causing mutations have been shown to involve promoters, but this class of defect is probably greatly under-represented because the promoters of most genes have been poorly characterized at the present time in terms of what sequences are truly important for promoter activity. Prediction of transcription factor binding sites by computer analysis remains an inexact science and is an area for further study in the future as the human genome sequence undergoes greater detailed scrutiny and annotation.

FINDING DISEASE GENES

In establishing the molecular basis of an inherited skin disease, there are two key steps. First, the gene linked to a particular disorder must be identified, and second, pathogenic mutations within that gene should be determined. Diseases can be matched to genes either by genetic linkage analysis or by a candidate gene approach.[10] Genetic linkage involves

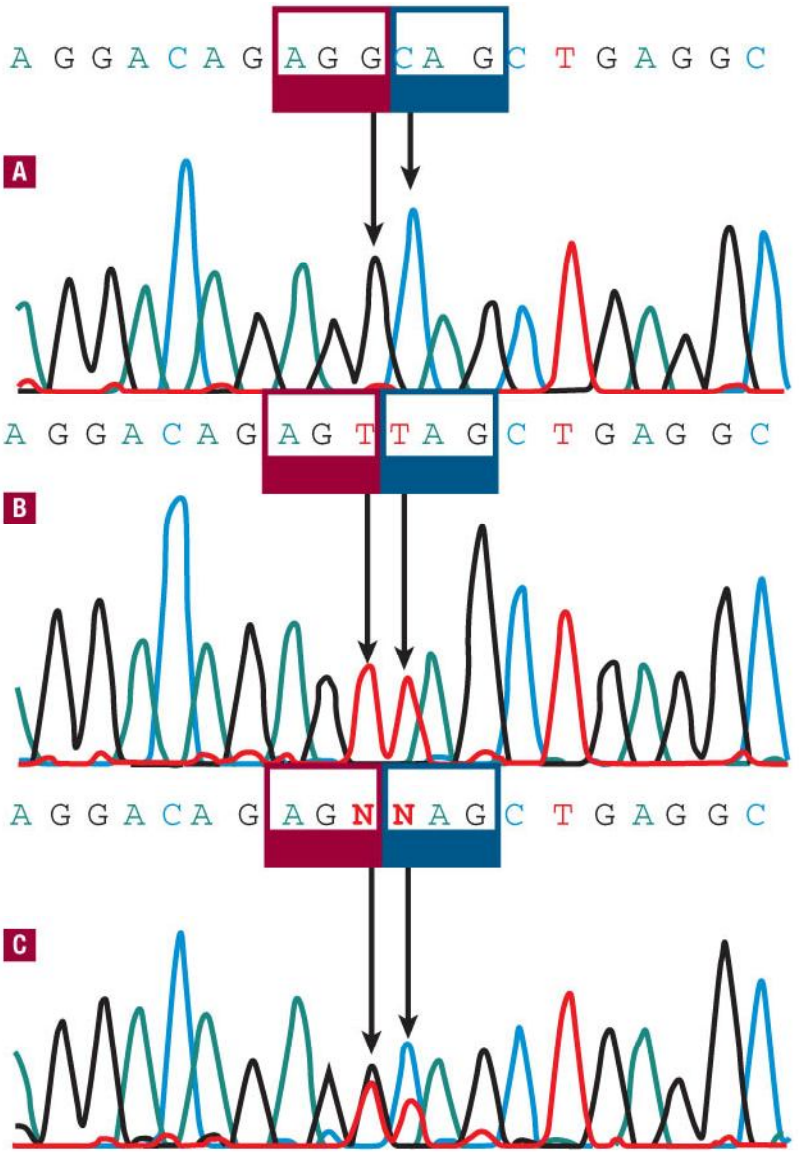
studying pedigrees of affected and unaffected individuals and isolating which bits of the genome are specifically associated with the disease phenotype. The goal is to identify a region of the genome that all the affected individuals and none of the unaffected individuals have in common; this region is likely to harbor the gene for the disorder, as well as perhaps other non-pathogenic neighboring genes that have been inherited by linkage disequilibrium. Traditionally, genome-wide linkage strategies make use of variably-sized microsatellite markers scattered throughout the genome, although for recessive diseases involving consanguineous pedigrees, a more rapid approach may be to carry out homozygosity mapping using single nucleotide polymorphism (SNP) chip arrays. By contrast, the candidate gene approach involves first looking for a clue to the likely gene by finding a specific disease abnormality, perhaps in the expression (or lack thereof) of a particular protein or RNA, or from an ultrastructural or biochemical difference between the disease and control tissue. Nevertheless, the genetic linkage and candidate gene approaches are not mutually exclusive and are often used in combination. For example, to identify the gene responsible for the autosomal recessive disorder, lipoid proteinosis (see Chap. 137), genetic linkage using microsatellites was first used to establish a region of linkage on 1q21 that contained 68 genes.[11] The putative gene for this disorder, *ECM1* encoding extracellular matrix protein 1, was then identified by a candidate gene approach that searched for reduced gene expression (lack of fibroblast complementary DNA) in all these genes. A reduction in *ECM1* gene expression in lipoid proteinosis compared with control provided the clue to the candidate gene because there were no differences in any of the other patterns of gene expression.

Having identified a putative gene for an inherited disorder, the next stage is to find the pathogenic mutation(s). This can be done by sequencing the entire gene, a feat which is becoming easier as technologic advances make automated nucleotide sequencing faster, cheaper, and more accessible. However, the large size of some genes may make comprehensive sequencing impractical, and therefore initial screening approaches to identify the region of a gene that contains the mutation may be a necessary first step. There are many mutation detection techniques available to scan for sequence changes in cellular RNA or genomic DNA, and these include denaturing gradient gel electrophoresis, chemical cleavage of mismatch, single stranded conformation polymorphism, heteroduplex analysis, conformation sensitive gel electrophoresis, denaturing high-performance liquid chromatography and the protein truncation test.[12] The most critical factor that determines the success of any gene screening protocol is the sensitivity of the detection technique. In addition, when choosing a mutation screening strategy using genomic DNA, the size of the gene and its number of exons must be taken into account. The sensitivities of these methods vary greatly, depending on the size of template screened. For example, single-stranded conformation polymorphism has a sensitivity of > 95 percent for fragments of 155 bp, but this is reduced to only 3 percent for 600 bp. Once optimized, denaturing gradient gel electrophoresis has a sensitivity of about 99 percent for fragments of up to 500 bp, and conformation sensitive gel electrophoresis is expected to have a sensitivity of 80 percent to 90 percent for fragments of up to 600 bp. Chemical cleavage of mismatch, on the other hand, has a sensitivity of 95 percent to 100 percent for fragments > 1.5 kilobases (kb) in size and is ideal for screening compact genes where more than one exon can be amplified together using genomic DNA as the template. All these techniques detect sequence changes such as truncating and missense mutations as well as polymorphisms; however, the protein truncation test screens only for truncating mutations and is predicted to have a sensitivity of > 95 percent and can be used for RNA or DNA fragments in excess of 3 kb. Whichever approach is taken, having identified a difference in the patient's DNA compared with the control sample, the next stage is to determine how this segregates within a particular family and also whether it is pathogenic or not.

GENE MUTATIONS AND POLYMORPHISMS

Within the human genome, the genetic code of two healthy individuals may show a number of sequence dissimilarities that have no relevance to disease or phenotypic traits. Such changes within the normal population are referred to as *polymorphisms* (Fig. 8-2). Indeed, even within the coding region of the genome, clinically irrelevant substitutions of one bp, known as *SNPs*, are common and occur approximately once every 250 bp.[13] Oftentimes, these SNPs do not change the amino acid composition; for example, a C-to-T transition in the third position of a proline codon (CCC to CCT) still encodes for proline, and is referred to as a *silent mutation*. Some SNPs, however, do change the nature of the amino acid; for example, a C-to-G transversion at the second position of the same proline codon (CCC to CGC) changes the residue to arginine. It then becomes necessary to determine whether a missense change such as this represents a non-pathogenic polymorphism or a pathogenic mutation. Factors favoring the latter include the sequence segregating only with the disease phenotype in a particular family, the amino acid change occurring within an evolutionarily conserved residue, the substitution affecting the function of the encoded protein (size, charge, conformation, etc.), and the nucleotide switch not being detectable in at least 100 ethnically matched control chromosomes. Non-pathogenic polymorphisms do not always involve single nucleotide substitutions; occasionally, deletions and insertions may also be non-pathogenic.

A mutation can be defined as a change in the chemical composition of a gene. A missense mutation changes one amino acid to another. Mutations may also be insertions or deletions of bases, the consequences of which will depend on whether this disrupts the normal reading frame of a gene or not, as well as nonsense mutations, which lead to premature termination of translation (see Fig. 8-2). For example, a single nucleotide deletion within an exon causes a shift in the reading frame, which usually leads to a downstream stop codon, thus giving a truncated protein, or often an unstable mRNA that is readily degraded by the cell. However, a deletion of three nucleotides (or multiples thereof) will not significantly perturb the overall reading frame, and the consequences will depend on the nature of what has been deleted. Nonsense mutations typically, but not exclusively, occur at CpG dinucleotides, where methylation of a cytosine nucleotide often occurs. Inherent chemical instability of this modified cytosine leads to a high rate of mutation to thymine. Where this alters the codon (e.g., from CGA to TGA), it will change an arginine residue to a stop codon. Nonsense mutations usually lead to a reduced or absent expression of the mutant allele at the mRNA and protein levels. In the heterozygous state, this may have no clinical



▲ **FIGURE 8-2** Examples of nucleotide sequence changes resulting in a polymorphism and a nonsense mutation. **A.** Two adjacent codons are highlighted. Outlined in purple, the AGG codon encodes arginine and the blue boxed codon, CAG encodes glutamine. **B.** The sequence shows two homozygous nucleotide substitutions. In the purple box, AGG now reads AGT (i.e., coding for serine rather than arginine). This is a common sequence variant in the normal population and is referred to as a *non-pathogenic missense polymorphism*. In contrast, in the blue box, the glutamine codon CAG now reads TAG, which is a stop codon. This is an example of a homozygous nonsense mutation. **C.** This sequence is from one of the parents of the subject sequenced in **B** and shows heterozygosity for both the missense polymorphism AGG > AGT and the nonsense mutation CAG > TAG, indicating that this individual is a carrier of both sequence changes.

effect [e.g., parents of individuals with Herlitz junctional EB are typically carriers of nonsense mutations in one of the laminin 332 (laminin 5) genes but have no skin fragility themselves; see Chap. 60], but a heterozygous nonsense mutation in the desmoplakin gene, for example, can result in the autosomal dominant skin disorder, striate palmoplantar keratoderma (see Chap. 48). This phenomenon is referred to as *haploinsufficiency* (i.e., half the normal amount of protein is insufficient for function).

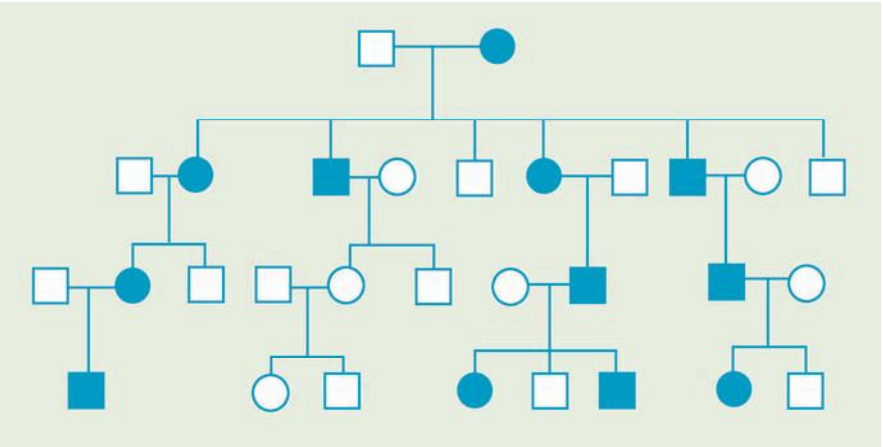
Apart from changes in the coding region that result in frameshift, missense, or nonsense mutations, approximately 15 percent of all mutations involve alterations in the gene sequence close to the boundaries between the intron and exons, referred to as *splice site mutations*. This type of mutation may abolish the usual acceptor and donor splice sites that normally splice out the introns during gene transcription. The consequences of splice site mutations are complex; sometimes they lead to skipping of the adjacent exon, and other times they result in the generation of new mRNA transcripts through utilization of cryptic splice sites within the neighboring exon or intron.

Mutations within one gene do not always lead to a single inherited disorder. For example, mutations in the *ERCC2* gene may lead to xeroderma pigmentosum (type D), trichothiodystrophy, or cerebrofacioskeletal syndrome, depending on the position and type of mutation. Other trans-acting factors may further modulate phenotypic expression. This situation is known as *allelic heterogeneity*. Conversely, some inherited diseases can be caused by mutations in more than one gene (e.g., non-Herlitz junctional EB; see Chap. 60) and can result from mutations in either the *COL17A1*, *LAMA3*, *LAMB3*, or *LAMC2* genes. This is known as *genetic heterogeneity*. In addition, the same mutation in one particular gene may lead to a range of clinical severity in different individuals. This variability in phenotype produced by a given genotype is referred to as the *expressivity*. If an individual with such a genotype has no phenotypic manifestations, the disorder is said to be *non-penetrant*. Variability in expression reflects the complex interplay between the mutation, modifying genes, epigenetic factors, and the environment and demonstrates that interpreting what a specific gene mutation does to an individual involves more than just detecting one bit of mutated DNA in a single gene.

MENDELIAN DISORDERS

There are approximately 5000 human single-gene disorders and, although the molecular basis of less than one-half of these has been established, understanding the pattern of inheritance is essential for counseling prospective parents about the risk of having affected children. The four main patterns of inheritance are autosomal dominant, autosomal recessive, X-linked dominant, and X-linked recessive.

For individuals with an autosomal dominant disorder, one parent is affected, unless there has been a de novo mutation in a parental gamete. Males and females are affected in approximately equal numbers, and the disorder can be transmitted from generation to generation; on average, half the offspring will have the condition (Fig. 8-3). It is important to counsel affected individuals that the risk of transmitting the disorder is 50 percent for each of their



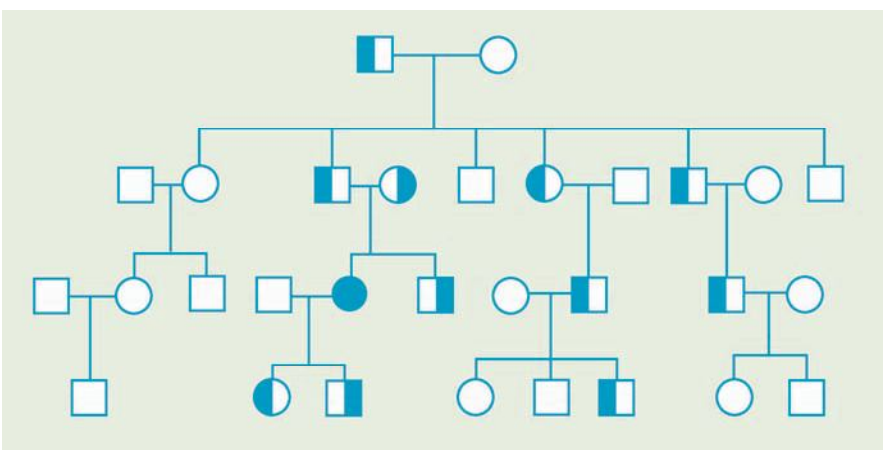
▲ **FIGURE 8-3** Pedigree illustration of an autosomal dominant pattern of inheritance. Key observations include: the disorder affects both males and females; on average, 50 percent of the offspring of an affected individual will be affected; affected individuals have one normal copy and one mutated copy of the gene; affected individuals usually have one affected parent, unless the disorder has arisen de novo. Importantly, examples of male-to-male transmission, seen here, distinguish this from X-linked dominant and are therefore the best hallmark of autosomal dominant inheritance. Filled circles indicate affected females; filled squares indicate affected males; unfilled circles/squares represent unaffected individuals.

children, and that this is not influenced by the number of previously affected or unaffected offspring. Any offspring that are affected will have a 50 percent risk of transmitting the mutated gene to the next generation, whereas for any unaffected offspring, the risk of the next generation being affected is negligible, providing that the partner does not have the autosomal dominant condition.

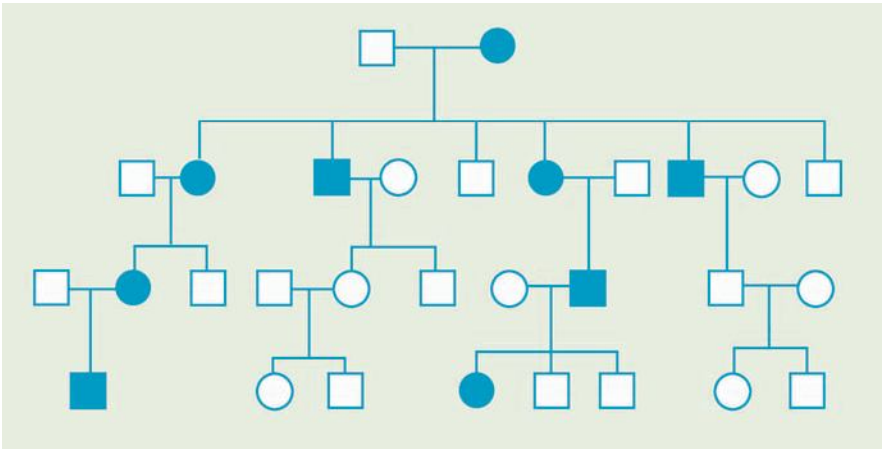
In autosomal recessive disorders, both parents are carriers of one normal and one mutated allele for the same gene and, typically, they are phenotypically unaffected (Fig. 8-4). If both of the mutated alleles are transmitted to the offspring, this will give rise to an autosomal recessive disorder, the risk of which is 25 percent. If one mutated and one wild-type allele is inherited by the offspring, the child will be an unaffected carrier, similar to the parents. If both wild-type alleles are transmitted, the child will be genotypically and phenotypically normal with respect to an affected individual. If the mutations from both parents are the same, the individual is referred to as a *homozygote*, but if different parental mutations within a gene have been inherited, the individual is termed a *compound heterozygote*. For someone who has an autosomal recessive condition, be it a homozygote or compound heterozygote, all offspring will be carriers of one of the mutated alleles but will be unaffected because of inheritance of a wild-type allele from the other, clinically and genetically unaffected, parent. This assumes that the unaffected parent is not a carrier. Although this is usually the case in nonconsanguineous relationships, it may not hold true in first-cousin marriages or other circumstances where there is a familial interrelationship. For example, if the partner of an individual with an autosomal recessive disorder is also a carrier of the same mutation, albeit clinically unaffected, then there is a 50 percent chance of the offspring inheriting two mutant alleles and therefore also inheriting the same autosomal recessive disorder. This pattern of inheritance is referred to as *pseudo-dominant*.

In X-linked dominant inheritance, both males and females are affected, and the pedigree pattern may resemble that of autosomal dominant inheritance (Fig. 8-5). There is, however, one important difference. An affected male transmits the disorder to all his daughters and to none of his sons. X-linked dominant inheritance has been postulated as a mechanism in incontinentia pigmenti (see Chap. 73), Conradi-Hünermann syndrome, and focal dermal hypoplasia (Goltz syndrome), conditions that are almost always limited to females. In most X-linked dominant disorders with cutaneous manifestations, affected males may be aborted spontaneously or die before implantation (for example, most male patients with incontinentia pigmenti have a postzygotic mutation in NEMO, and no affected mother; in this disorder, transmission tends to be female-to-female).

X-linked recessive conditions occur almost exclusively in males, but the gene is transmitted by carrier females, who have the mutated gene only on one X chromosome (heterozygous state). The sons of an affected male will all be normal (because their single X chromosome comes from their clinically unaffected mother) (Fig. 8-6). However, the daughters of an affected male will all be carriers (because all had to have received the single X chromosome that their father had, and that X chromosome carries the mutant copy of the corresponding gene). Some females show clinical abnormalities as evidence of the carrier state (such as in hypohidrotic ectodermal dysplasia;



▲ **FIGURE 8-4** Pedigree illustration of an autosomal recessive pattern of inheritance. Key observations include: the disorder affects both males and females; there are mutations on both inherited copies of the gene; the parents of an affected individual are both heterozygous carriers and are usually clinically unaffected; autosomal recessive disorders are more common in consanguineous families. Filled circle indicates affected female; half-filled circles/squares represent clinically unaffected heterozygous carriers of the mutation; unfilled circles/squares represent unaffected individuals.



▲ **FIGURE 8-5** Pedigree illustration of an X-linked dominant pattern of inheritance. Key observations include: affected individuals are either hemizygous males or heterozygous females; affected males will transmit the disorder to their daughters but not to their sons (no male-to-male transmission); affected females will transmit the disorder to half their daughters and half their sons; some disorders of this type are lethal in hemizygous males and only heterozygous females survive. Filled circles indicate affected females; filled squares indicate affected males; unfilled circles/squares represent unaffected individuals.

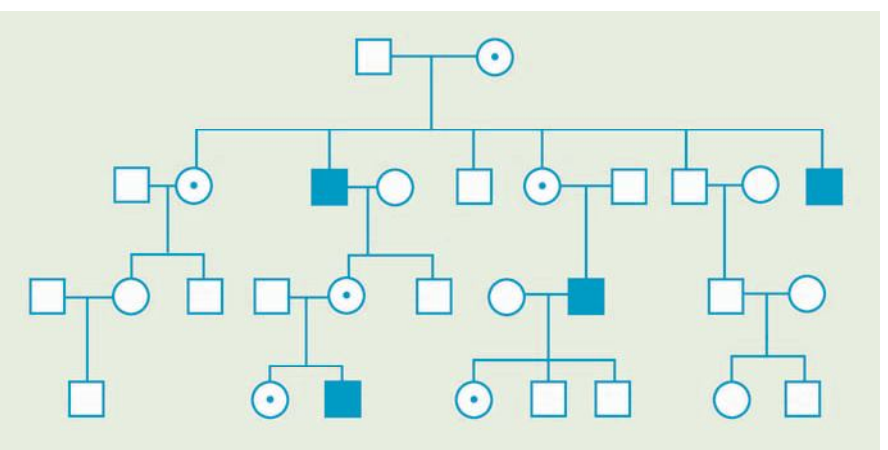
see Chap. 143); the variable extent of phenotypic expression can be explained by lyonization, the normally random process that inactivates either the wild-type or mutated X chromosome in each cell during the first weeks of gestation and all progeny cells.[14] Other carriers may not show manifestations because the affected region on the X chromosome escapes lyonization (as in recessive X-linked ichthyosis) or the selective survival disadvantage of cells in which the mutated X chromosome is activated (as in the lymphocytes and platelets of carriers of Wiskott-Aldrich syndrome; see Mosaicism).

CHROMOSOMAL DISORDERS

Aberrations in chromosomes are common. They occur in about 6 percent of all conceptions, although most of these lead to miscarriage, and the frequency of chromosomal abnormalities in live births is about 0.6 percent. Approximately two-thirds of these involve abnormalities in either the number of sex chromosomes or the number of autosomes; the remainder are chromosomal rearrangements. The number and arrangement of the chromosomes is referred to as the *karyotype*. The most common numerical abnormality is trisomy, the presence of an extra chromosome. This occurs because of non-disjunction, when pairs of homologous chromosomes fail to separate during meiosis, leading to gametes with an additional chromosome. Loss of a complete chromosome, monosomy, can affect the X chromosome but is rarely seen in autosomes because of non-viability. A number of chromosomal disorders are also associated with skin abnormalities, as detailed in Table 8-2.

Structural aberrations (fragility breaks) in chromosomes may be random, although some chromosomal regions appear more vulnerable. Loss of part of a chromosome is referred to as a *deletion*. If the deletion leads to loss of neighboring genes this may result in a contiguous gene disorder, such as a deletion on the X chromosome giving rise to X-linked ichthyosis (see Chap. 47) and Kallman syndrome. If two chromosomes break, the detached fragments may be exchanged, known as *reciprocal translocation*. If this process involves no loss of DNA it is referred to as a *balanced translocation*. Other structural aberrations include duplication of sections of chromosomes, two breaks within one chromosome leading to inversion, and fusion of the ends of two broken chromosomal arms, leading to joining of the ends and formation of a ring chromosome.

A further possible chromosomal abnormality is the inheritance of both copies of a chromosome pair from just one parent (paternal or maternal), known as *uniparental disomy*.[15] *Uniparental heterodisomy* refers to the presence of a pair of chromosome homologs, whereas *uniparental isodisomy* describes two identical copies of a single homolog, and *meroisodisomy* is a mixture of the two. Uniparental disomy with homozygosity of recessive alleles is being increasingly recognized as the molecular basis for several autosomal recessive disorders, and there have been more than 35 reported cases of recessive diseases, including junctional and dystrophic EB (see Chap. 60), resulting from this type of chromosomal abnormality. For certain chromosomes, uniparental disomy can also result in distinct phenotypes depending on the parental origin of the chromosomes, a phenomenon known as *genomic imprinting*.[16,17] This parent-of-origin, specific gene expression is determined by epigenetic modification of a specific gene or, more often, a group of genes, such that gene transcription is



▲ **FIGURE 8-6** Pedigree illustration of an X-linked recessive pattern of inheritance. Key observations include: usually affects only males but females can show some features because of lyonization (X-chromosome inactivation); transmitted through female carriers, with no male-to-male transmission; for affected males, all daughters will be heterozygous carriers; female carrier will transmit the disorder to half her sons, and half her daughters will be heterozygous carriers. Dots within circles indicate heterozygous carrier females who may or may not display some phenotypic abnormalities; filled squares indicate affected males; unfilled circles/squares represent unaffected individuals.

TABLE 8-2
Chromosomal Disorders with a Skin Phenotype

Chromosomal Abnormality	Synonym	General Features	Skin Manifestations
Trisomy 21	Down syndrome	Small head with flat face Nose short and squat Ears small and misshapen Slanting palpebral fissures Thickened eyelids Eyelashes short and sparse Shortened limbs, lax joints Fingers short, sometimes webbed Hypoplastic iris, lighter outer zone (Brushfield's spots)	1–10 yr: dry skin, xerosis, lichenification 10+ yr: increased frequency of atopic dermatitis, alopecia areata, single crease in palm and fifth finger Other associations: skin infections, angular cheilitis, geographic tongue, blepharitis, red cheeks, folliculitis, seborrheic dermatitis, boils, onychomycosis, fine hypopigmented hair, vitiligo, delayed dentition and hypoplastic teeth, acrocyanosis, livedo reticularis, cutis marmorata, calcinosis cutis, palmoplantar keratoderma, pityriasis rubra pilaris, syringomas, elastosis perforans serpiginosa, anetoderma, hyperkeratotic form of psoriasis, collagenoma, eruptive dermatofibromas, urticaria pigmentosa, leukemia cutis, keratosis follicularis spinulosa decalvans
Trisomy 18	Edwards syndrome	Severe mental deficiency Abnormal skull shape Small chin, prominent occiput Low-set, malformed ears "Rocker bottom" feet Short sternum Malformations of internal organs Only 10% survive beyond first year	Cutis laxa (neck), hypertrichosis of forehead and back, superficial hemangiomas, abnormal dermatoglyphics, single palmar crease, hyperpigmentation, ankyloblepharon filiforme adnatum
Trisomy 13	Patau syndrome	Mental retardation Sloping forehead due to forebrain maldevelopment (holoprosencephaly) Microphthalmia or anophthalmia Cleft palate/cleft lip Low-set ears "Rocker bottom" feet Malformations of internal organs Survival beyond 6 mo is rare	Vascular anomalies (especially on forehead) Hyperconvex nails Localized scalp defects Cutis laxa (neck) Abnormal palm print (distal palmar axial triradius)
Chromosome 4, short arm deletion		Microcephaly Mental retardation Hypospadias Cleft lip/palate Low-set ears, preauricular pits	Scalp defects
Chromosome 5, short arm deletion		Mental retardation Microcephaly Cat-like cry Low-set ears, preauricular skin tag	Premature graying of hair
Chromosome 18, long arm deletion		Hypoplasia of mid-face Sunken eyes Prominent ear anti-helix Multiple skeletal and ocular abnormalities	Eczema in 25% of cases
45 XO	Turner syndrome	Early embryonic loss; prenatal ultrasound findings of cystic hygroma, chylothorax, ascites and hydrops Short stature, amenorrhea Broad chest, widely spaced nipples Wide carrying angle of arms Low misshapen ears, high arched palate Short fourth/fifth fingers and toes Skeletal abnormalities, coarctation of aorta	Redundant neck skin and peripheral edema Webbed neck, low posterior hairline Cutis laxa (neck, buttocks) Hypoplastic, soft up-turned nails Increased incidence of keloids Increased number of melanocytic nevi and halo nevi Failure to develop full secondary sexual characteristics Lymphatic hypoplasia/lymphedema
47 XXY	Klinefelter syndrome	No manifestations before puberty Small testes, poorly developed secondary sexual characteristics Infertility Tall, obese, osteoporosis	May develop gynecomastia Sparse body and facial hair Increased risk of leg ulcers Increased incidence of systemic lupus erythematosus

TABLE 8-2
Chromosomal Disorders with a Skin Phenotype (Continued)

Chromosomal Abnormality	Synonym	General Features	Skin Manifestations
48 XXYY		Similar to Klinefelter syndrome	Multiple cutaneous angiomas Acrocyanosis, peripheral vascular disease
47 XYY		Phenotypic males (tall) Mental retardation Aggressive behavior	Severe acne
49 XXXXY		Low birth weight Slow mental and physical development Large, low-set, malformed ears Small genitalia	Hypotrichosis (variable)
Fragile X syndrome		Mental retardation Mild dysmorphism Hyperextensible joints, flat feet	—

altered, and only one inherited copy of the relevant imprinted gene(s) is expressed in the embryo. This means that, during development, the parental genomes function unequally in the offspring. The most common examples of genomic imprinting are Prader–Willi (OMIM #176270) and Angelman (OMIM #105830) syndromes, which can result from maternal or paternal uniparental disomy for chromosome 15, respectively. Three phenotype abnormalities commonly associated with uniparental disomy for chromosomes with imprinting are intrauterine growth retardation, developmental delay, and reduced stature.[18]

MITOCHONDRIAL DISORDERS

In addition to the 3.3 billion bp nuclear genome, each cell contains hundreds or thousands of copies of a further 16.5-kb mitochondrial genome, which is inherited solely from an individual's mother. This closed, circular genome contains 37 genes, 13 of which encode proteins of the respiratory chain complexes, whereas the other 24 genes generate 22 transfer RNAs and two ribosomal RNAs used in mitochondrial protein synthesis.[19] Mutations in mitochondrial DNA were first reported in 1988, and more than 250 pathogenic point mutations and genomic rearrangements have been shown to underlie a number of myopathic disorders and neurodegenerative diseases, some of which show skin manifestations, including lipomas, abnormal pigmentation or erythema, and hypo- or hypertrichosis.[20] Mitochondrial DNA has the capacity to form a mixture of both wild-type and mutant DNA within a cell, leading to cellular dysfunction only when the ratio of mutated to wild-type DNA reaches a certain threshold. The phenomenon of having mixed mitochondrial DNA species within a cell is known as *heteroplasmy*. Mitochondrial mutations can induce, or be induced by, reactive oxygen species, and may be found in, or contribute to, both chronologic aging and photoaging. Somatic mutations in mitochondrial DNA have also been reported in several premalignant and malignant tumors, including malignant melanoma, although it is not yet known whether these mutations are causally linked to cancer development or simply a secondary bystander effect as a consequence of nuclear DNA instability. Indeed, currently there is little understanding of the interplay between the nuclear and mitochondrial genomes in both health and disease. Nevertheless, it is evident that the genes encoded by the mitochondrial genome have multiple biologic functions linked to energy production, cell proliferation, and apoptosis.[21]

COMPLEX TRAIT GENETICS

For Mendelian disorders, identifying genes that harbor pathogenic mutations has become relatively straightforward, with hundreds of disease-associated genes being discovered through a combination of linkage, positional cloning, and candidate gene analyses. By contrast, for complex traits, such as psoriasis and atopic dermatitis, these traditional approaches have been largely unsuccessful in mapping genes influencing the disease risk or phenotype because of low statistical power and other factors.[22,23] Complex traits do not display simple Mendelian patterns of inheritance, although genes do have an influence, and close relatives of affected individuals may have an increased risk. To dissect out genes that contribute to, and influence susceptibility to, complex traits, several stages may be necessary, including establishing a genetic basis for the disease in one or more populations; measuring the distribution of gene effects; studying statistical power using models; and carrying out marker-based mapping studies using linkage or association. It is possible to establish quantitative genetic models to estimate the heritability of a complex trait, as well as to predict the distribution of gene effects and to test whether one or more quantitative trait loci exist. These models can predict the power of different mapping approaches, but often only provide approximate predictions. Moreover, low power often limits other strategies such as transmission analyses, association studies, and family-based association tests. Another potential pitfall of association studies is that they can generate spurious associations due to population admixture. To counter this, alternative strategies for association mapping include the use of recent founder populations or unique isolated populations that are genetically homogeneous, and the use of unlinked markers (so-called *genomic controls*) to assign different regions of the genome of an admixed individual to particular source populations. In addition, and relevant to several studies on psoriasis, linkage disequilibrium observed in a sample of unrelated affected and normal individuals can also be used to fine-map a disease susceptibility locus in a candidate region.

Recently, however, a conventional genetics approach has revealed fascinating new insight into the pathophysiology of one particular complex trait, namely

atopic dermatitis. This finding emanated from the discovery that the disorder ichthyosis vulgaris was due to loss-of-function mutations in the gene encoding the skin barrier protein filaggrin (see Chaps. 14 and 47).[24] To dermatologists, the clinical association between this condition and atopic dermatitis is well known, and the same loss-of-function mutations in filaggrin have subsequently been shown to be a major susceptibility risk factor for atopic dermatitis, as well as asthma associated with atopic dermatitis, but not asthma alone.[4] This suggests that asthma in individuals with atopic dermatitis may be secondary to allergic sensitization, which develops because of the defective epidermal barrier that allows allergens to penetrate the skin to make contact with antigen-presenting cells. Indeed, transmission-disequilibrium tests have demonstrated an association between filaggrin gene mutations and extrinsic atopic dermatitis associated with high total serum immunoglobulin E levels and concomitant allergic sensitizations.[25] These recent data on the genetics of atopic dermatitis demonstrate how the study of a "simple" genetic disorder can also provide novel insight into a complex trait. Mendelian disorders, therefore, may be useful in the molecular dissection of more complex traits.[26]

MOSAICISM

The presence of a mixed population of cells bearing different genetic or chromosomal characteristics leading to phenotypic diversity is referred to as *mosaicism*. There are several different types of mosaicism, including single gene, chromosomal, functional, and revertant mosaicism.[27]

Mosaicism for a single gene, referred to as *somatic mosaicism*, indicates a mutational event occurring after fertilization. The earlier this occurs, the more likely it is there will be clinical expression of a disease phenotype as well as involvement of gonadal tissue (gonosomal mosaicism); for example, when individuals with segmental neurofibromatosis subsequently have offspring with full-blown neurofibromatosis (see Chap. 142). However, in general, if the mutation occurs after generation of cells committed to gonad formation, then the mosaicism will not involve the germline, and the reproductive risk of transmission is negligible. *Gonosomal mosaicism* refers to involvement of both gonads and somatic tissue, but mosaicism can occur exclusively in gonadal tissue, referred to as *gonadal mosaicism*. Clinically, this may explain recurrences among siblings of autosomal dominant disorders such as tuberous sclerosis or neurofibromatosis, when none of the parents has any clinical manifestations and gene screening using genomic DNA from peripheral blood samples yields no mutation. Segmental mosaicism for autosomal dominant disorders is thought to occur in one of two ways: either there is a postzygotic mutation with the skin outside the segment and genomic DNA being normal (type 1), or there is a heterozygous genomic mutation that is then exacerbated by loss of heterozygosity within a segment or along the lines of Blaschko (type 2). This pattern has been described in several autosomal dominant disorders, including Darier disease, Hailey-Hailey disease (see Chap. 49), superficial actinic porokeratosis (see Chap. 50), and tuberous sclerosis (see Chap. 141).

The lines of Blaschko were delineated over 100 years ago; the pattern is attributed to the lines of migration and proliferation of epidermal cells during embryogenesis (i.e., the bands of abnormal skin represent clones of cells carrying a mutation in a gene expressed in the skin).[28] Apart from somatic mutations [either in dominant disorders, such as bullous ichthyosiform erythroderma leading to linear epidermolytic hyperkeratosis (see Chap. 47), or in conditions involving mutations in lethal dominant genes such as in McCune-Albright syndrome], mosaicism following Blaschko's lines is also seen in chromosomal mosaicism and functional mosaicism (random X-chromosome inactivation through lyonization). Chromosomal mosaicism results from nondisjunction events that occur after fertilization. Clinically, this is found in the linear pigmentary disorders hypomelanosis of Ito (see Chap. 73) and linear and whorled hyperpigmentation. It is important to point out that hypomelanosis of Ito is not a specific diagnosis but may occur as a consequence of several different chromosomal abnormalities that perturb various genes relevant to skin pigmentation. Functional mosaicism relates to genes on the X chromosome, because during embryonic development in females, one of the X chromosomes, either the maternal or the paternal, is inactivated. For X-linked dominant disorders, such as focal dermal hypoplasia (Goltz syndrome) or incontinentia pigmenti (see Chap. 73), females survive because of the presence of some cells in which the X chromosome without the mutation is active and able to function. For males, these X-linked dominant disorders are typically lethal, unless associated with an abnormal karyotype (e.g., Klinefelter syndrome; 47, XXY) or if the mutation occurs during embryonic development. For X-linked recessive conditions, such as X-linked recessive hypohidrotic ectodermal dysplasia (see Chap. 143), the clinical features are evident in hemizygous males (who have only one X chromosome), but females may show subtle abnormalities due to mosaicism caused by X-inactivation, such as decreased sweating or reduced hair in areas of the skin in which the normal X is selectively inactivated. There are 1317 known genes on the X chromosome, and most undergo random inactivation but a small percentage (approximately 27 genes on Xp, including the steroid sulfatase gene, and 26 genes on Xq) escape inactivation.

Revertant mosaicism, also known as *natural gene therapy*, refers to genetic correction of an abnormality by presence of a second mutation that either corrects a mutant gene or silences it.[29,30] Such events have been described in a few genes expressed in the skin, including the keratin 14, laminin 332, and collagen XVII genes in different forms of EB (Fig. 8-7; see Chap. 60). However, the clinical relevance of the conversion process depends on several factors, including the number of cells involved, how much reversal actually occurs, and at what stage in life the reversion takes place.

Apart from mutations in nuclear DNA, mosaicism can also be influenced by environmental factors, such as viral DNA sequences (retrotransposons) that can be incorporated into nuclear DNA, replicate, and activate or silence genes through methylation or demethylation. This phenomenon is known as *epigenetic mosaicism*; such events may be implicated in tumorigenesis but have not been associated with any genetic skin disorder.

EPIGENETICS

Disease phenotypes reflect the result of the interaction between a particular genotype and the environment, but it is evident that some variation, for example, in monozygotic twins, is attributable to neither. Additional influences at the biochemical, cellular, tissue, and organism levels occur, and these are referred to as *epigenetic phenomena*.[31] Single genes are

▲ **FIGURE 8-7** Revertant mosaicism in an individual with non-Herlitz junctional epidermolysis bullosa. The subject has loss-of-function mutations on both alleles of the type XVII collagen gene, *COL17A1*, but spontaneous genetic correction of the mutation in some areas has led to patches of normal-appearing skin (areas within black marker outline) that do not blister. (From Jonkman MF et al: Revertant mosaicism in epidermolysis bullosa caused by mitotic gene conversion. *Cell* **88**:543, 1997, with permission.)

not solely responsible for each separate function of a cell. Genes may collaborate in circuits, be mobile, exist in plasmids and cytoplasmic organelles, and can be imported by nonsexual means from other organisms or as synthetic products. Even prion proteins can simulate some gene properties. Epigenetic effects reflect chemical modifications to DNA that do not alter DNA sequence but do alter the probability of gene transcription. Analysis of these changes is known as *epigenomics*.[32] Examples of modifications include direct covalent modification of DNA by methylation of cytosines and alterations in proteins that bind to DNA. Such changes may affect DNA accessibility to local transcriptional complexes as well as influencing chromatin structure at regional and genome-wide levels, thus providing a link between genome structure and regulation of transcription. Indeed, epigenome analysis is now being carried out in parallel with gene expression to identify genome-wide methylation patterns and profiles of all human genes. For example, there is considerable interindividual variation in cytosine methylation of CpG dinucleotides within the major histocompatibility complex (MHC) region genes, although whether this has any bearing on the expression of skin disorders such as psoriasis remains to be seen. A further but as yet unresolved issue is whether there is heritability of epigenetic characteristics. Likewise, it is unclear whether environmentally induced changes in epigenetic status, and hence gene transcription and phenotype, can be transmitted through more than one generation. Such a phenomenon might account for the cancer susceptibility of grandchildren of individuals who have been exposed to diethylstilbestrol, but this has not been proved. Germline epimutations, however, have been identified in other human diseases, such as colorectal cancers characterized by microsatellite instability and hypermethylation of the *MLH1* DNA mismatch repair gene, although the risk of transgenerational epigenetic inheritance of cancer from such a mutation is not well established and probably small. Over the course of an individual's lifespan, epigenetic mutations may occur more frequently than DNA mutations, and it is expected that, over the next decade, the role of epigenetic phenomena in influencing phenotypic variation will gradually become better understood.[33]

HISTOCOMPATABILITY ANTIGEN DISEASE ASSOCIATION

HLA molecules are glycoproteins that are expressed on almost all nucleated cells. The HLA region is located on the short arm of chromosome 6, at 6p21, referred to as the *MHC*. There are three classic loci at HLA class I: HLA-A, -B, and -Cw, and five loci at class II: HLA-DR, -DQ, -DP, -DM, and -DO. The HLA molecules are highly polymorphic, there being many alleles at each individual locus. Thus, allelic variation contributes to defining a unique "fingerprint" for each person's cells, which allows an individual's immune system to define what is foreign and what is self. The clinical significance of the HLA system is highlighted in human tissue transplantation, especially in kidney and bone marrow transplantation, where efforts are made to match at the HLA-A, -B, and -DR loci. MHC class I molecules, complexed to certain peptides, act as substrates for $CD8^+$ T-cell activation, whereas MHC class II molecules on the surface of antigen-presenting cells display a range of peptides for recognition by the T-cell receptors of $CD4^+$ T helper cells (see Chap. 10). MHC molecules, therefore, are central to effective adaptive immune responses. Conversely, however, genetic and epidemiologic data have implicated these molecules in the pathogenesis of various autoimmune and chronic inflammatory diseases. Several skin diseases, such as psoriasis (see Chap. 18), psoriatic arthropathy (central and peripheral), dermatitis herpetiformis, pemphigus, reactive arthritis syndrome (see Chap. 20), and Behçet disease (see Chap. 167), all show an association with inheritance of certain HLA haplotypes (i.e., there is a higher incidence of these conditions in individuals and families with particular HLA alleles). However, the molecular mechanisms by which polymorphisms in HLA molecules confer susceptibility to certain disorders are still unclear. This situation is further complicated by the fact that, for most diseases, it is unknown which autoantigens (presented by the disease-associated MHC molecules) are primarily involved. For many diseases, the MHC class association is the main genetic association. Nevertheless, for most of the MHC-associated diseases, it has been difficult to unequivocally determine the primary disease-risk gene(s), owing to the extended linkage disequilibrium in the MHC region. However, recent genetic and functional studies support the long-held assumption that common MHC class I and II alleles themselves are responsible for many disease associations, such as the HLA cw6 allele in psoriasis.

GENETIC COUNSELING

In 2006, the National Society of Genetic Counselors (http://www.nsgc.org) defined genetic counseling as "the process of helping people understand and adapt to the medical, psychological and familial implications of genetic contributions to disease." Genetic counseling should include: (1) interpretation of family and medical histories to assess the chance of disease occurrence or recurrence; (2) education about inheritance, testing, management, prevention, resources, and research; and (3) counseling to promote informed choice and adaptation to the risk or condition.[34]

Genetic counseling is an integral part of the practice of dermatology. Once the diagnosis of an inherited skin disease is established and the mode of inheritance is known, every dermatologist should be able to advise patients correctly and appropriately, although additional support from specialists in medical genetics is often necessary. Genetic counseling must be based on an understanding of genetic principles and on a familiarity with the usual behavior of hereditary and congenital abnormalities. It is also important to be familiar with the range of clinical severity of a particular disease, the social consequences of the disorder, the availability of therapy (if any), and the options for mutation detection and prenatal testing in subsequent pregnancies at risk for recurrence (one useful site is http://www.genetests.com).

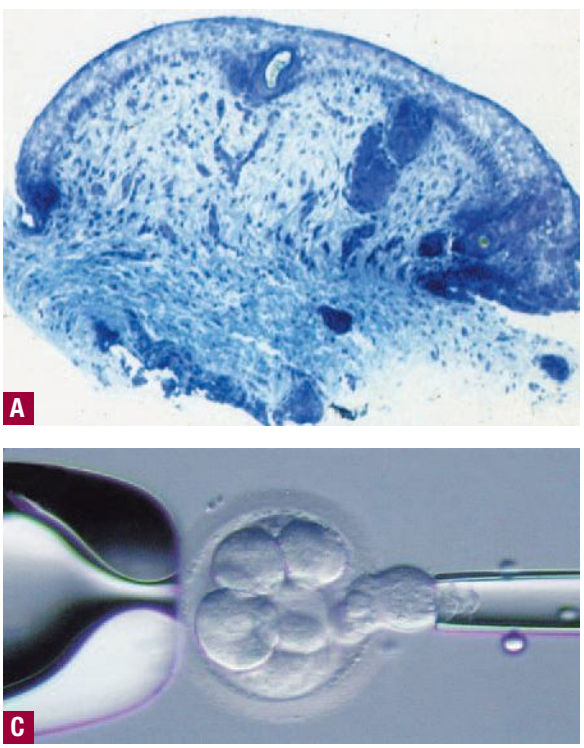
A key component of genetic counseling is to help parents, patients, and families know about the risks of recurrence or transmission for a particular condition. This information is not only practical but often relieves guilt and can allay rather than increase anxiety. For example, it may not be clear to the person that he or she cannot transmit the given disorder. The unaffected brother of a patient with an X-linked recessive disorder such as Fabry disease (see Chap. 136), X-linked ichthyosis (see Chap. 47), Wiskott-Aldrich syndrome (see Chap. 144), or Menkes syndrome (see Chap. 86) need not worry about his children being affected or even carrying the abnormal allele, but he may not know this.

Prognosis and counseling for conditions such as psoriasis in which the genetic basis is complex or still unclear is more difficult (see Chap. 18). Persons can be advised, for example, that if both parents have psoriasis, the probability is 60 percent to 75 percent that a child will have psoriasis; if one parent and a child of that union have psoriasis, then the chance is 30 percent that another child will have psoriasis; and if two normal parents have produced a child with psoriasis, the probability is 15 percent to 20 percent for another child with psoriasis.[35]

PRENATAL DIAGNOSIS

In recent years, there has been considerable progress in developing prenatal testing for severe inherited skin disorders (Fig. 8-8). Initially, ultrastructural examination of fetal skin biopsies was established in a limited number of conditions. In the late 1970s, the first diagnostic examination of fetal skin was reported for epidermolytic hyperkeratosis and Herlitz junctional EB (see Chap. 60).[36,37] These initial biopsies were performed with the aid of a fetoscope to visualize the fetus. However, with improvements in sonographic imaging, biopsies of fetal skin are now taken under ultrasound guidance. The fetal skin biopsy samples obtained during the early 1980s could be examined only by light microscopy and transmission electron microscopy. However, the introduction of a number of monoclonal and polyclonal antibodies to various basement membrane components during the mid-1980s led to the development of immunohistochemical tests to help complement ultrastructural analysis in establishing an accurate diagnosis, especially in cases of EB.[38] Fetal skin biopsies are taken during the mid-trimester. For disorders such as EB, testing at 16 weeks' gestation is appropriate. However, for some forms of ichthyosis, the disease-defining structural pathology may not be evident at this time, and fetal skin sampling may need to be deferred until 20 to 22 weeks of development.

Nevertheless, since the early 1990s, as the molecular basis of an increasing number of genodermatoses has been elucidated, fetal skin biopsies have gradually been superseded by DNA-based diagnostic screening using fetal DNA from amniotic fluid cells or samples of chorionic villi; the latter are usually taken at 10 to 12 weeks' gestation (i.e., at the end of the first trimester).[39,40] In addition, advances with in vitro fertilization and embryo micromanipulation have led to the feasibility of even earlier DNA-based assessment through preimplantation genetic diagnosis, an approach first successfully applied in 1990, for risk of recurrence of cystic fibrosis.[41] Successful preimplantation testing has also been reported for severe inherited skin disorders.[42] This is likely to become a more



◀ **FIGURE 8-8** Options for prenatal testing of inherited skin diseases. **A.** Fetal skin biopsy, here shown at 18 weeks' gestation. **B.** Chorionic villi sampled at 11 weeks' gestation. **C.** Preimplantation genetic diagnosis. A single cell is being extracted from a 12-cell embryo using a suction pipette.

popular, though still technically challenging, option for some couples, in view of recent advances in amplifying the whole genome in single cells and the application of multiple linkage markers in an approach termed *preimplantation genetic haplotyping*.[43] For some disorders, alternative less invasive methods of testing are now also being developed, including analysis of fetal DNA from within the maternal circulation and the use of three-dimensional ultrasonography.

In the current absence of effective treatment for many hereditary skin diseases, prenatal diagnosis can provide much appreciated information to couples at risk of having affected children, although detailed and supportive genetic counseling is also a vital element of all prenatal testing procedures.

GENE THERAPY

The field of gene therapy can be subdivided in different ways.[44] First, there are approaches aimed at treatment of recessive genetic diseases where homozygous or compound heterozygous loss-of-function mutations lead to complete absence or complete functional ablation of a vital protein. These types of diseases are amenable to gene replacement therapy, and it is this form of gene therapy that has tended to predominate because it is generally technically more feasible than treatment of dominant genetic conditions.[45] In dermatology, these include diseases such as lamellar ichthyosis (see Chap. 47), where in most cases, there is hereditary absence of transglutaminase-1 activity in the outer epidermis, or the severe Hallopeau-Siemens form of recessive dystrophic EB, where there is complete absence of type VII collagen expression due to recessive mutations.[46]

The second form of gene therapy, in broad terms, is aimed at treatment of dominant-negative genetic disorders and is known as *gene inhibition therapy*. Here, there is a completely different type of problem to be tackled because these patients already carry one normal copy of the gene and one mutated copy. The disease results because an abnormal protein product produced by the mutant allele, dominant-negative mutant protein, binds to and inhibits the function of the normal protein produced by the wild-type allele. In many cases, it can be shown from the study of rare recessive variants of dominant diseases that one allele is sufficient for normal skin function, and so if a means could be found of specifically inhibiting the expression of the mutant allele, this should be therapeutically beneficial. However, finding a gene therapy agent that is capable of discriminating the wild-type and mutant alleles, which can differ by as little as one bp of DNA, is challenging , until recently, has resulted in little success. A typical dominant-negative genetic skin disease is EB simplex (see Chap. 60), caused by mutations in either of the genes encoding keratins 5 or 14. The vast majority of cases are caused by dominant-negative missense mutations, changing only a single amino acid, carried in a heterozygous manner on one allele.[47]

The other way that gene therapy approaches can be broadly subdivided is according to whether they involve in vivo or ex vivo strategies.[44] Using an in vivo approach, the gene therapy agent would be applied directly to the patient's skin or another tissue. In an ex vivo approach, a skin biopsy would be taken, keratinocytes or fibroblasts would be grown and expanded in culture, treated with the gene therapy agent, and then grafted onto or injected back into the patient. The skin is a good organ system for both these approaches because it is very accessible for in vivo applications. In addition, the skin can be readily biopsied, and cell culture and re-grafting of keratinocytes can be adapted for ex vivo gene therapy.

A disadvantage of the skin as a target organ for gene therapy is that it is a barrier tissue that is fundamentally designed to prevent entry of foreign nucleic acid in the form of viruses or other pathogenic agents. This is an impediment to in vivo gene therapy development but is not insurmountable due to developments in liposome technology and other methods for cutaneous macromolecule delivery.[48]

Gene replacement therapy systems have been developed for lamellar ichthyosis (see Chap. 47) and the recessive forms of EB (see Chap. 60), among other diseases. These mostly consist of expressing the normal complementary DNA encoding the gene of interest from some form of gene therapy vector adapted from viruses that can integrate their genomes stably into the human genome. Such viral vectors can therefore lead to long-term stable expression of the replacement gene.[49] Early studies tended to use retroviral vectors or adeno-associated viral vectors, but these have a number of limitations. For example, retroviruses only transduce dividing cells and therefore fail to target stem cells; consequently, gene expression is quickly lost due to turnover of the epidermis through keratinocyte differentiation. Furthermore, there have been some safety issues in small-scale human trials for both retroviral and adeno-associated viral vectors. Lentiviral vectors, derived from short integrating sequences found in a number of immunodeficiency viruses, have the advantage of being able to stably transduce dividing and non-dividing cells, with close to 100 percent efficiency and at low copy number. These may be the current vector of choice, but they also have potential problems because their preferred integration sites in the human genome are currently ill-defined and may lead to concerns about safety. However, with a wide variety of vectors under development and testing, it should become clear in future years which vectors are effective and safe for human use. Ultimately, like all novel therapeutics, animal testing can only act as a guide because the human genome is quite different and may react differently to foreign DNA integration, so that phase I, II, and III human trials or adaptations thereof will ultimately have to be performed to determine efficacy and safety. Currently, small-scale clinical trials are ongoing for junctional EB and are planned for a number of other genodermatoses, mainly concentrating on the more severe recessive conditions.

Treatment of dominant-negative disorders has recently started to receive a great deal of attention with the discovery of the RNA inhibition pathway in humans and the finding that small synthetic double-stranded RNA molecules of 19 to 21 bp, known as *short inhibitory RNA* (siRNA), can efficiently inhibit expression of human genes in a sequence-specific, user-defined manner.[47,50] There is currently a great deal of attention being focused on development of siRNA inhibitors to selectively silence mutant alleles in dominant-negative genetic diseases, such as the keratin disorders EB simplex or pachyonychia congenita. Because siRNAs can be designed against many different mRNA sequences with ease, and because they are much smaller molecules than gene therapy vectors, this new, rapidly evolving technology fits in between small molecule therapy and gene therapy. In a number of cases, siRNAs have been identified that can discriminate between normal and mutant alleles that differ by only a single bp mutation. In parallel, a number of groups are working on means of delivering siRNA to skin and other organ systems, and there is currently much optimism about these developing into clinically applicable agents in the near future. Some small scale clinical trials are under way and others are planned, including for keratinizing disorders. A number of animal models have shown positive results with low toxicity, including in non-human primates. However, at least one

study has shown liver toxicity with certain sequences but not others.

CHAPTER 9

Basic Science Approaches to the Pathophysiology of Skin Disease

Paul R. Bergstresser

TOOLS TO INVESTIGATE SKIN DISEASE

Dermatologists and skin biologists, like scientists in other disciplines, use as many tools as possible to unravel mechanisms of disease. They even invent tools to address the unique features of skin. Contemporary medical science is virtually universal in its techniques, and investigators from diverse fields commonly use the same cutting-edge methods to address the pathogenesis of disease. A significant portion of ground-breaking activity does not occur in conventional basic science or clinical departments, but, rather, in department-independent "centers" (or "centers of excellence"), which combine the resources and special expertise of investigators from several disciplines.

BASIC SCIENCE APPROACHES: A HISTORICAL PERSPECTIVE

With this preamble about the universality of methods used by investigators, this chapter continues with a simple question: "How have *basic science approaches to the pathophysiology of skin disease* fit into contemporary models of biomedical investigation?" This question is addressed with an assertion and four principles (Table 9-1).

The best way to illustrate how new knowledge has been generated for skin disease is through examples of successful achievement. What follows are three examples of effective laboratory research, each with important contemporary effects. These examples begin 40 years ago, and they illustrate that the principles for scientific success have not changed.

Repair of Ultraviolet Radiation-Induced Damage: A Model of Discovery

BACKGROUND Treatment of skin cancer has occupied an increasingly large portion of dermatologists' clinical activity since the 1950s, as life expectancies have increased, and as leisure time has led to more outdoor recreation. Importantly, ultraviolet radiation (UVR) retains its position as the major relevant etiologic factor. Because of the central role of skin cancer and skin cancer therapy in dermatologic practice, detailed knowledge about the very rare genetic disorder xeroderma pigmentosum serves as a useful model for how basic science and clinical observations have come together.

KNOWLEDGE LINKS TO THE LABORATORY The seminal discovery in understanding the pathogenesis of xeroderma pigmentosum was made by James Cleaver who, as a Ph.D. scientist, headed a basic science laboratory at the University of California in San Francisco.[1] His work had included the development of techniques to study DNA repair in cells in vitro. Making use of the rich intellectual environment of an academic medical center, he introduced himself to one of the dermatologists, John Epstein, asking whether there might be a genetic human photosensitive skin disease in which there was excess of skin cancer. Dr. Epstein told him that xeroderma pigmentosum would be his best choice.

STUDIES IN HUMANS The advice to examine patients with xeroderma pigmentosum led to the first set of observations made in vitro, that the repair of UVR-induced damage in fibroblasts taken from patients with the disease was defective.[1] Cleaver's work was followed rapidly by a second paper from John Epstein and his associates, in which the repair of DNA after ultraviolet irradiation in vivo was observed to be defective in both keratinocytes and fibroblasts.[2] This work set the stage for a series of discoveries made by an increasingly large number of scientists, who demonstrated that the genetic error in xeroderma pigmentosum was a loss in the ability to excise DNA that had been damaged through irradiation.

SUBSEQUENT OBSERVATIONS Subsequently, cell fusion studies based on the concept of "complementation" demon-

TABLE 9-1
Assertion and Principles about Basic Science Approaches to Skin Disease

- Assertion: Basic science research in dermatology at academic medical centers is successful to the extent that it "fits" the resources and core values of that institution.
- Principle 1 (core values): Highly effective laboratory research in skin disease is more likely to occur when conducted in centers with core values and resources that promote research.
- Principle 2 (people): Institutions do not conduct research; people do. Well-trained, energetic, optimistic, and enthusiastic people do the best research, although intelligence helps as well.
- Principle 3 (collaboration): Research is now so complex that scientific collaboration is required. (Scientists work, not as individuals, but in groups. Many groups are international in scope.)
- Principle 4 (resources): It takes time to do research, and time costs money.

strated that there was a family of excision defects, any one of which could be responsible for the disease.[3] Complementation through cell fusion was an established genetic technique, and its use in defining xeroderma pigmentosum illustrated the application of a general genetic concept to skin disease. Tracking down the specific steps in the DNA excision process opened an entirely new field of DNA repair,[4] and a journal is now devoted entirely to this field.[5] An important intellectual circle has been closed recently: James Cleaver delivered the Lila Gruber Cancer Research Lecture at the Annual Meeting of the American Academy of Dermatology in 1976 in which he described his initial work, and in 2007 Errol Friedberg did so again, 31 years later, with a presentation entitled "DNA Repair and DNA Damage Tolerance: Fundamental Mechanisms That Protect Against Cancer."

These experiments were not conducted in a vacuum, without attention to the possibility of benefiting patients. In addition to preventing skin cancer through protection against UVR, pharmaceutical enhancement of DNA repair has now been developed.[6] It appears to diminish the rate of cancer development, at least in patients with xeroderma pigmentosum. This line of investigation began with a series of questions: (1) Is it possible for repair enzymes from a bacterial source to repair UVR-induced damage in human cells? (2) Is it possible to develop a liposome system that allows one to introduce the enzymes into cells? (3) Can one obtain an effect by topical application of liposomes containing the enzymes? (4) Is it possible to develop and manufacture a clinical product (drug) that repairs UVR-induced damage in humans? and (5) Does this product reduce the incidence of malignancy in patients with xeroderma pigmentosum? Through an extensive series of experiments and clinical trials, the answer to each question appears to be "yes."

Each of these developments was rooted in the original observation of James Cleaver, and returning to that observation, what were the critical elements?

Principle 1 (core values): The University of California in San Francisco has been an institution where basic science and clinical science have been valued and promoted for several generations.

Principle 2 (people): Dr. John Epstein studied photosensitive diseases, knew how to find patients with xeroderma pigmentosum, and had energy, inventiveness, and ability. James Cleaver then took the right questions to the laboratory, using contemporary genetic techniques.

Principle 3 (collaboration): Increasing numbers of investigators have been involved with each step of this process.

Principle 4 (resources): Talking, planning, thinking, and learning all take time. The amount of personal investment of time and talent has been considerable.

Recessive Dystrophic Epidermolysis Bullosa and Skin Cancer: A Second Model of Discovery

BACKGROUND A related sequence of observations may be found in a paper published, not 30 years ago, but 2 years ago, in which clinical insight led to a critical set of observations.[7] It began with studies of recessive dystrophic epidermolysis bullosa (RDEB), which is caused by any one of several collagen VII defects; some mutations produce no protein, and some produce a truncated protein. This work was derived from ongoing general studies of epidermolysis bullosa at Stanford University, with the ultimate goal of developing techniques of gene therapy.

THE PROBLEM OF CANCER It was also known that patients with RDEB commonly develop lethal squamous cell carcinomas. This clinical knowledge was key to the subsequent paper. However, this work could only be conducted in laboratories in which in vitro models of cutaneous carcinogenesis were already in development, as was happening in the department of dermatology at Stanford University.

THE CRITICAL EXPERIMENTS The investigators examined Ras-driven tumorigenesis in keratinocytes taken from patients with RDEB. It was noted that cells entirely devoid of collagen VII did not form tumors (in mice), whereas those retaining specific collagen VII fragments were tumorigenic. Importantly, the forced expression of fragments restored tumorigenicity to the collagen VII-null epidermis. Finally, fibronectin-like sequences in that portion of the fragment promoted tumor cell invasion. Thus, tumor-stroma interactions mediated by collagen VII appeared to promote neoplasia. The conclusion is that the retention of collagen VII sequences in a subset of RDEB patients may contribute to their increased susceptibility for squamous cell carcinoma.

But the critical issue was the intellectual context in which this work took place. Ultimately, it was the knowledge that carcinogenesis is common in patients with RDEB, combined with ongoing laboratory studies in cutaneous carcinogenesis and in the blistering diseases that led to this important discovery. Of course, one should not ignore the impact of energetic and inquisitive investigators.

Principle 1 (core values): Stanford University has been an institution where basic science and clinical science have been valued and promoted.

Principle 2 (people): Dating back to the 1980s, investigators at Stanford, led initially by Dr. Eugene Bauer, were interested in epidermolysis bullosa, stemming from his work on collagenase at Washington University in St. Louis. With the arrival of Drs. Khavari and Marinkovich, models of carcinogenesis and models of blistering skin diseases were developed. One of the investigators developed the idea that type VII might be a critical element in carcinogenesis.

Principle 3 (collaboration): Increasing numbers of investigators have been involved with each step of this process.

Principle 4 (resources): Talking, planning, thinking, and learning all take time.

Of course, success is not limited to laboratories in the San Francisco Bay area of California; similar events occur in academic medical centers around the world.

Pemphigus Vulgaris: One Observation Opens a New Field

BACKGROUND A landmark study in characterizing the pathogenesis of pemphigus vulgaris illustrates how one study can precipitate decades of investigation. In the early 1960s, under the leadership of Ernst Witebsky, Ernst Beutner and his colleagues at the University of Buffalo had been studying diseases in which circulating autoantibodies might cause injury to organs such as the thyroid. At the same time, the chair of dermatology at the medical center, James Jordon, oversaw the care of patients with pemphigus. It turned out that his son, Robert Jordan, worked as a medical student in Ernst Beutner's immunologic laboratory on diseases affecting organs other than skin. It should be noted that the observation that follows did not take place in a vacuum. Walter Lever had studied pemphigus for some time, and he had already

differentiated pemphigus and pemphigoid on the basis of classical histopathologic observations.[8] On the other hand, it was not an accident that the observation was made in Buffalo. Ernst Beutner had been interested in fundamental aspects of autoimmunity for many years, and he was a participant in an active group of investigators put together by Witebsky, beginning in 1935.

THE OBSERVATION Thus, given a convergence among clinical responsibilities (James Jordon), basic immunologic science (Ernst Beutner), and an enterprising medical student (Robert Jordon), the researchers demonstrated by direct immunofluorescence microscopy that patients with pemphigus possessed autoantibodies directed against an epidermal intercellular substance.[8,9] Antibodies were found precisely where the pathology develops.

SUBSEQUENT STUDIES This observation was followed over the next 40 years by a series of studies identifying the molecular characteristics of such antibodies, their specific targets, and increasingly novel therapies for patients with the disease. In fact, there are too many investigators who have played important roles in extending the original observation to recognize any one in particular, although the summary of a recent conference written in 2005 by Goldsmith,[10] as well as the relevant chapters in this text, are sufficient to assign credit appropriately.

So, how does this observation conform with the rules cited previously:

- Principle 1 (core values): In 1964, the University of Buffalo was a recognized center for immunologic research. Dr. Beutner had established a highly effective laboratory; Dr. James Jordon had access to a suitable cohort of patients with the disease, and the future Dr. Robert Jordon did the major portion of the work.
- Principle 2 (people): Drs. James Jordon and Ernst Beutner included all that was necessary, once the energy and enthusiasm of Robert Jordon were harnessed.
- Principle 3 (collaboration): Even 40 years ago, this work could not have been accomplished without the collaboration cited above.
- Principle 4 (resources): This work did take time, and the time of Robert Jordon was offered without compensation. Moreover, Dr. Beutner's laboratory was appropriately funded.

TABLE 9-2
Authors, Institutions, and Countries of Origin for Manuscripts[a]

	1956 (27:1–469, 1956) (JULY THROUGH DECEMBER)	2006 (126:1429–1921) (JULY AND AUGUST)
Manuscripts (total)	46	42
Authors		
Authors/manuscript (mean)	2.2	8.1
Single-author manuscripts	14	0
Origin of manuscripts		
One institution	40	11
Two institutions (one country)	6	15
Two or more countries (two continents)	0	16 (10)

[a]Published in two volumes of the *Journal of Investigative Dermatology*, separated by 50 years.

This last example introduces a more complicated set of issues, because the disease under study is not caused by a single gene defect. Rather, the example shows that investigators must address complex diseases, such as psoriasis, atopic dermatitis, cutaneous T-cell lymphoma, and toxic epidermolytic necrolysis, in which many genes play roles. Recent progress in all of these diseases will be found in the chapters that follow, and perhaps there will be even more to say in the next edition of this book.

These examples also presage a trend toward increased collaboration across laboratories and across cities and nations. As a result, contemporary cutaneous research has become international in scope. In the three examples cited above in the sections Repair of Ultraviolet Radiation-Induced Damage: A Model of Discovery; Recessive Dystrophic Epidermolysis Bullosa and Skin Cancer: A Second Model of Discovery; and Pemphigus Vulgaris: One Observation Opens a New Field; collaboration occurred primarily within one institution. It should be noted, however, that the expertise required for cutting-edge research now often requires collaboration by investigators in more than one institution and even among investigators in more than one country. This may be seen in the *Journal of Investigative Dermatology (JID)*, which has served as one of the preferred repositories of cutaneous research results for more than 50 years. Importantly, the extent of collaboration among investigators has increased substantially over that time. Two 6-month periods separated by 50 years in the *JID* were examined (Table 9-2). The unequivocal and dramatic results make two points. First, the number of authors per paper has increased four-fold in 50 years, reflecting the increasing requirement for collaboration among investigators. Second, collaboration now includes investigators located in different institutions, sometimes in the same country (36 percent) and often in different countries (38 percent), even from different continents (24 percent). Fully one-fourth of the manuscripts in 2006 included collaborating investigators from two different continents. The countries represented in 1956 were six in number: the United States, Israel, Brazil, Hungary, Spain, and the Netherlands. By 2006, 16 countries were represented (11 in Europe, 4 in Asia, and 1 in North America). The world of science is becoming smaller.

THE FUTURE OF LABORATORY INVESTIGATION IN DERMATOLOGY

A Resurgence of Clinical Science Can Be Anticipated

Although it is likely that the pace in the development of scientific technologies will only accelerate with time, access to such technologies may not be the rate-limiting step in cutaneous research. In fact, a strong case may be made that the limiting step will be the availability of well-characterized patient populations for study.[11]

In nearly 70 years of publication, one can observe in the *JID* several transitions in emphasis, each reflecting changes in the scientific communities that it represents. In the first half of its life, clinical observation was gradually replaced by experimentation. By the 1970s, there was increasing emphasis on laboratory investigation, as was required by the cutaneous scientists who laid the foundation of scientific dermatology. Of course, this was aided by knowledge that competition among the specialties for national and international funding required excellence in the laboratory. And, since the 1980s, one can observe continuing interest in biochemistry and physiology,

with a growing interest in genetics and bioinformatics. An astounding array of genetic characterizations and identifications have been reported, however primarily for single gene "defects."

More recently, however, there has been growing emphasis on clinical investigation and clinical science. These studies have required well-characterized and uniform patient populations, and the papers reveal a trend in which cohorts of patients are required for the cutting-edge laboratory studies that are now reported in the *JID*. It is not to say that biochemistry and physiology and single-patient studies have been abandoned; rather, this has been a process of supplementation. Four examples can be cited:

1. Winter and colleagues identified a single nucleotide polymorphism changing the sequence of keratin K6HF gene, which was "required" for the expression of pseudofolliculitis barbae in African American men.[12] Their discovery began with access to a well-defined population of American servicemen in Germany.
2. Alamartine and colleagues reported that interleukin 10 promoter polymorphisms conferred susceptibility to cutaneous squamous cell carcinomas in recipients of renal transplants.[13] This discovery required access to a well-defined cohort of renal transplant patients.
3. Warren and colleagues reported that autoantibodies to desmoglein 1 of the immunoglobulin G4 subclass alone were required for the expression of endemic pemphigus foliaceus in Brazil.[14] Access to multiple sera samples from patients and control subjects in a unique region of the world was required for this work.
4. Palmer and colleagues studied the effect of solar-simulated radiation on elicitation phases of contact sensitivity (contact allergic dermatitis).[15] These investigators tested the hypothesis that patients with polymorphic light eruption are resistant to the expected suppression of contact sensitivity elicitation reactions by UVR. Importantly, their hypothesis arose from the earlier observation that patients with this disease were resistant to the UVR-induced suppression that occurs normally during sensitization. Their ultimate conclusion that mechanisms of immunologic sensitization and elicitation diverge substantially depended on the availability of patients with a unique cutaneous disorder.

Impact of Priorities Set By the National Institutes of Health

The largest source of funding for skin research in the United States is the National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS), 1 of 27 institutes and centers under the umbrella of the National Institutes of Health. The leaders at NIAMS published recently a "Long-Range Plan for Research" (http://www.niams.nih.gov/an/stratplan/index.htm), which is useful in examining the future of basic science approaches to the pathophysiology of skin disease. Although other institutes within the National Institutes of Health, especially the National Cancer Institute, also fund cutaneous research, because of the size of its funding, NIAMS takes the lead in setting priorities. It should be noted that reports of this sort possess substantial influence on the direction of biomedical research, including the types of laboratory science that are funded and the priorities for funding. Although the entire report should be examined, a brief summary provides considerable insight into the future. Leaders of NIAMS anticipate the following:

1. New emphasis on biologic mechanisms of disease, genetic and environmental influences, and neuroimmune and neuroendocrine pathways;
2. A search for biomarkers of skin diseases;
3. Increasing emphasis on clinical research;
4. A search for complex genetic influences on disease;
5. Interest in new animal models;
6. Emphasis on research infrastructure; and
7. Emphasis on disease-specific research.

Finally, research needs and opportunities are predicted by NIAMS to be in the disciplines of:

- Developmental and molecular biology
- Percutaneous penetration and absorption
- Wound healing
- Inflammatory and immune skin diseases
- Molecular genetics of skin diseases
- Technology research
- Drug therapies and biologic agents for skin diseases
- Gene therapies for skin diseases or gene therapies that use skin
- Regenerative medicine
- Clinical and outcomes research
- Skin disease prevention and aging skin

Cutting-edge laboratory investigation today, and for the foreseeable future, will continue to follow the principles enumerated in Table 9-1. It will most likely be conducted in academic centers with core values and resources that promote research, by people who are motivated and well trained, commonly by investigators who collaborate with others, and where financial resources are available. Finally, clinicians who care for patients will have opportunities with increasing frequency to play critical roles in patient-centered investigation. National borders have virtually disappeared in cutaneous science, as investigators collaborate often, and with whomever they believe to be appropriate. Importantly, collaboration with scientists in other countries means that there is a chance for a lively exchange of personal and cultural information; simply put, doing science can be informative and rewarding.

CHAPTER 10

Innate and Adaptive Immunity in the Skin

Robert L. Modlin
Jenny Kim
Dieter Maurer
Christine Bangert
Georg Stingl

The human immune system is comprised of two distinct functional parts: innate and adaptive. These two components have different types of recognition receptors and differ in the speed in which they respond to a potential threat to the host (Fig. 10-1). Cells of the innate immune system, including macrophages and dendritic cells (DCs), use pattern recognition receptors encoded directly by the germline DNA, respond to biochemical structures commonly shared by a variety of different pathogens, and elicit a rapid response against these pathogens, although no lasting immunity is generated. In contrast, cells of the adaptive immune system, T and B lymphocytes, bear specific antigen receptors encoded by rearranged genes, and in comparison to the innate response, adaptive immunity develops more slowly. A unique feature of the adaptive immune response is its ability to generate and retain memory; thus, it has the capability of providing a more rapid response in the event of subsequent immunologic challenge. Although the innate and adaptive immune responses are distinct, they interact and can each influence the magnitude and type of their counterpart. Together, the innate and adaptive immune systems act in synergy to defend the host against infection and cancer. This chapter describes the roles of the innate and adaptive immune response in generating host defense mechanisms in skin.

◀ Psoriasis vulgaris: chronic stable type. Multiple large scaling plaques on the trunk, arm, buttocks, and abdomen. Lesions are polycyclic and confluent and form geographic patterns. This patient was cleared by acitretin/psoralen and ultraviolet A light combination treatment within 4 weeks.

INNATE IMMUNE RESPONSE

Immune mechanisms that are used by the host to immediately defend itself are referred to as *innate immunity*. These include physical barriers such as the skin and mucosal epithelium; soluble factors such as complement, antimicrobial peptides, chemokines, and cytokines; and cells, including monocytes/macrophages, DCs, natural killer cells (NK cells), and polymorphonuclear leukocytes (PMNs) (Fig. 10-2).

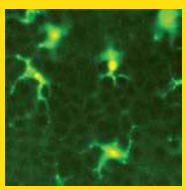
Physical and Chemical Barriers[1]

Physical structures prevent most pathogens and environmental toxins from harming the host. The skin and the epithelial lining of the respiratory, gastrointestinal, and the genitourinary tracts provide physical barriers between the host and the external world. Skin, once thought to be an inert structure, plays a vital role in protecting the individual from the external environment. The epidermis impedes penetration of microbial organisms, chemical irritants, and toxins; absorbs and blocks solar and ionized radiation; and inhibits water loss (see Chap. 45).

Molecules of the Innate Immune System

COMPLEMENT[2] (See eFig. 10-2.1 in online edition; see also Chap. 36) One of the first innate defense mechanisms that

INNATE AND ADAPTIVE IMMUNITY AT A GLANCE



- Innate immune responses are
  - used by the host to immediately defend itself;
  - determine the quality and quantity of many adaptive immune responses;
  - are short lived;
  - have no memory;
  - include physical barriers (skin and mucosal epithelia);
  - include soluble factors such as complement, antimicrobial peptides, chemokines, and cytokines;
  - include cells such as monocytes/macrophages, dendritic cells, natural killer cells, and polymorphonuclear leukocytes.
- Adaptive immune responses
  - have memory;
  - have specificity;
  - are long-lasting;
  - in skin, are initiated by dendritic antigen-presenting cells in the epidermis (Langerhans cells) and by dermal dendritic cells;
  - are executed by T lymphocytes and antibodies produced by B lymphocytes.

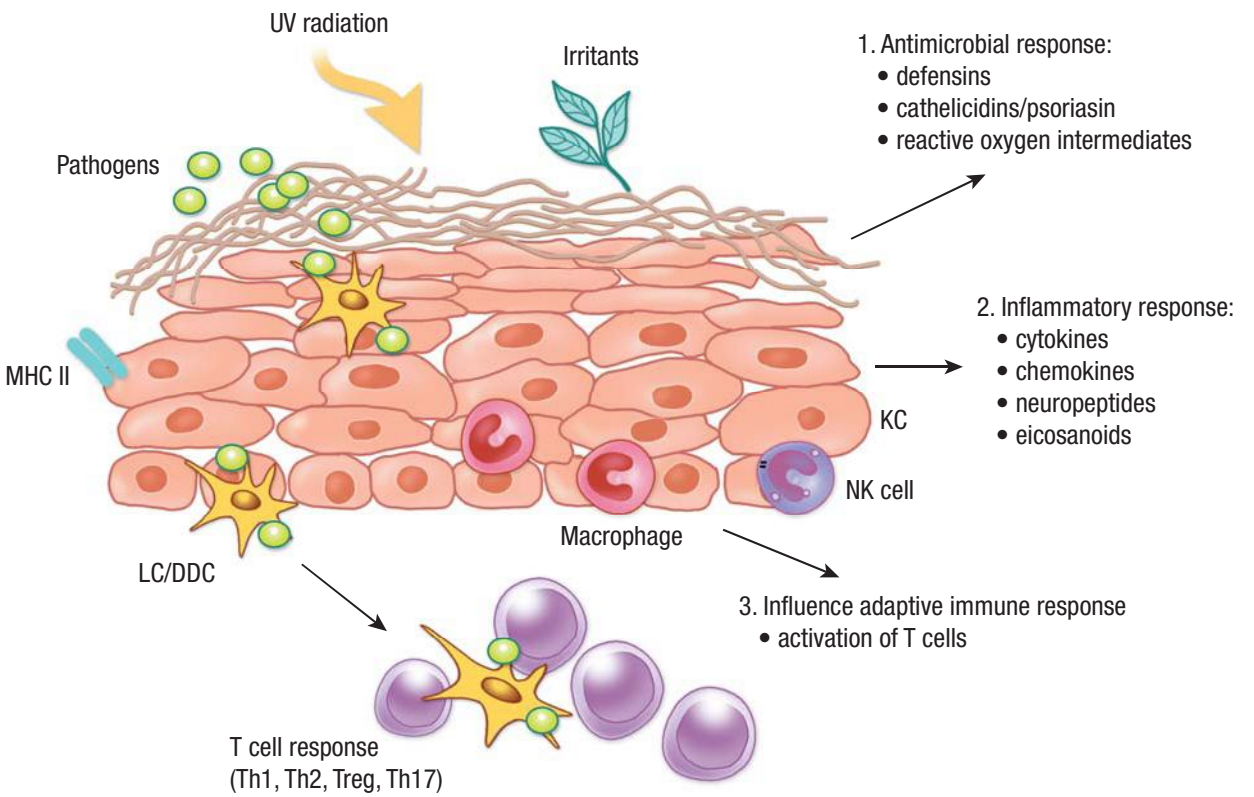
▲ **FIGURE 10-1** The immune system of higher vertebrates uses both innate and adaptive immune responses. These immune responses differ in the way they recognize foreign antigens and the speed with which they respond; yet, they complement each other in eradicating foreign pathogens.

awaits pathogens that overcome the epithelial barrier is the alternative pathway of complement. Unlike the classic complement pathway that requires antibody triggering, the lectin-dependent pathway as well as the alternative pathway of complement activation can be spontaneously activated by microbial surfaces in the absence of specific antibodies (see eFig. 10-2.1 in on-line edition). In this way, the host defense mechanism is activated immediately after encountering the pathogen without the 5 to 7 days required for antibody production.

NEUROPEPTIDES The skin is a rich source of neuropeptides, including neurotransmitters [e.g., calcitonin gene–related peptide (CGRP), substance P, somatostatin] and neurohormones (see Chap. 101). The inhibitory effects of CGRP and substance P on Langerhans cell (LC) antigen presentation function are discussed later. The neurohormone proopiomelanocortin (POMC) is produced by the pituitary gland as well as by a number of cell types, including keratinocytes.

ANTIMICROBIAL PEPTIDES[6] Antimicrobial peptides are an important evolutionarily conserved innate host defense mechanism in many organisms. Also, keratinocytes produce such peptides, including cathelicidins (LL-37) and β-defensins (BD-1, BD-2, BD-3). Their antimicrobial mechanism of action may relate to



▲ **FIGURE 10-2** The innate immune response in skin. In response to exogenous factors, such as foreign pathogens, ultraviolet (UV) radiation, and chemical irritants, innate immune cells [granulocytes, mononuclear phagocytes, natural killer (NK) cells, keratinocytes] mount different types of responses including: (1) release of antimicrobial agents; (2) induction of inflammatory mediators, such as cytokines, chemokines, neuropeptides, and eicosanoids; and (3) initiation and modulation of the adaptive immune response. DDC = dermal dendritic cell; KC = keratinocyte; LC = Langerhans cell; MHC II = major histocompatibility complex class II; Th1, Th2, 17 = T helper 1, 2, Th17; Treg = T regulatory cell.

membrane insertion and pore formation. Adrenomedullin, members of the CGRP superfamily, α melanocyte-stimulating hormone, and secretory leukocyte protease inhibitor (antileukoprotease, human seminal inhibitor I) are among previously identified peptides whose antimicrobial activities were discovered later.

β-Defensins are cysteine-rich cationic low-molecular-weight antimicrobial peptides. The first human β-defensin, HBD-1, was isolated from human hemofiltrate obtained from a patient with end-stage renal disease. It is constitutively expressed in the epidermis and is not transcriptionally regulated by inflammatory agents. HBD-1 has antimicrobial activity against Gram-negative bacteria and appears to play a role in keratinocyte differentiation. A second human β-defensin, HBD-2, was discovered in extracts of lesions from psoriasis patients.[7] Unlike HBD-1 expression, HBD-2 expression is inducible by microbes, including *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Candida albicans*.[7] Not only can microbes stimulate expression of HBD-2, but pro-inflammatory cytokines such as tumor necrosis factor-α (TNF-α) and interleukin 1 (IL-1) can also induce HBD-2 transcription in keratinocytes.[7] When tested for antimicrobial activity, HBD-2 showed effective activity against Gram-negative bacteria such as *Escherichia coli* and *P. aeruginosa* but not against Gram-positive bacteria such as *S. aureus*.[7] A third β-defensin, HBD-3, has now been isolated and characterized. Contact with TNF-α and with bacteria was found to induce HBD-3 messenger RNA expression in keratinocytes. In addition, HBD-3 demonstrated potent antimicrobial activity against *S. aureus* and vancomycin-resistant *Enterococcus faecium*. Therefore, HBD-3 is among the first human β-defensins in skin to demonstrate effective antimicrobial activity against Gram-positive bacteria. The localization of human β-defensins to the outer layer of the skin and the fact the β-defensins have antimicrobial activity against a variety of microbes suggest that human β-defensins are an essential part of cutaneous innate immunity. Furthermore, evidence indicating that human β-defensins attract DCs and memory T cells via CC chemokine receptor 6 (CCR6)[8] provides a link between the innate and the adaptive immunity in skin.

Cathelicidins are cationic peptides with a structurally variable antimicrobial domain at the C-terminus. Whereas in mammals like pigs or cattle a variety of cathelicidin genes exists, men (and mice) possess only one gene. The human precursor protein hCAP18 (human cathelicidin antimicrobial protein 18) is produced by skin cells, including keratinocytes, mast cells, neutrophils, and ductal cells of eccrine glands. Neutrophil proteases (i.e., proteinase 3) process hCAP18 into the effector molecule LL-37, which plays an important role in cutaneous host defense because of its pronounced antibacterial,[9,10] antifungal,[11] and antiviral[12,13] activities. LL-37 further contributes to innate immunity by attracting mast cells and neutrophils via formyl peptide receptor–like 1 and by inducing mediator release from the latter cells via a G protein–dependent, immunoglobulin E (IgE)–independent mechanism.[14] It has now been shown that LL-37 is secreted into human sweat, where it is cleaved by a serine protease–dependent mechanism into its peptides RK-31 or KS-30. Interestingly, these components display an even more potent antimicrobial activity than intact LL-37.[15]

In atopic dermatitis (see Chap. 14), LL-37 is downregulated, probably due to the effect of the T2 cytokines IL-4 and IL-13, which renders atopic skin more susceptible to skin infections with, for example, *S. aureus*, vaccinia virus (eczema vaccinatum), or herpes simplex virus (eczema herpeticum).[10,12,13]

Another important human antimicrobial peptide has now been identified, psoriasin (S100A7).[16] It is secreted predominantly by keratinocytes and plays a major role in killing the common gut bacterium *E. coli*. In fact, in vivo treatment of human skin with anti-psoriasin antibodies results in the massive growth of *E. coli*.[16]

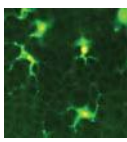
OTHER MEDIATORS Other secreted protein mediators that can be synthesized and released from keratinocytes and that may play a role in host defense are the complement components C3 and factor B. Keratinocytes are among the cells that synthesize eicosanoids, an ensemble of lipid mediators regulating inflammatory and immunologic reactions. They can produce and release the cyclooxygenase product prostaglandin E_2, which has both pro-inflammatory and immunosuppressive properties and, when acting on DCs, promotes the development of IL-4–dominated type 2 T-cell responses.[17] Other keratinocyte-derived eicosanoids include the neutrophil chemoattractant leukotriene B_4, the pro-inflammatory 12-lipoxygenase product 12(s)-hydroxyeicosatetraenoic acid, and 15-hydroxyeicosatetraenoic acid, an anti-inflammatory and immunosuppressive metabolite of the 15-lipoxygenase pathway.

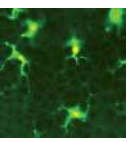
Another group of biologic response modifiers originating in keratinocytes and other epidermal cells is free radical molecules, now generally referred to as *reactive oxygen species*. These include the superoxide radical ($O_2^{\cdot -}$), hydrogen peroxide (H_2O_2), the hydroxyl radical ($OH^{\cdot}$), nitric oxide (NO), and others. These radicals are generally viewed as dangerously reactive entities threatening the integrity of many tissues. The skin is particularly at risk because it is exposed to oxygen from both inside and outside and because of the activation of oxygen by light (see Chaps. 88 and 89). Free radicals probably contribute to solar damage and photoaging of the skin. However, certain reactive oxygen species have potent inflammation-inducing properties (e.g., free oxygen radicals) as well as immunomodulatory properties (e.g., NO), and thus provide an important host defense mechanism against microbial invasion. For discussion of these molecules, the reader is referred to the review by Bickers and Athar.[18]

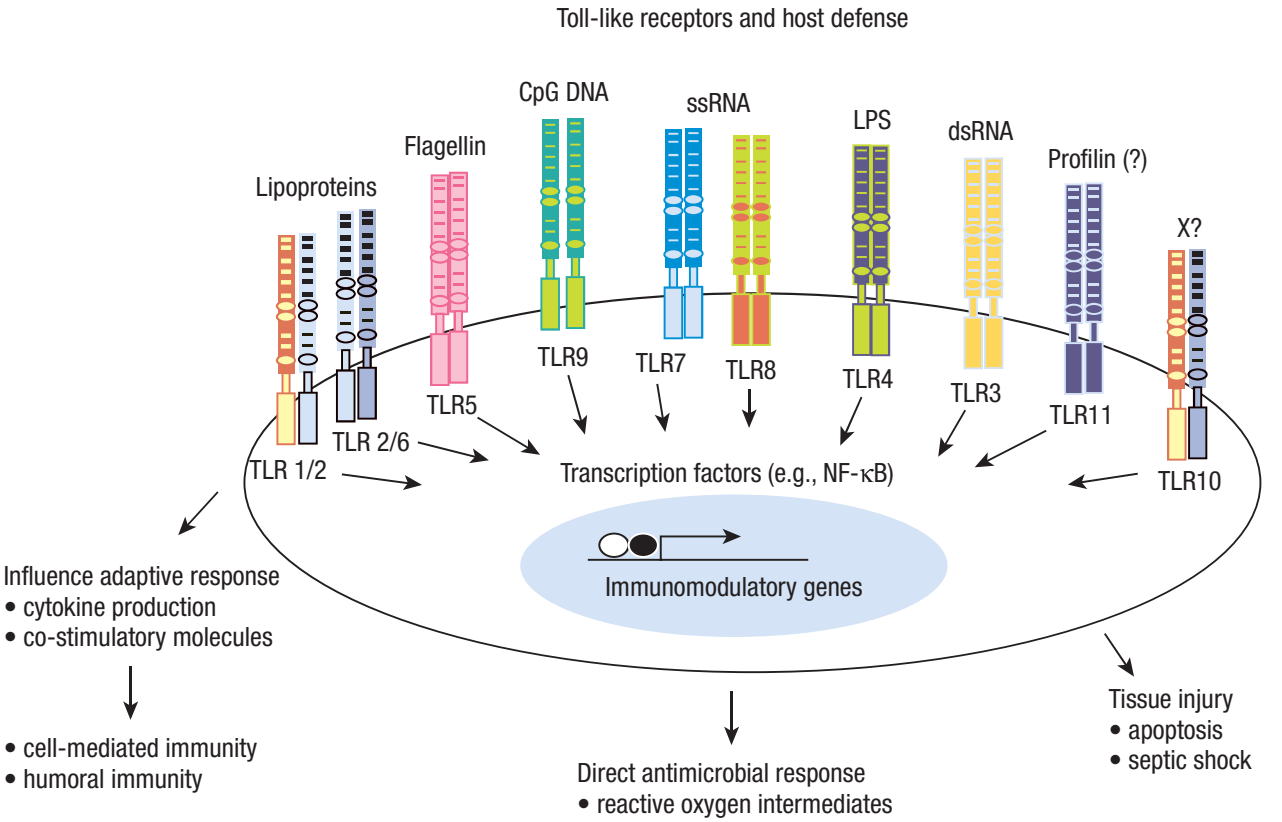
PATTERN RECOGNITION RECEPTORS How do the cells of the innate immune system recognize foreign pathogens? One way that pathogens can be recognized and destroyed by the innate immune system is via receptors on phagocytic cells. Unlike adaptive immunity, the innate immune response relies on a relatively small set of germline-encoded receptors that recognize conserved molecular patterns that are shared by a large group of pathogens. These are usually molecular structures required for survival of the microbes and therefore are not subject to selective pressure. In addition, pathogen-associated molecular patterns are specific to microbes and are not expressed in the host system. Therefore, the innate immune system has mastered a clever way to distinguish between self and nonself and relays this message to the adaptive immune system.

Of key importance was the discovery of the Toll-like receptors (TLRs), named after the *Drosophila* Toll gene whose protein product, Toll, participates in innate immunity and in dorsoventral development in the fruit fly.[19,20] The importance of Toll signaling in mammalian cells was confirmed by the demonstration that the transmembrane leucine-rich protein TLR4 is involved in lipopolysaccharide (LPS) recognition.[21]

In addition to TLRs, there exist a variety of other transmembrane molecules







▲ **FIGURE 10-3** Toll-like receptors (TLRs) mediate innate immune response in host defense. Activation of TLRs by specific ligands induces (1) cytokine release and co-stimulatory molecules that instruct the type of adaptive immune response; (2) direct antimicrobial response; and (3) tissue injury. CpG DNA = immunostimulatory cytosine- and guanine-rich sequences of DNA; dsRNA = double-stranded RNA; LPS = lipopolysaccharide; NF-κB = nuclear factor κB; ssRNA = single-stranded RNA; X = ligand unknown.

that sense the presence of pathogens. These include the triggering receptors expressed on myeloid cells (TREM) proteins,[25] the family of Siglec molecules,[26] and a group of C-type lectin receptors.[27] The latter are prominently expressed on antigen-presenting cells (APCs) as, for instance, dectin-1 and DC-SIGN [DC-specific intercellular adhesion molecule 3 (ICAM-3) grabbing nonintegrin]. They are able to mediate efficient binding of microorganisms such as yeast and mycobacteria, respectively; achieve their phagocytosis; and induce activation of signaling pathways that result in the maturation of phagosomes as well as in the production of reactive oxygen and nitrogen derivatives.

Members of the TREM protein family function as amplifiers of innate responses. Extreme examples of the consequences of microbe activation of TREM proteins are life-threatening septicemia and the deadly hemorrhagic fevers caused by Marburg and Ebola virus infection.[28]

TOLL-LIKE RECEPTORS[29] There is now substantial evidence to support a role for mammalian TLRs in innate immunity (Fig. 10-3). First, TLRs recognize pathogen-associated molecular patterns present in a variety of bacteria, fungi, and viruses. Second, TLRs are expressed at sites that are exposed to microbial threats. Third, the activation of TLRs induces signaling pathways that, on the one hand, stimulate the production of effector molecules (reactive oxygen species, NO), and, on the other, promote the expression of co-stimulatory molecules and the release of cytokines and, as a result, the augmentation of the adaptive response. Fourth, TLRs directly activate host defense mechanisms that then combat the foreign invader.

TLRs were initially found to be expressed in all lymphoid tissues but were most highly expressed in peripheral blood leukocytes, including monocytes, B cells, T cells, granulocytes, and DCs. Certain TLRs (e.g., TLR2) are internalized after ligation. In such a situation, TLRs are recruited to the pathogen-containing phagosomes and discriminate between Gram-positive and Gram-negative bacteria,[31] thus surveying the intracellular compartments of the cells for microbial invaders.

The expression of TLRs on cells of the monocyte/macrophage lineage is consistent with the role of TLRs in modulating inflammatory responses via cytokine release. Because these cells migrate into sites that interface with the environment—lung, skin, and gut—the location of TLR-expressing cells would situate them to defend against invading microbes. TLR expression by adipocytes, intestinal epithelial cells, and dermal endothelial cells supports the notion that TLRs serve a sentinel role with regard to invading microorganisms. The regulation of TLR expression is critical to their role in host defense, yet few factors have been identified that modulate this process. IL-4 acts to downregulate TLR expression,[32] which suggests that T helper 2 (Th2) adaptive immune responses might inhibit TLR activation.

In *Drosophila*, Toll is critical for host defense. The susceptibility of mice with spontaneous mutations in TLRs to bacterial infection indicates that mammalian TLRs play a similar role. Activation of TLR2 by microbial lipoproteins induces activation of the inducible NO synthase (NOS-II or iNOS) promoter,[37] which leads to the production of NO, a known antimicrobial agent. There is strong evidence that TLR2 activation

leads to killing of intracellular *Mycobacterium tuberculosis* in both mouse and human macrophages.[38] In mouse macrophages, bacterial lipoprotein activation of TLR2 leads to a NO-dependent killing of intracellular tubercle bacilli. In human monocytes and alveolar macrophages, bacterial lipoproteins similarly activate TLR2 to kill intracellular *M. tuberculosis*; however, this occurs by an antimicrobial pathway that is NO independent, but dependent on the activation of the vitamin D receptor and potentially the induction of cathelicidin.[39] These data provide evidence that mammalian TLRs have retained not only the structural features of *Drosophila* Toll that allow them to respond to microbial ligands but also the ability to directly activate antimicrobial effector pathways at the site of infection.

The activation of TLRs can also be detrimental, leading to tissue injury. The administration of LPS to mice can result in manifestations of septic shock, which is dependent on TLR4.[21] Evidence suggests that TLR2 activation by *Propionibacterium acnes* induces inflammatory responses in acne vulgaris, which lead to tissue injury.[40] Aliprantis et al. demonstrated that microbial lipoproteins induce features of apoptosis via TLR2.[41] Thus, microbial lipoproteins have the ability to elicit both TLR-dependent activation of host defense and tissue pathology. This dual signaling pathway is similar to TNF receptor and CD40 signaling, which leads to both nuclear factor-κB activation and apoptosis.[42,43] In this manner, it is possible for the immune system to use the same molecules to activate host defense mechanisms and then, by apoptosis, to downregulate the response from causing tissue injury. Activation of TLR can lead to the inhibition of the major histocompatibility complex (MHC) class II antigen presentation pathway, which can downregulate immune responses leading to tissue injury but may also contribute to immunosuppression.[44] Finally, Toll activation has been implicated in bone destruction.[35]

The critical biologic role of TLRs in human host defense can be deduced from the finding that TLR4 mutations are associated with LPS hypo-responsiveness in humans.[45] By inference, one can anticipate that humans with genetic alterations in TLR may have increased susceptibility to certain microbial infections. Furthermore, it should be possible to exploit the pathway of TLR activation as a means to endorse immune responses in vaccines and treatments for infectious diseases as well as to abrogate responses detrimental to the host.

Cells of the Innate Immune System

PHAGOCYTES Two key cells of the innate immune system are characterized by their phagocytic function: macrophages and PMNs. These cells have the capacity to take up pathogens, recognize them, and destroy them. Some of the functions of these cells are regulated via TLRs and complement receptors as outlined earlier.

PMNs are normally not present in skin; however, during inflammatory processes, these cells migrate to the site of infection and inflammation, where they are the earliest phagocytic cells to be recruited. These cells have receptors that recognize pathogens directly (see Pattern Recognition Receptors), and due to their expression of FcγRIII/CD16 and C3bR/CD35, can phagocytose microbes coated with antibody and with the complement component C3b. As a consequence, granules (containing myeloperoxidase, elastase, lactoferrin, collagenase, and other enzymes) are released, and microbicidal superoxide radicals (O_2^-) are generated (see Chap. 30).

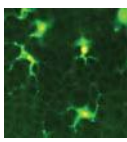
Effector Functions of Phagocytes. Activation of phagocytes by pathogens induces several important effector mechanisms, for example, triggering of cytokine production. A number of important cytokines are secreted by macrophages in response to microbes, including IL-1, IL-6, TNF-α, IL-8, IL-12, and IL-10. IL-1, IL-6, and TNF-α play a critical role in inducing the acute-phase response in the liver and in inducing fever for effective host defense. TNF-α induces a potent inflammatory response to contain infection. IL-8 is important as a mediator of PMN chemotaxis to the site of infection (see also Chap. 11 on cytokines).

Another important defense mechanism triggered in phagocytes in response to pathogens is the induction of direct antimicrobial responses. Phagocytic cells such as PMNs and macrophages recognize pathogens, engulf them, and induce antimicrobial effector mechanisms to kill the pathogens. PMNs generate oxygen-dependent or oxygen-independent killing. The release of toxic oxygen radicals, lysosomal enzymes, and antimicrobial peptides such as the human neutrophil defensins leads to direct killing of the microbial organisms.[6] Similarly, activation of TLRs on macrophages by microbial ligands upregulates iNOS (NOS-II), which results in rapid generation of NO and powerful microbicidal activity.[37] Macrophages use this mechanism to contain some infectious organisms not susceptible to PMN attack, such as mycobacteria, certain fungi, and parasites.

Phagocytic cells of the innate immune system can also be activated by cells of the adaptive immune system. CD40 is a 50-kd glycoprotein present on the surface of B cells, monocytes, DCs, and endothelial cells. The ligand for CD40 is CD40L, a type II membrane protein of 33 kd, preferentially expressed on activated $CD4^+$ T cells and mast cells. CD40-CD40L interaction plays a crucial role in the development of effector functions. $CD4^+$ T cells activate macrophages and monocytes to produce TNF-α, IL-1, IL-12, interferon-γ (IFN-γ), and NO via CD40-CD40L interaction. CD40L has also been shown to rescue circulating monocytes from apoptotic death, thus prolonging their survival at the site of inflammation. In addition, CD40-CD40L interaction during T-cell activation by APCs results in IL-12 production. Therefore, it can be concluded that CD40-CD40L interactions between T cells and macrophages play a role in maintenance of Th1-type cellular responses and mediation of inflammatory responses. Other studies have established a role for CD40-CD40L interactions in B-cell activation, differentiation, and Ig class switching.[55] In addition, CD40-CD40L interaction leads to upregulation of B7.1 (CD80) and B7.2 (CD86) on B cells. This co-stimulatory activity induced on B cells then acts to amplify the response of T cells. These mechanisms underscore the importance of the interplay between the innate and the adaptive immune system in generating an effective host response.

EOSINOPHILS (See Chap. 30) Eosinophils are a distinct class of bone marrow–derived granulocytes that normally constitute only a small fraction of peripheral blood leukocytes and occur in even smaller numbers in peripheral tissues. The cytokines granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3 and, most importantly, IL-5 are critical for their development and maturation.

NATURAL KILLER CELLS[58] NK cells appear as large granular lymphocytes. In humans, the vast majority of these cells exhibit the $CD3^-$, $CD56^+$, $CD16^+$, $CD94^+$, $CD161^+$ phenotype. Their function is to



survey the body looking for altered cells, be they transformed or infected with viruses (e.g., cytomegalovirus), bacteria (e.g., *Listeria monocytogenes*), or parasites (e.g., *Toxoplasma gondii*). These pathogens are then killed directly via perforin/granzyme- or Fas/FasL-dependent mechanisms or indirectly via the secretion of cytokines (e.g., IFN-γ).

How do NK cells discriminate between normal and transformed or pathogen-infected tissue?

All nucleated cells express the MHC class I molecules. NK cells have receptors, termed *killer inhibitory receptors*, that recognize the self MHC class I molecules. This recognition results in the delivery of a negative signal to the NK cell that paralyzes it. If a nucleated cell loses expression of its MHC class I molecules, however, as often happens after malignant transformation or virus infection, the NK cell, on encountering it, will become activated and kill it.

In addition, NK cells have activating receptors that bind MHC-like ligands on target cells. One such receptor is NKGD2, which binds to the human non-classic MHC class I chain-related A and B molecules, MICA and MICB.[59] MICA and MICB are not expressed in substantial amounts on normal tissues but are overexpressed on carcinomas.[60] NK cells are able to kill MICA/MICB-bearing tumors, which suggests a role for NKGD2 in immune surveillance.

Another cell type that, at least in mice, could serve a similar function is the IFN-producing killer DC, which shares several features with DCs and NK cells.[61,62] Their human equivalent has yet to be identified.

KERATINOCYTES Once thought to be inert, keratinocytes, the predominant cells in the epidermis, can mount an immune and/or inflammatory response through secretion of cytokines and chemokines, arachidonic acid metabolites, complement components, and antimicrobial peptides.

Keratinocytes of unperturbed skin produce only a few of these mediators, such as the cytokines IL-1, IL-7, and transforming growth factor-β (TGF-β), constitutively. Resident keratinocytes contain large quantities of pre-formed and biologically active IL-1α as well as immature IL-1β in their cytoplasm.[63] The likely in vivo role of this stored intracellular IL-1 is that of an immediate initiator of inflammatory and repair processes after epidermal injury. IL-7 is an important lymphocyte growth factor that may have a role in the survival and proliferation of the T lymphocytes of human skin. Some evidence exists for the IL-7–driven propagation of lymphoma cells in Sézary syndrome.

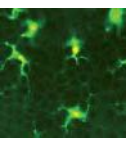
TGF-β, in addition to its growth-regulating effects on keratinocytes and fibroblasts, modulates the inflammatory as well as the immune response[64] and is important for LC development (see further in Development, Maintenance, and Fate of Skin Dendritic Cells under Langerhans Cells and Other Dendritic Cells).[65] On delivery of certain noxious, or at least potentially hazardous, stimuli (e.g., hypoxia, trauma, non-ionizing radiation, haptens or other rapidly reactive chemicals like poison ivy catechols, silica, LPSs, and microbial toxins), the production and/or release of many cytokines is often dramatically enhanced. The biologic consequences of this event are manifold and include the initiation of inflammation (IL-1, TNF-α, IL-6, members of the chemokine family), the modulation of LC phenotype and function (IL-1, GM-CSF, TNF-α, IL-10, IL-15), T-cell activation (IL-15, IL-18),[66,67] T-cell inhibition (IL-10, TGF-β),[68] and skewing of the lymphocytic response in either the type 1 (IL-12, IL-18),[69] type 2 (thymic stromal lymphopoietin),[70] or Th17 (IL-23) direction.[71] In some cases, keratinocytes may also play a role in amplifying inflammatory signals in the epidermis originating from numerically minor epidermal cell subsets. One prominent example is the induction of pro-inflammatory cytokines such as TNF-α in keratinocytes by LC-derived IL-1β in the initiation phase of allergic contact dermatitis.[72] In the presence of a robust stimulus, keratinocyte-derived cytokines may be released into the circulation in quantities that cause systemic effects. During a severe sunburn reaction, for example, serum levels of IL-1, IL-6, and TNF-α are clearly elevated and probably responsible for the systemic manifestations of this reaction, such as fever, leukocytosis, and the production of acute-phase proteins.[73] There is also evidence that the ultraviolet (UV) radiation–inducible cytokines IL-6 and IL-10 can induce the production of autoantibodies and thus be involved in the exacerbation of autoimmune diseases such as lupus erythematosus. The fact that secreted products of keratinocytes can reach the circulation could conceivably also be used for therapeutic purposes. The demonstration by Fenjves et al.[74] that grafting of apolipoprotein E gene–transfected human keratinocytes onto mice results in the detection of apolipoprotein E in the circulation of the mouse supports the feasibility of such an approach.

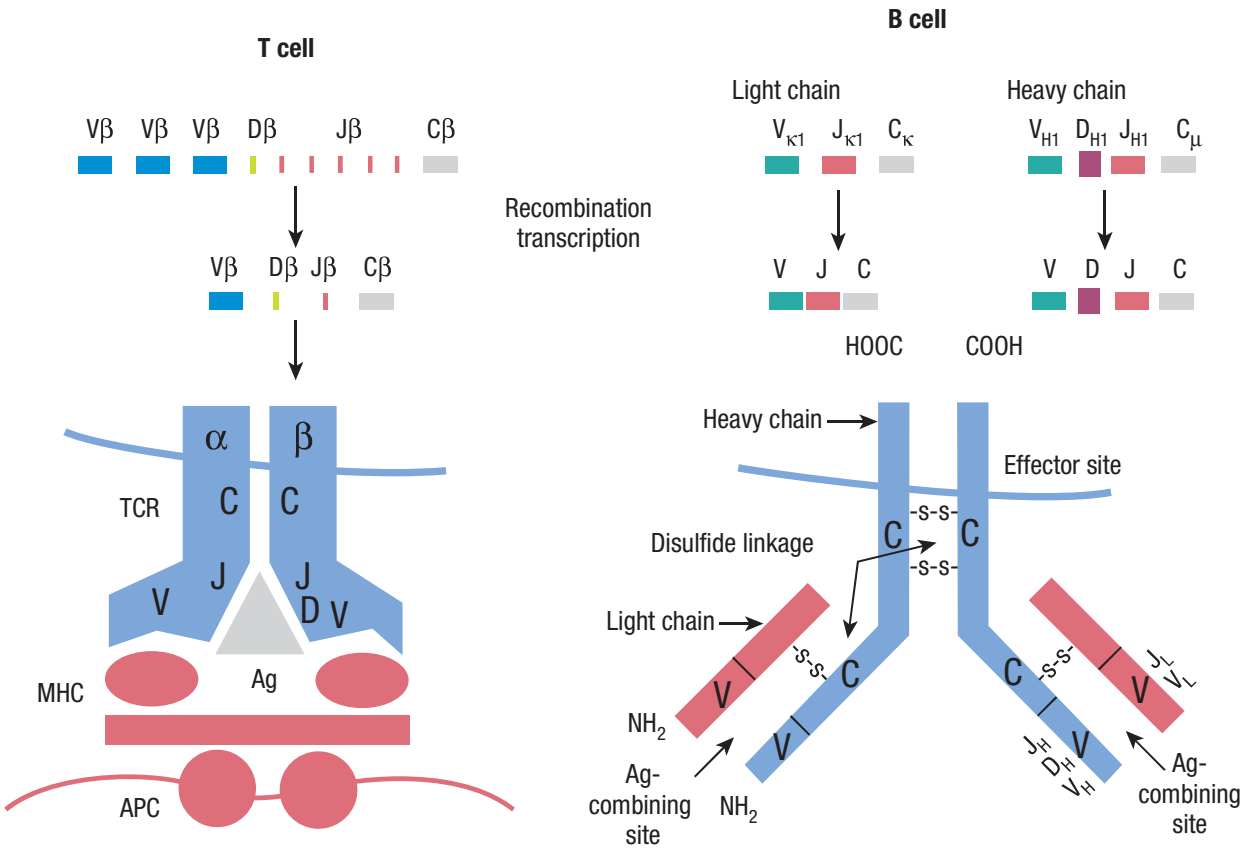
Another important function of keratinocytes is the production/secretion of factors governing the influx and efflux of leukocytes into and out of the skin. Two good examples are the chemokines thymus and activation-regulated chemokine (TARC; CC chemokine ligand 17, or CCL17) and cutaneous T cell–attracting chemokine (CTACK)/CCL27 and their corresponding receptors CCR4 and CCR10, selectively expressed on skin-homing T lymphocytes. Blocking of both chemokines drastically inhibits the migration of T cells to the skin in a murine model of contact hypersensitivity (CHS).[75] Another more distinct function of a keratinocyte-derived chemokine in the recruitment of leukocyte sub-populations to the epidermis is suggested by the selective expression of the macrophage inflammatory protein 3α (MIP-3α)/CCL20 receptor, CCR6, on LCs and LC precursors[76] (see Development, Maintenance, and Fate of Skin Dendritic Cells and T Lymphocyte Sub-Populations).

The demonstration of cytokine receptors on and cytokine responsiveness by keratinocytes established that the functional properties of these cells can be subject to regulation by cells of the immune system. As a consequence, keratinocytes express or are induced to express immunologically relevant surface moieties that can be targeted by leukocytes for stimulatory or inhibitory signal transduction.

In addition to cytokines, keratinocytes secrete other factors such as neuropeptides, eicosanoids, and reactive oxygen species. These mediators have potent inflammatory and immunomodulatory properties and play an important role in the pathogenesis of cutaneous inflammatory and infectious diseases as well as in aging.

Keratinocytes can also synthesize complement and related receptors, including the C3b receptor [complement receptor 1 (CR1), CD35], the Epstein-Barr virus receptor CR2 (C3d receptor, CD21), the C5a receptor (CD88), the membrane co-factor protein (CD46), the decay-accelerating factor (CD55), and complement protectin (CD59). CD59 may protect keratinocytes from attack by complement. Its engagement by CD2 stimulates the secretion of pro-inflammatory cytokines from keratinocytes. Membrane co-factor (CD46) is reported to be a receptor for M protein of group A streptococci and for measles virus.[80] Its ligation induces pro-inflammatory cytokines in keratinocytes such as IL-1α, IL-6, and GM-CSF.





▲ **FIGURE 10-4** T-cell receptor (TCR) gene rearrangements. This diagram shows how diversity in TCRs and antibodies is generated by gene rearrangement. For the TCR, rearrangement of the β chain is shown, and for antibodies, that of immunoglobulin M heavy and light chains is depicted. The encoded antibody recognizes the nominal antigen per se, whereas the encoded TCR recognizes antigen in the context of an appropriate antigen-presenting molecule. Ag = antigen; APC = antigen-presenting cell; C = constant segment; D = diversity segment; J = joining segment; MHC = major histocompatibility complex; V = variable segment.

ADAPTIVE IMMUNE RESPONSE

The strength and the type of the innate response determines both the quantity and quality of an adaptive response initiated by dendritic APCs in the epidermis (LCs) and dermis (dermal DCs or DDCs) and executed by T lymphocytes and antibodies.

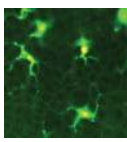
Lymphocytes

The adaptive immune response is mediated by T and B lymphocytes. The unique role of these cells is the ability to recognize antigenic specificities in all their diversity. All lymphocytes derive from a common bone marrow stem cell. This finding has been exploited in various clinical settings, with attempts to restore the entire lymphocyte pool by bone marrow or stem cell transplantation.

TYPES OF LYMPHOCYTES B cells mature in the fetal liver and adult bone marrow. They produce antibodies—protein complexes that bind specifically to particular molecules defined as antigens. As a consequence of recombinatorial events in different Ig gene segments (V or variable; D or diversity; J or joining), each B cell produces a different antibody molecule (Fig. 10-4). Some of this antibody is present on the surface of the B cell, conferring the unique ability of that B cell to recognize a specific antigen. B cells then differentiate into plasma cells, the actual antibody-producing and -secreting cells. The secreted antibody mediates humoral immune responses. In skin, humoral immunity contributes to the immune defense against extracellular pathogens. Antibodies bind to microbial agents and neutralize them or facilitate uptake of the pathogen by phagocytes that destroy them. Antibodies are also responsible for mediating certain pathologic conditions in skin. In particular, antibodies against self-antigens lead to autoimmune disease, typified in the pathogenesis of pemphigus and bullous pemphigoid. Furthermore, IgE antibodies to foreign substances elicit anaphylactic reactions (e.g., penicillin urticaria).

T cells mature in the thymus, where they are selected to live or to die. Those T cells that will have the capacity to recognize foreign antigens are positively selected and can enter the circulation. Those T cells that react to self are negatively selected and destroyed. If the immune system is envisioned as a bureaucracy, the T cell is the ideal bureaucrat. T cells have the unique ability to direct other cells of the immune system. They do this, in part, by releasing cytokines. For example, T cells contribute to cell-mediated immunity (CMI), required to eliminate intracellular pathogens, by releasing cytokines that activate macrophages and other T cells. T cells release cytokines that activate NK cells and also release cytokines that permit the growth, differentiation, and activation of B cells.

During their maturation in the thymus, thymocytes start to express the molecules that allow T cells to display their unique functional capacity, that is, to specifically recognize antigen in an MHC-restricted fashion (see General Principles of Antigen Presentation). These are the T-cell antigen receptor (TCR) and the accessory molecules CD4 and CD8. The vast majority of positively selected mature thymocytes are either $CD4^+/CD8^-$ (single positive) MHC class II–restricted cells or $CD8^+/$



CD4⁻ (single positive) MHC class I–restricted cells, but some of them express the TCR but no accessory molecules (double-negative thymocytes). These mature thymocytes leave the thymus and migrate to the peripheral lymphoid tissues (lymph nodes, spleen, Peyer's patches, etc.). This process is most active in early infancy and childhood but continues with decreasing output well into adult life.

The TCR is a complex of molecules consisting of an antigen-binding heterodimer (α/β or γ/δ chains) that is noncovalently linked with five CD3 subunits (γ, δ, ε, ζ/η). TCR α/β or TCR γ/δ molecules must be paired with CD3 molecules to be inserted into the T-cell surface membrane[81] (see Fig. 10-4).

The TCR chains form the actual antigen-binding unit, whereas the CD3 complex mediates signal transduction, which results in either productive activation or nonproductive silencing of the T lymphocyte.

The TCR chains have amino acid sequence homology with and structural similarities to Ig heavy and light chains. The genes encoding TCR molecules are encoded as clusters of gene segments (V, J, D, C or constant) that rearrange during T-cell maturation. Together with the addition of nucleotides at the junction of rearranged gene segments, this recombinatorial process, which involves the enzymes recombinase activating gene 1 and 2, results in a heterogeneity and diversity of the antigen recognition unit that is broad enough to allow for a successful host defense.

The accessory molecules CD4 and CD8 stabilize the interaction of the TCR with the MHC-linked peptide antigen. Although CD4 binds to MHC class II molecules, CD8 acts as an adhesive by binding to MHC class I molecules.

T-LYMPHOCYTE SUB-POPULATIONS T cells can be classified and subdivided in different ways: (1) on the basis of the accessory molecules CD4 and CD8, (2) on the basis of their activation status (naive, memory, effector T cells), and (3) on the basis of their functional role in the immune response, which is often linked to the cytokine secretion property of the respective cell population.

As far as the activation status of T cells is concerned, it appears that the strength of the antigenic signal also determines the ultimate fate of a naive T cell. On robust activation, these cells differentiate into effector cells, which are then selected to enter the memory pool according to their capacity to access and use survival signals. Effector-memory cells home to peripheral tissues and are responsible for immediate protection against challenge. CCR7⁺ central-memory cells, on the other hand, home to secondary lymphoid organs and are responsible for secondary or long-term responses to antigen and might be involved in long-term maintenance of effector-memory cells.[82]

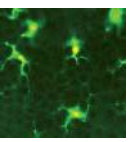
With regard to the functional capacities of various T-cell subsets, it was originally assumed that CD4⁺ cells predominantly subserve helper functions and that CD8⁺ cells act as killer cells. Many exceptions to this rule are now known to exist; for example, both CD4⁺ and CD8⁺ regulatory cells are found, but CD4⁺ cells are still commonly referred to as helper T cells (Th cells) and CD8⁺ cells as cytotoxic T cells.

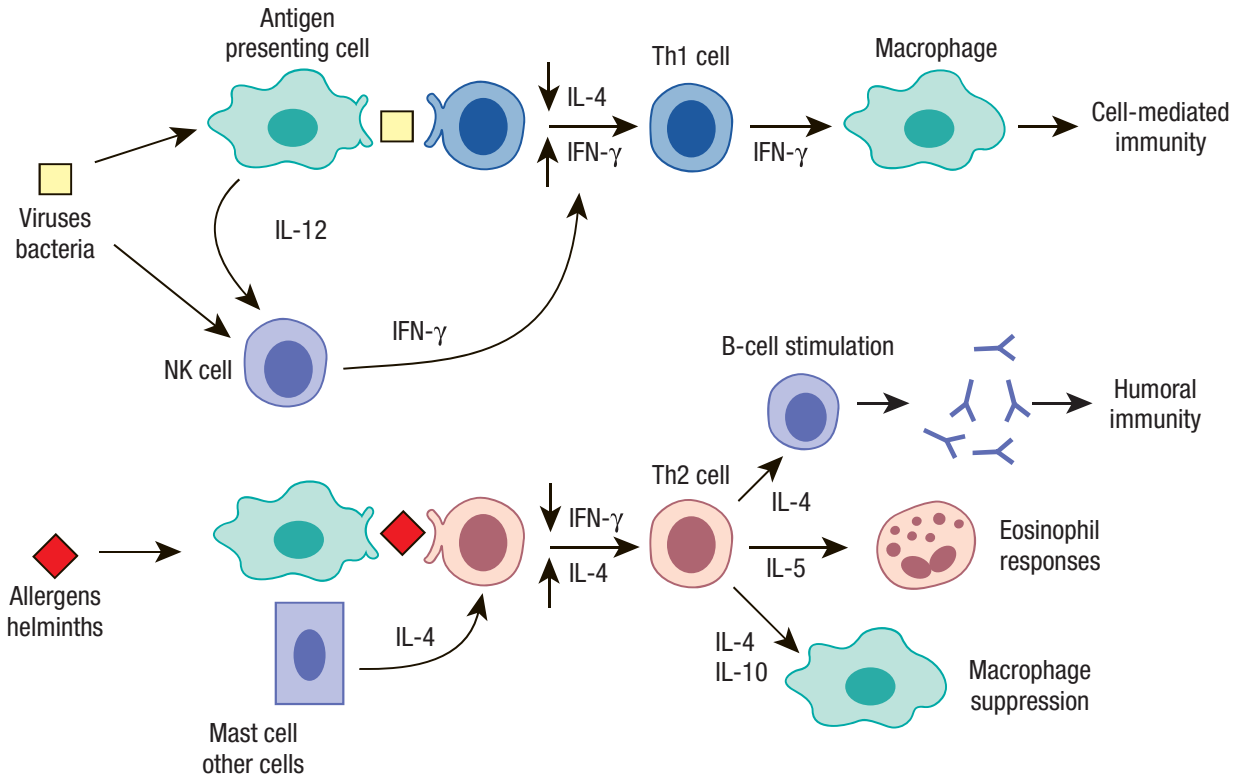
Naive Th cells, so-called *Th0 cells*, can differentiate into several functional classes of cells during an immune response: (1) Th1 cells (type 1 T cells); (2) Th2 cells (type 2 T cells); (3) Th17 cells; (4) regulatory T cells (Treg); and (5) natural killer T cells (NKT).

T HELPER 1/T HELPER 2 PARADIGM T cells that produce IL-2, IFN-γ, and TNF are termed *Th1 cells*. They are the main carriers of CMI. Other T cells produce IL-4, IL-5, IL-6, IL-13, and IL-15. These are termed *Th2 cells* and are primarily responsible for extracellular immunity (see later).[83,84] Many factors influence whether an uncommitted Th cell develops into a mature Th1 or Th2 cell. The cytokines IL-12 and IL-4, acting through signal transducer and activator of transcription (STAT) 4 and 6, respectively, are key determinants of the outcome, as are antigen dose, level of co-stimulation, and genetic modifiers. Certain transcription factors have causal roles in the gene-expression programs of Th1 and Th2 cells. For example, the T-box transcription factor T-bet is centrally involved in Th1 development, inducing both transcriptional competence of the IFN-γ locus and selective responsiveness to the growth factor IL-12.[85] By contrast, the zinc-finger transcription factor GATA-3 seems to be crucial for inducing certain key attributes of Th2 cells, such as the transcriptional competence of the Th2 cytokine cluster, which includes the genes encoding IL-4, IL-5, and IL-13.[86,87]

In murine models of intracellular infection, resistant versus susceptible immune responses appear to be regulated by these two T-cell sub-populations.[50,51,88] Th1 cells, primarily by the release of IFN-γ, activate macrophages to kill or inhibit the growth of the pathogen and trigger cytotoxic T-cell responses, which results in mild or self-curing disease. In contrast, Th2 cells facilitate humoral responses and inhibit some cell-mediated immune responses, which results in progressive infection. These cytokine patterns are cross-regulatory. The Th1 cytokine IFN-γ downregulates Th2 responses. The Th2 cytokines IL-4 and IL-10 downregulate both Th1 responses and macrophage function. The result is that the host responds in an efficient manner to a given pathogen by making either a Th1 or Th2 response. Sometimes the host chooses an inappropriate cytokine pattern, which results in clinical disease.

The discovery that Th1/Th2 responses could contribute to the outcome of human disease due to a single antigen was first delineated by the study of leprosy. Because leprosy presents as a spectrum of clinical manifestations that correlate with the immune response to the pathogen, it provides an extraordinary window into immune regulation in humans. At one end of the spectrum, patients with tuberculoid leprosy typify the resistant response that restricts the growth of the pathogen. The number of lesions is few, although tissue and nerve damage is frequent. At the opposite end of this spectrum, patients with lepromatous leprosy represent extreme susceptibility to *M. leprae* infection. In lepromatous leprosy, the skin lesions are numerous and growth of the pathogen is unabated, which results in many viable *M. leprae* throughout the skin lesions. These clinical presentations correlate with the level of CMI against *M. leprae*. The standard measure of CMI to the pathogen is the Mitsuda reaction. Patients are challenged by intradermal injection of *M. leprae*, and induration is measured 3 weeks later. The test result is positive in tuberculoid patients and negative in lepromatous patients. It is widely agreed that T cells involved in CMI are pivotal in determining the outcome of infection with *M. leprae*, because, in correlation with skin test results, lymphocyte reactivity is positive in tuberculoid patients but is negative in lepromatous patients. Yet, there is an interesting paradox in that CMI and humoral responses exhibit an inverse relationship. Anti–*M. leprae* antibody levels are most elevated





▲ **FIGURE 10-5** The role of innate immunity in determining the type of cytokine response. IFN = interferon; IL = interleukin; NK = natural killer; Th1, Th2 = T helper 1, 2.

in patients with the lepromatous form of the disease and therefore are not thought to play a role in protection.

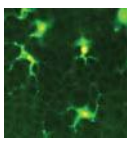
This paradox can best be explained in terms of the patterns of cytokines in the lesions.[52,89] The Th1 cytokines, principally, IL-2 and IFN-γ, are more strongly expressed in tuberculoid lesions, whereas the Th2 cytokines, notably IL-4, IL-5, and IL-10, are characteristic of lepromatous lesions. These cytokine patterns can be assigned to the major T-cell subsets observed in the lesions: $CD4^+$ T cells predominate in tuberculoid lesions and $CD8^+$ T cells predominate in lepromatous lesions. All of the *M. leprae*–specific $CD4^+$ T cells derived from tuberculoid patients produce IL-2 and IFN-γ and are designated $CD4^+$ *type 1* cells. The $CD8^+$ T cells derived from lepromatous lesions produce high levels of IL-4 and low levels of IFN-γ and are designated $CD8^+$ *type 2* cells.

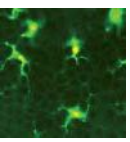
In terms of the immunopathogenesis of leprosy (see Chap. 186), the abundance of IL-2 and IFN-γ in tuberculoid lesions is likely to contribute to the resistant state of immunity in these patients. IL-2 may contribute to the host defense by inducing the clonal expansion of activated, cytokine-producing T cells and augments the production of IFN-γ. IFN-γ is well known to enhance production of reactive oxygen and nitrogen intermediates by macrophages and stimulates them to kill or restrict the growth of intracellular pathogens. The cytokines found to be increased in lepromatous lesions might be expected to contribute to the immune unresponsiveness and failure of macrophage activation in these individuals. IL-4 and IL-10 may contribute to the elevated anti–*M. leprae* antibodies in lepromatous patients via their role in differentiation and Ig class switching of B cells, but they also have a negative immunoregulatory effect on CMI, downregulating T-cell and macrophage function.

Of particular interest to immunologists is the delineation of factors that influence the T-cell cytokine pattern. The innate immune response is one important factor involved in determining the type of T-cell cytokine response (Fig. 10-5).

The ability of the innate immune response to induce the development of a Th1 response is mediated by release of IL-12, a 70-kd heterodimeric protein.[46] For example, in response to an intracellular pathogen, macrophages release IL-12, which acts on NK cells to release IFN-γ. The presence of IL-12, IL-2, and IFN-γ, with the relative lack of IL-4, facilitates Th1 responses. In contrast, in response to allergens or extracellular pathogen, mast cells or basophils release IL-4, which in the absence of IFN-γ leads to differentiation of T cells along the Th2 pathway. It is intriguing to speculate that keratinocytes may also influence the nature of the T-cell cytokine response. Keratinocytes can produce IL-10, particularly after exposure to UVB radiation.[68] The released IL-10 can specifically downregulate Th1 responses, thus facilitating the development of Th2 responses.

T HELPER 17 CELLS Not every T cell–mediated disease can be easily explained by the Th1/Th2 paradigm. Some T-cell sub-populations are characterized by the secretion of IL-17. These cells are therefore termed *Th17 cells*. IL-23, a member of the IL-12 family, is apparently of key importance for the development of Th17 cells,[90] which have been linked to a growing list of autoimmune and inflammatory diseases such as neuroinflammatory disorders, asthma, lupus erythematosus, rheumatoid arthritis, and, most notably, psoriasis.[71] IL-17 is believed to contribute to the pathogenesis of these diseases by acting as a potent pro-inflammatory mediator. It was originally assumed that Th1 and Th17 cells arise from a common Th1 precursor, but it now appears that Th17 cells are a completely separate and early lineage of effector $CD4^+$ Th cells produced directly from naive $CD4^+$ T cells.





CYTOTOXIC T CELLS In responding to an intracellular pathogen (e.g., a virus) the T cell must lyse the infected cell. To do so, it must be able to recognize and respond to antigenic peptides encoded by this pathogen and displayed on the cell surface. For this to occur, antigens arising in the cytosol are cleaved into small peptides by a complex of proteases, called the *proteasome*. The peptide fragments are then transported from the cytosol into the lumen of the endoplasmic reticulum, where they associate with MHC class I molecules. These peptide–class I complexes are exported to the Golgi apparatus and then to the cell surface (see General Principles of Antigen Presentation for more details). The maturation of a $CD8^+$ T cell to a killer T cell requires not only the display of the antigenic signal but also the delivery of helper signals from $CD4^+$ T cells, for which the functional interaction between CD40 on the APC and CD40L on the $CD8^+$ T cell can substitute.

Two distinct subsets of cytotoxic T cells have been identified and can be differentiated by the mechanism by which they kill targets,[91] the end result being the induction of a programmed cell death known as *apoptosis*.[92,93] The first mechanism of cytotoxicity involves the interaction of two cell surface proteins, Fas ligand (CD95L) on the T cells and Fas (CD95) on the target. Ligation of these molecules delivers a signal through Fas that induces the apoptosis cascade in the target. The second mechanism involves the release of cytoplasmic granules present in such T cells. These granules contain perforin, which induces a pore in the target, and granzymes, serine esterases that, when injected into cells, trigger the apoptotic pathway. Such granules also contain granulysin, a protein with a broad spectrum of antimicrobial activity against bacteria, fungi, and parasites.[91,94] In this manner, cytotoxic T cells can directly kill microbial invaders. Besides contributing to host defense against infection and tumors, cytotoxic T cells can also contribute to tissue injury. For example, cytotoxic T cells recognize self-antigens of melanocytes and thus may contribute to the pathogenesis of vitiligo.[95]

REGULATORY T CELLS An important type of immunomodulatory T cells that controls immune responses is the so-called *regulatory T cells (Treg cells)*, formerly known as *T suppressor cells*.[96] Treg cells are induced by immature APCs/DCs and play key roles in maintaining tolerance to self-antigens in the periphery. Loss of Treg cells is the cause of organ-specific autoimmunity in mice that results in thyroiditis, adrenalitis, oophoritis/orchitis, and so on. Treg cells are also critical for controlling the magnitude and duration of immune responses to microbes. Under normal circumstances, the initial antimicrobial immune response results in the elimination of the pathogenic microorganism and is then followed by an activation of Treg cells to suppress the antimicrobe response and prevent host injury. Some microorganisms (e.g., *Leishmania* parasites, mycobacteria) have developed the capacity to induce an immune reaction in which the Treg component dominates the effector response. This situation prevents elimination of the microbe and results in chronic infection.

Regulatory functions are mediated by distinct groups of $CD4^+$, $CD8^+$, and NKT cells. The best-characterized Treg subset is the $CD4^+/CD25^+/CTLA\text{-}4^+/$GITR (glucocorticoid-induced TNF receptor family–related gene)$^+/FoxP3^+$ lymphocytes. The transcription factor FoxP3 is specifically linked to the suppressor function, as evidenced by the findings that mutations in the FoxP3 gene cause the fatal autoimmune and inflammatory disorder of scurfy in mice and IPEX (*i*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, *X*-linked) in humans. The cytokines TGF-β and IL-10 are thought to be the main mediators of suppression.

$CD8^+$ cells can be activated to become suppressor cells by antigenic peptides that are presented in the context of an MHC class Ib molecule [Qa1 in mice; human leukocyte antigen E (HLA-E) in humans]. $CD8^+$ Treg cells suppress T cells that have intermediate affinity for self or foreign antigens and are primarily involved in self-nonself discrimination.

NKT cells are a distinctive population of T cells. They have properties of NK cells but, at the same time, express TCR α/β that consists of an invariant α chain (Vα24-JαQ) paired with various Vβ chains. These cells specifically recognize certain tumor cell–associated or bacterial glycolipids in the context of CD1 molecules and are therefore implicated in tumoricidal and bactericidal host responses (see CD1-Dependent Antigen Presentation). On antigenic stimulation, NKT cells produce large quantities of cytokines, particularly IL-4 and IL-10, and can use them to suppress Th1 responses. The biologic relevance of these in vitro data can be deduced from the observation that depletion of NKT cells can aggravate and accelerate Th1-mediated autoimmune diseases in mice, such as insulin-dependent diabetes, multiple sclerosis, and inflammatory bowel disease.[97]

LYMPHOCYTES OF THE SKIN Normal skin is the prototype of a nonlymphoid organ, that is, an organ in which primary lymphocyte responses are not initiated.

As opposed to normal mouse skin, in which a resident population of dendritic epidermal T cells uniformly equipped with a nonpolymorphic, canonical TCR γ/δ exists, normal human skin contains only small numbers of lymphocytes, the majority of which are located in the dermis and express TCR α/β rather than γ/δ.[98,99] These T cells of normal human dermis are preferentially clustered around postcapillary venules of the superficial plexus high in the papillary dermis and are often situated just beneath the dermal-epidermal junction and within, or in close proximity to, adnexal appendages such as hair follicles and eccrine sweat ducts. Most of them belong to the $CD45RO^+$ memory population—with the $CD4^+/CD8^-$ dominating over the $CD4^-/CD8^+$ phenotype—and express the skin-homing receptor cutaneous lymphocyte–associated antigen (CLA).[100]

At perivascular sites, most T cells stain positively for HLA-DR and CD25, which indicates that some of them represent effector cells and others perhaps Treg cells.

Epidermal T cells account for approximately 2 percent to 3 percent of all $CD3^+$ cells in normal human skin. They reside primarily in the basal and suprabasal layers, often in close apposition to LCs. Most of them are $CD8^+/CD4^-$ lymphocytes that bear TCR α/β dimers. There also exists a minor subset of double-negative ($CD4^-/CD8^-$) intraepidermal T cells with TCRs of either the α/β or the γ/δ phenotype. Their relationship, if any, to the murine dendritic epidermal T cell is not known.

The mechanism by which T lymphocytes traffic into skin depends on a chain of molecular events between cells. In skin-draining lymph nodes, the interaction of naive T cells with antigen-bearing cutaneous DCs (LCs, DDCs) results in the induction of the cell surface molecule CLA.[101]

CLA is a glycoprotein that defines a subset of memory T cells that home to skin. CLA is a glycosylated form of P-selectin glycoprotein ligand 1 that is expressed constitutively on all human peripheral blood T cells. The level of CLA

on cells is regulated by an enzyme, α(1,3)-fucosyl transferase VII, that modifies P-selectin glycoprotein ligand 1. In this manner, CLA^+ cells bind to both E-selectin and P-selectin, strengthening the interaction between circulating T cells and cutaneous endothelium, whereas CLA^- cells bind P-selectin but do not bind E-selectin.[102,103]

In patients with allergic contact dermatitis (see Chap. 13), the CLA^+ subset, but not the CLA^- subset, contains the T cells with the capacity to respond to the allergen.[104] Furthermore, more than 90 percent of T cells in inflammatory skin disease are CLA^+. CLA facilitates the entry of T lymphocytes into skin by mediating tethering and rolling of T cells on vascular endothelial cells through binding to E-selectin. Chemokines released by the endothelial cells increase the binding affinity of T-cell adhesion molecules. T cells firmly adhere to endothelium by the interaction of lymphocyte function–associated antigen 1 (LFA-1) with ICAM-1 and very late antigen 4 with vascular cell adhesion molecule. The interaction with the endothelial cells is now sufficiently strong to permit transmigration of the T cells into the skin and allow their participation in the inflammatory process.

A diversity of chemokines (see Chap. 12) contributes to tissue-specific T-cell homing. Leukocytes and nonleukocytes residing in the skin can produce chemokines with T-cell chemotactic properties, such as IL-8/CXC chemokine ligand 8 (CXCL8), Gro α/CXCL1, IFN-γ inducible protein-10/CXCL10, monokine induced by IFN-γ/CXCL9, macrophage chemoattractant protein-1 (MCP-1)/CCL2, MCP-2/CCL8, MCP-3/CCL7, regulated on activation normal T-cell expressed and secreted (RANTES)/CCL5, MIP-1α/CCL3, MIP-1β/CCL4, and lymphotactin/XCL1.

Of particular importance for skin homing of memory T cells is the interaction of TARC/CCL17 and CTACK/CCL27 with their corresponding chemokine receptors on CLA^+ T cells, CCR4 and CCR10, respectively.

The CC chemokine TARC/CCL17 is expressed by vascular endothelial cells of venules in normal and inflamed human skin[105] (see Chap. 163). CLA^+ memory T cells in peripheral blood displaying CCR4 adhere to cutaneous vessels via TARC/CCL17-induced binding to ICAM-1 and are thereby attracted to the skin. In addition, the recruitment of type 2 (Th2) T cells into diseased skin can be mediated by TARC/CCL17. In atopic dermatitis, a prominent example for a Th2-mediated immune response, this chemokine is known to be upregulated in basal keratinocytes.[106]

CTACK/CCL27, another CC chemokine, is also critically involved in the homing process under physiologic and inflammatory conditions.[75] It is constitutively produced by basal keratinocytes and is also displayed on the surface of dermal endothelial cells. Its expression is upregulated by IL-1β and TNF-α and downregulated by glucocorticosteroids. The receptor for CCL27, CCR10, is expressed on CLA^+ T cells, and in vivo experiments have demonstrated a pivotal role for CCL27-CCR10 interactions in T cell–mediated skin inflammation.[107]

Adhesion molecule interactions that help to anchor T cells in the epidermis include the attachment of LFA-1 (CD11a)–bearing T cells to $ICAM\text{-}1^+$ (CD54) keratinocytes in inflamed skin and, more physiologically, the $\alpha_E\beta_7$-E-cadherin–mediated binding of T cells to nonactivated keratinocytes.

The accumulation of T cells in skin is not stochastic. It is abundantly clear that specific populations of T cells, identified by cell surface determinants and their cytokine profile, localize to the skin. Various cell surface determinants on T cells allow detection of their presence. Initially, functional T-cell populations could be delineated in skin according to their expression of the CD4 and CD8 molecules. In the majority of inflammatory conditions studied, including lichen planus, psoriasis, and atopic dermatitis, $CD4^+$ T cells outnumber $CD8^+$ T cells, in proportions similar to or somewhat greater than those seen in the peripheral blood. However, in the study of the skin lesions of human leprosy, $CD4^+$ T cells were found to be predominant in the tuberculoid form of the disease, whereas $CD8^+$ T cells were found to be predominant in the lepromatous form of the disease.[108] Because all leprosy patients have an excess of $CD4^+$ T cells in their blood, the abundance of $CD8^+$ T cells in lepromatous skin lesions provides clear evidence for the specific accumulation of T-cell populations in skin.

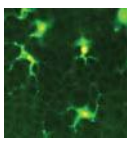
A perhaps more relevant marker of T-cell populations is the diversity of their TCRs. The clearest example is the clonality of the T-cell population in cutaneous T-cell lymphoma, in which a single V gene usage is found to predominate in different skin lesions from the same individual[109,110] (see Chap. 146).

The dominant expression of several TCR V genes in an infiltrate is thought to indicate that a small number of antigens drive the local inflammatory response. Unlike in normal human skin whose TCR repertoire is rather divergent,[111] a limited TCR V gene usage has been reported to be present in the skin lesions of leprosy,[112] psoriasis,[113] basal cell carcinoma, and countless other reactions in which T cells are present. However, in no instance has the limited set of antigens been defined and correlated with the TCR usage.

The most direct indication of relevant T-cell populations in skin is determination of the number of T cells that recognize the antigen. It has been documented that 1 in 1000 to 1 in 10,000 T cells in the peripheral blood recognize a given antigen. In the skin, however, approximately 1 in 50 to 1 in 100 T cells recognize the antigen causing the disease.[114,115] Thus there is as much as a 100-fold enrichment of antigen-reactive T cells at the site of cutaneous inflammation.

With regard to survival and/or expansion of T cells of human skin/epidermis, it appears that IL-2, IL-7, and IL-15[111] play important roles. The latter two T-cell growth factors can be produced by human epidermal cells, and all are overexpressed in T cell–rich skin lesions of patients with tuberculoid leprosy.

The Th1/Th2 paradigm provides insight into the pathogenesis of many skin diseases in which T cells have an immunologic role. There is ample evidence that the Th1/Th2 paradigm is not rigid; there are situations in which a mixture of cytokines is found and examples of T-cell clones, known as *Th0 cells*, that secrete a combination of Th1 and Th2 cytokines. However, it has been possible to find a number of dermatologic conditions in which either a Th1 or Th2 cytokine pattern predominates. In the realm of cutaneous infection, leprosy (see T Helper 1/T Helper 2 Paradigm) and leishmaniasis are outstanding examples of diseases with a clinical spectrum in which Th1 and Th2 cytokines appear to have a pathogenic role. Leishmaniasis, like leprosy, is not a single disease entity but a set of clinical entities, each with a differing immunopathogenesis. As in leprosy, the type 1 cytokine pattern is characteristic of leishmaniasis lesions (see Chap. 206) in which CMI to the parasite is strong and the lesions self-cure; the type 2 pattern typifies lesions in which immunity to the parasite is weak and the cutaneous lesions are progressive.[117,118] Studies in animal models suggest that it may be possible to induce effective CMI by vac-



cination using a combination of parasite antigens and recombinant IL-12.[119] This immunotherapeutic strategy engenders a Th1 cytokine response. Th1 responses are involved in immunologic resistance to *Borrelia burgdorferi*[120] and *Treponema pallidum*,[121] the causative agents of Lyme disease and syphilis, respectively.

Concepts of the pathogenesis of atopic dermatitis (see Chap. 14) include a central role for allergen-specific T cells that produce Th2 or type 2 cytokines, including IL-4 and IL-5. Allergen-specific T cells with this cytokine profile have been demonstrated in the peripheral blood and skin lesions of subjects with active disease.[122–124] In addition, the lesions of atopic dermatitis contain abundant expression of IL-10, although the source of this cytokine is likely to be tissue macrophages and keratinocytes.[125] The Th2 pattern of cytokines together is thought to induce increased Ig production, particularly of IgE, mast cell growth, and the infiltration of eosinophils. These cytokines may also downregulate Th1 responses, which would account for the increased susceptibility to cutaneous bacterial infection.

Evidence suggests that pruritus, a key symptom of atopic dermatitis, may also be linked to the Th2 response. The cytokine IL-31 induces severe pruritus and dermatitis in mice and is preferentially expressed in Th2 cells. Human IL-31 is significantly upregulated in pruritic forms of skin inflammation (atopic dermatitis, prurigo nodularis) but not in non-pruritic forms (psoriasis), and circulating CLA^+ memory T cells of patients with atopic dermatitis produce higher levels of IL-31 that the T cells of donors with psoriasis.[126,127]

Clinical trials attempting to alter the Th2 response in atopic dermatitis through the administration of IFN-γ have shown that this treatment induces significant but modest clinical improvement but no reduction in IgE levels in some patients.[128] This was noteworthy, because Th2 cytokines help B cells produce autoantibodies in pemphigus vulgaris[129] (see Chap. 52). The beneficial effect of IFN-γ came as somewhat of a surprise in that a mediator shift has been described in atopic dermatitis, with Th2 cytokines dominating in acute lesions and Th1 cytokines in chronic lesions.[130]

In allergic contact dermatitis (see Chap. 13), sensitization involves the development of a Th1 response, as evidenced by the predominating IL-2 and IFN-γ production of murine T cells sensitized in vitro to haptenated APCs.[131] The situation in the elicitation phase is less clear. In nickel contact dermatitis, antigen-specific Th1-type T-cell clones were described,[132] as were Th2-type infiltrating T cells in lesional skin.[133]

Th1/Th2 responses may be involved in antitumor immunity. For example, IL-4 and IL-10 predominate in the lesions of basal cell and squamous cell carcinoma, whereas the Th1 response is present in benign neoplasms[54] (see Chaps. 114 and 115). The source of the IL-10 in these cutaneous carcinomas is the tumor itself, a mechanism by which the cancer can downregulate antitumor T-cell responses. Within the spectrum of cutaneous T-cell lymphoma, mycosis fungoides represents a Th1 cytokine response, whereas patients with the more progressive Sézary syndrome exhibit a Th2 cytokine response[134] (see Chap. 146). It was originally assumed that Th1 cytokine responses predominate in involved and, to a lesser extent, uninvolved skin of patients with psoriasis.[135] More recent evidence suggests that IL-23, rather than IL-12, is the key cytokine in this disease[136] and that it exerts its effects by triggering IL-22 production by Th17 cells, which results in dermal inflammation and acanthosis.[137] Although it is uncertain, these Th17 cells may be autoimmune, responding to self-antigens in the epidermis.

Whatever the role for the observed cytokine patterns in human disease, the Th1-Th2-Th17 paradigm exposes new targets for therapy. Trials are under way to exploit this knowledge through the use of cytokine agonists and antagonists to shift the balance between the different Th patterns for the benefit of the patient.

Langerhans Cells and Other Dendritic Cells

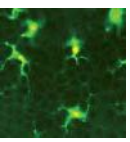
DEFINITION In 1868, the medical student Paul Langerhans, driven by his interest in the anatomy of skin nerves, identified a population of dendritically shaped cells in the suprabasal regions of the epidermis after impregnating human skin with gold salts.[138] These cells, which later were found in virtually all stratified squamous epithelia of mammals, are now eponymously referred to as *Langerhans cells*. There also exist substantial numbers of dendritic leukocytes in the dermis. Although some of them represent LCs on their way into or out of the epidermis, most of these cells are phenotypically slightly different from LCs and are generally referred to as *dermal dendritic cells*.[139] LCs and DDCs are lineage-negative (Lin^-), bone marrow–derived leukocytes endowed with exquisite migratory and antigen-presenting properties. Thus, they phenotypically and functionally resemble other DCs present in most, if not all, lymphoid and nonlymphoid tissues.[140] As the gatekeepers of the immune system, they control the response to events perturbing tissue homeostasis (Fig. 10-6A).

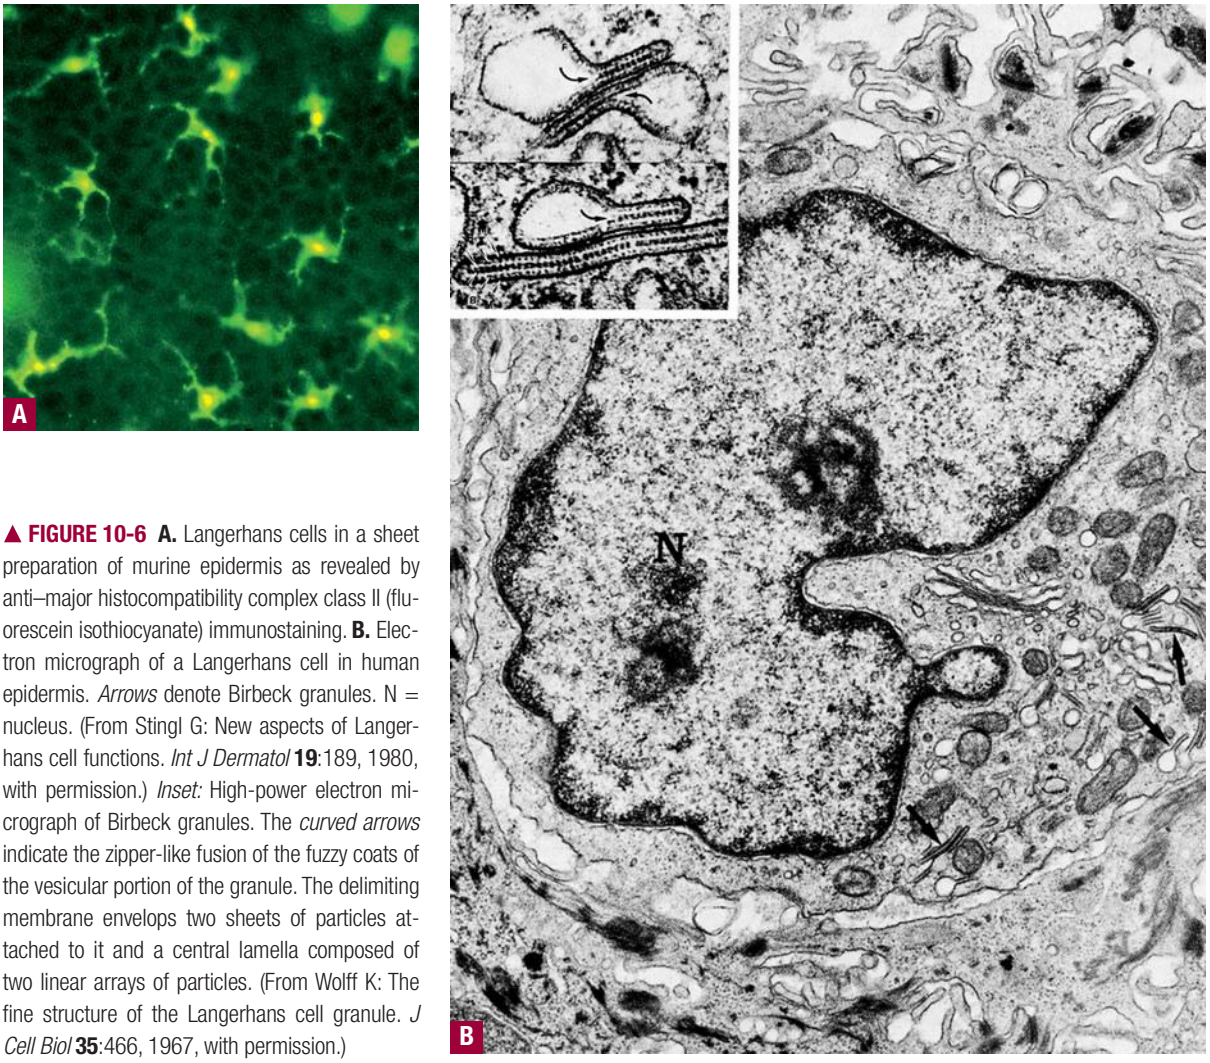
PHENOTYPIC PROPERTIES OF SKIN-BOUND LANGERHANS CELLS AND DERMAL DENDRITIC CELLS The expression of the Ca^{2+}-dependent lectin Langerin (CD207) is currently the single best feature discriminating LCs from other cells. Langerin is a transmembrane molecule associated with and sufficient to form Birbeck granules, the prototypic and cell type–defining organelles of LCs (see Fig. 10-6B). Birbeck granules are pentilaminar cytoplasmic structures frequently displaying a tennis racket shape at the ultrastructural level. The additional presence of Langerin on the LC cell surface coupled with its binding specificity for mannose suggests that Langerin is involved in the uptake of mannose-containing pathogens by LCs. However, the disruption of the Langerin gene in experimental animals does not result in a marked loss in LC functionality.[141] Notably, Langerin is expressed on virtually all LCs in stratified epithelia as well as on a major subset of DCs in the lung,[142] which may or may not be directly related to epidermal LCs.

The expression of additional molecules besides Langerin allows the identification of LCs within normal unperturbed epidermis. These include CD1a; the MHC class II antigens HLA-DR, HLA-DQ, and HLA-DP; and CD39, a membrane-bound, formalin-resistant, sulfhydryl-dependent adenosine triphosphatase (ATPase).

DDCs are phenotypically less well characterized. Their best markers are probably the molecules CD1b and CD1c as well as the subunit A of the clotting proenzyme factor XIII (factor XIIIa). DDCs can be distinguished from LCs by the absence of Langerin expression and Birbeck granules, and from macrophages by the abundant expression of MHC class II molecules, DEC205/CD205, and the absence of phagolysosomes at the ultrastructural level.

TISSUE DISTRIBUTION OF LANGERHANS CELLS AND DERMAL DENDRITIC CELLS In the epidermis, the density of the LC population varies regionally in human





▲ **FIGURE 10-6** **A.** Langerhans cells in a sheet preparation of murine epidermis as revealed by anti–major histocompatibility complex class II (fluorescein isothiocyanate) immunostaining. **B.** Electron micrograph of a Langerhans cell in human epidermis. *Arrows* denote Birbeck granules. skin. On head, face, neck, trunk, and limb skin, the LC density ranges between 600 and 1000/mm^2. Comparatively low densities (approximately 200/mm^2) are encountered in palms, soles, anogenital and sacrococcygeal skin, and the buccal mucosa. The density of human LCs decreases with age, and LC counts in skin with chronic actinic damage are significantly lower than those in skin not exposed to UV light.

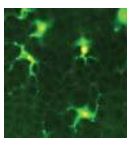
DDCs are located primarily in the vicinity of the superficial vascular plexus.

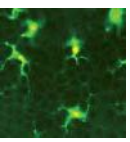
DEVELOPMENT, MAINTENANCE, AND FATE OF SKIN DENDRITIC CELLS (Fig. 10-7) HLA-DR$^+$/ATPase$^+$ DCs can be identified in the human epidermis by 6 to 7 weeks of estimated gestational age. These cells must originate from hemopoietic progenitor cells in the yolk sac or fetal liver, the primary sites of hemopoiesis during the embryonic period. Until the twelfth week of pregnancy, these cells are CD1a$^-$ and lack Birbeck granules. Thereafter, and coinciding with the initiation of bone marrow function, there occurs a dramatic increase in CD1a expression by epidermal DCs, which indicates the emergence of a true LC population. The relative numeric stability of LC counts during later life must be achieved by a delicate balance of LC generation and immigration into the epidermis and LC death and emigration from the epidermis.

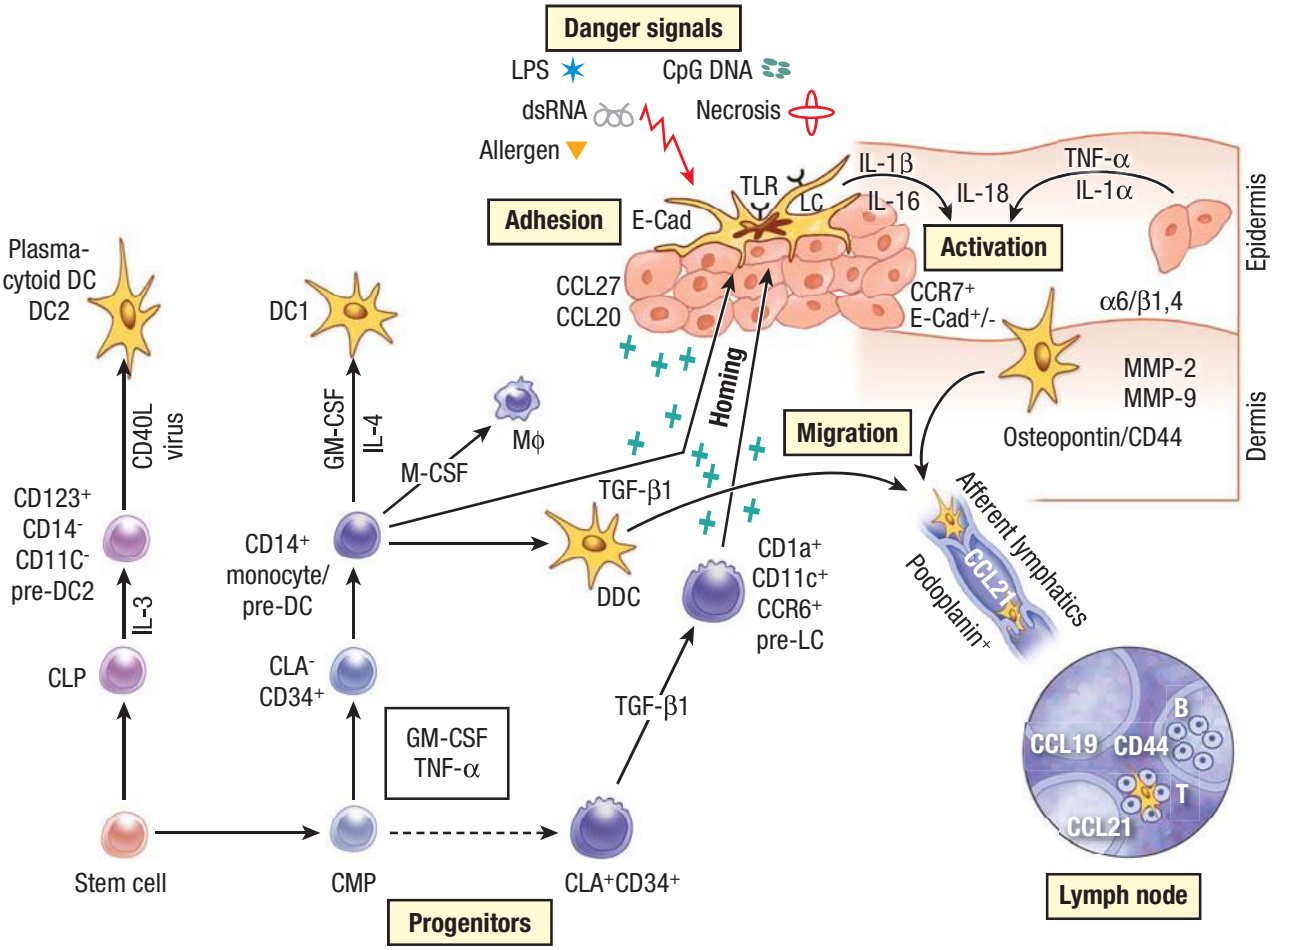
Within the epidermis, LCs are anchored to surrounding keratinocytes by E-cadherin–mediated homotypic adhesion.[147] This anchoring and the display of TGF-β1 also prevent terminal differentiation and migration (see later), thus securing intraepidermal residence for the cells under homeostatic conditions.

Two non–mutually exclusive pathways of LC repopulation of the epidermis may exist: LC division within the epidermis, and the differentiation of LCs from skin-resident or blood-borne precursors. Evidence for the first possibility is the demonstration of cycling/mitotic LCs in the epidermis,[148] although it remains to be established whether this cell division alone suffices for maintaining the epidermal LC population. Notably, it has now been discovered that DDCs proliferate constitutively in situ in murine and human quiescent dermis,[149] which indicates that homeostatic cell division also contributes to the maintenance of this skin DC population.

The observation that the half-life of LCs within unperturbed murine epidermis is around 2 to 3 months[150] suggests a significant turnover of the epidermal LC population even under noninflammatory conditions. In seeming contradiction stands the observation that the LC population of human skin grafted onto a nude mouse remains rather constant for the life of the graft, despite epidermal proliferation and the absence of circulating precursors for human LCs. Moreover, epidermal LCs in mice whose bone marrow was lethally irradiated and subsequently transplanted are only partially replaced by LCs of donor origin,[151] whereas DCs in other organs are efficiently exchanged for donor DCs.[152] Together, these observations







▲ **FIGURE 10-7** Schematic diagram of the ontogeny, migration, and maturation pathways of cutaneous dendritic leukocytes. $\alpha_6/\beta_{1,4}$ = $\alpha_6/\beta_{1,4}$ integrins; B = B cells; CCL = CC chemokine ligand; CCR = CC chemokine receptor; CD = cluster of differentiation-nomenclature of leukocyte antigens; CLA = cutaneous lymphocyte–associated antigen; CLP = common lymphoid progenitor cell; CMP = common myeloid progenitor cell; CpG DNA = immunostimulatory cytosine- and guanine-rich sequences of DNA; DC = dendritic cell; DDC = dermal dendritic cell; dsRNA = double-stranded RNA; E-Cad = E-cadherin; GM-CSF = granulocyte-macrophage colony-stimulating factor; IL = interleukin; LC = Langerhans cell; LPS = lipopolysaccharide; Mϕ = macrophage; M-CSF = macrophage colony-stimulating factor; MMP = matrix metalloproteinase; T = T cells; TGF-β1 = transforming growth factor-β1; TLR = Toll-like receptor; TNF-α = tumor necrosis factor-α.

suggest that a precursor cell population resides in the dermis that is engaged constantly in the self-renewal of the epidermal LC population under noninflammatory conditions. The prime candidate LC precursors are dermal $CD14^+$/$CD11c^+$ cells that have the potential to differentiate in vitro into LCs in a TGF-β1–dependent fashion.[153]

Under inflammatory conditions (e.g., UV radiation exposure, graft-versus-host disease), an additional pathway of epidermal LC recruitment becomes operative. In this situation, LC precursors enter the tissue, and their progeny populate the epidermis in a fashion dependent on chemoattraction mediated by LC-expressed chemokine receptors CCR2 and CCR6,[154] the ligands of which are secreted by endothelial cells and keratinocytes. Interestingly, a similar pathway of inflammation-dependent precursor recruitment exists for DDCs, which in contrast to that of LCs, relies on $CCR2^-$ but not CCR6-dependent cell migration.[149] Thus, CCR6 and its ligand MIP-3α/CCL20 may be essential for epidermal LC localization in vivo, as postulated previously in studies of LCs differentiated from human progenitor cells in vitro.[76] The action of MIP-3α/CCL20 may be assisted or replaced under noninflammatory situations by the chemokine BRAK/CXCL14, which is constitutively produced by keratinocytes.[155] The differentiation stage of the biologically relevant circulating LC precursors entering inflamed skin in vivo remains to be resolved. However, evidence exists that common myeloid progenitors, granulocyte-macrophage progenitors, monocytes, and even common lymphoid progenitors can give rise to the emergence of an epidermal LC population in experimental animals.[156,157]

Under inflammatory conditions, DC types that are not residents of the normal cutaneous environment appear in the skin. These include plasmacytoid DCs (pDCs) and DCs that phenotypically resemble myeloid DCs of the peripheral blood. The pDCs are DC precursors that are characterized by a highly developed endoplasmic reticulum, which results in their plasma cell-like appearance.[158] Functionally, pDCs display a unique ability to produce enormous amounts of natural IFNs in response to TLR ligands and thus were also named *principal type 1 IFN-producing cells*.[159] Under homeostatic conditions, pDCs are found in peripheral blood and T cell–rich areas of secondary lymphatic tissue. In certain types of skin inflammation (e.g., virus infection, lupus erythematosus, psoriasis, allergic contact dermatitis, atopic dermatitis), pDCs enter the skin in a fashion that engages the CXC chemokine receptor CXCR3.[160,161] Within the skin, pDCs localize in perivascular clusters with T cells and, on activation in situ, may contribute to antimicrobial

immune defense or (auto)immune-mediated tissue inflammation by the secretion of natural IFNs and other mechanisms that are still to be identified.

Another non-indigenous DC population originates from myeloid precursors and has been detected in inflammatory skin diseases such as atopic dermatitis and contact eczema. The so-called *inflammatory dendritic epidermal cells* are characterized by the expression of CD1a, CD1b, FcεRI, CD23, HLA-DR, and CD36.[162] Evidence exists that an immune response triggered by these cells is skewed in the Th1 direction.[163]

Finally, there remains the question as to the ultimate fate of the epidermal and dermal DC populations. Major perturbation of the cutaneous microenvironment (danger signal[164]) leads to their activation, which results either in their elimination via the stratum corneum in the case of LCs[165] or, more importantly, in the migration of LCs/DDCs to lymphoid tissues, where they initiate type 1 (Th1/cytotoxic T cell 1)–dominated T-cell responses (see The Skin–Initiation Site and Target of Immune Response). By contrast, it is less clear what happens in normal skin. Does LC shedding occur under physiologic (nondanger) conditions? Is there a natural flux of LCs/DDCs to the regional lymph nodes? If so, what are the functional consequences of such an occurrence? Evidence exists that melanin granules captured in the skin accumulate in the regional lymph nodes but not in other tissues. The further observation of only very few melanin granule–containing cells in TGF-$\beta1^{-/-}$ mice suggests that, under steady-state conditions, epidermal and/or dermal antigens are carried to the regional lymph nodes by TGF-β1–dependent cells (most likely LCs/DDCs) only. It appears that T lymphocytes encountering such APCs in vivo are rendered unresponsive in an antigen-specific manner.[166] It may therefore be assumed that absence of pathogenic T-cell autoimmunity and/or lack of reactivity against seemingly innocuous environmental compounds (e.g., aeroallergens) in the periphery is primarily the consequence of an active immune response rather than the result of its nonoccurrence.

On receipt of danger signals (e.g., TLR ligands, chemical haptens, hypoxia), the situation is quite different. After a few hours, LCs begin to enlarge, to display increased amounts of surface-bound MHC class II molecules, and to migrate downward in the dermis, where they enter afferent lymphatics and, finally, reach the T-cell zones of draining lymph nodes.[167] During this process, LCs undergo phenotypic changes similar to those that occur in single epidermal cell cultures[168]; that is, downregulation of molecules or structures responsible for antigen uptake and processing as well as for LC attachment to keratinocytes (e.g., Fc receptors, E-cadherin) and upregulation of moieties required for active migration and stimulation of robust responses of naive T cells (e.g., CD40, CD80, CD83, CD86). The mechanisms governing LC migration are becoming increasingly clear. TNF-α and IL-1β (in a caspase 1–dependent fashion) are critical promoters of this process, whereas IL-10 inhibits its occurrence. Increased cutaneous production and/or release of the pro-inflammatory cytokines is probably one of the mechanisms by which certain immunostimulatory compounds applied to or injected into the skin [e.g., imiquimod, unmethylated cytosine-phosphate-guanosine (CpG) oligonucleotides] accelerate LC/DDC migration. Interestingly enough, Cumberbatch et al.[169] reported that, in psoriasis, LCs are impaired in their migratory capacity. This was somewhat unexpected in view of the remarkable overexpression of TNF-α in psoriatic skin. These investigators also found that the failure of TNF-α and/or IL-1β to induce LC migration from uninvolved skin was not attributable to an altered expression of receptors for these cytokines. The nature of this LC migration inhibition factor is as yet unknown.

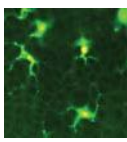
IL-16 also induces LC mobilization. This process could perhaps be operative in atopic dermatitis. In this disease, DCs of lesional skin exhibit surface IgE bound to high-affinity Fc receptors (FcεRI), and allergen-mediated receptor cross-linking results in enhanced IL-16 production.

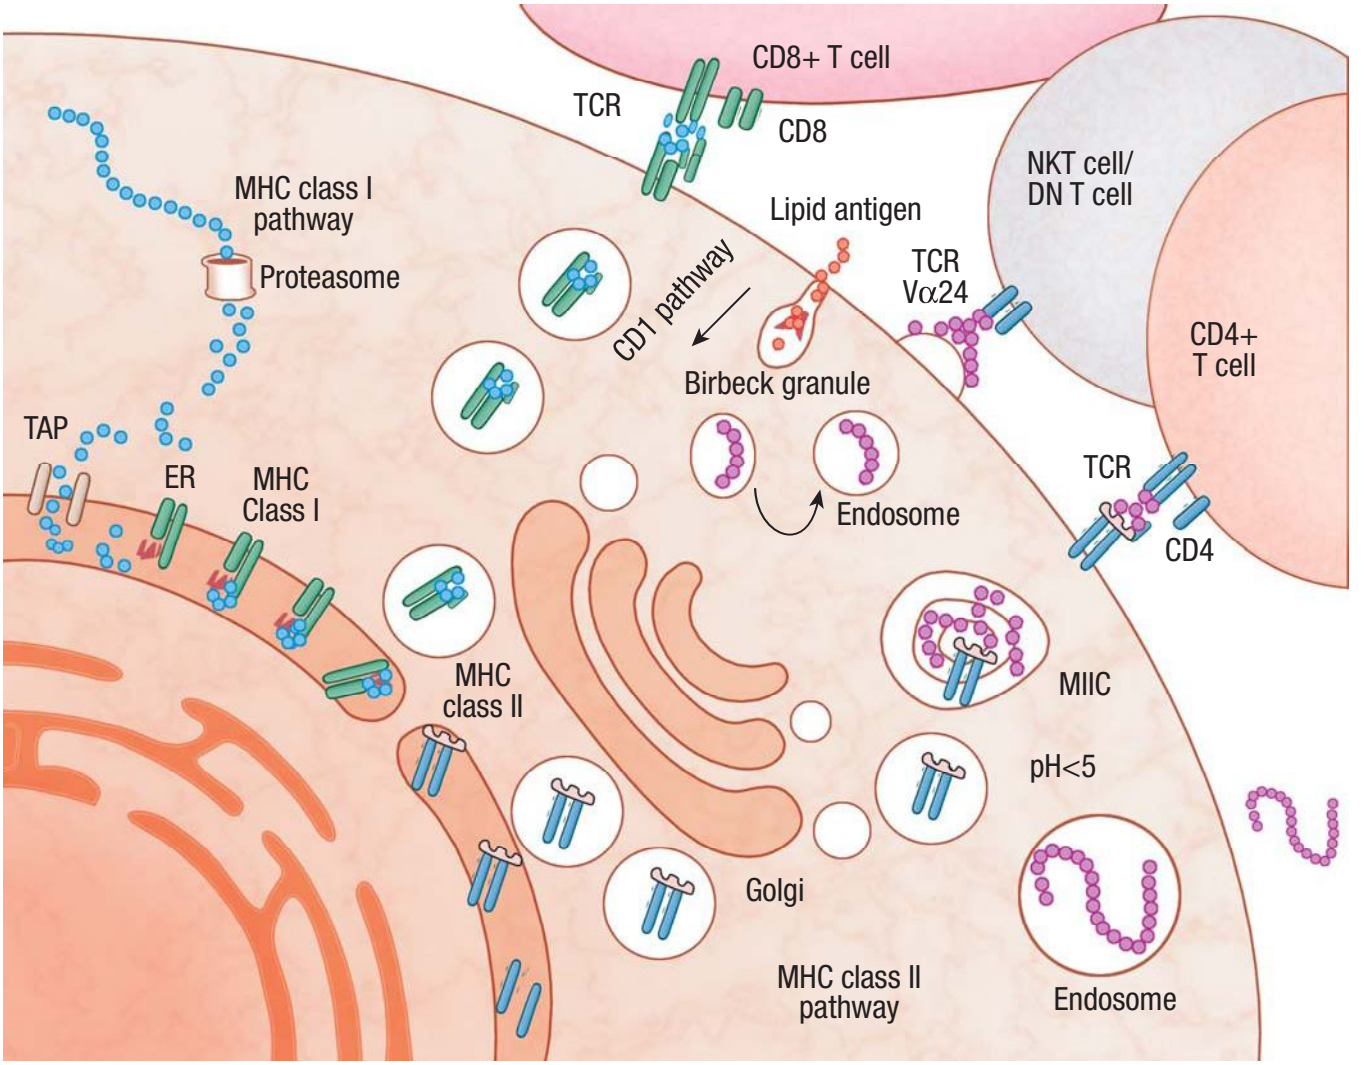
An important hurdle for emigrating LCs is the basement membrane. During their downward journey, LCs probably attach to it via α_6-containing integrin receptors and produce proteolytic enzymes such as type IV collagenase (matrix metalloproteinase 9) to penetrate it and to pave their way through the dense dermal network into the lymphatic system. Evidence is accumulating that LC/DDC migration occurs in an active, directed fashion. Osteopontin is a chemotactic protein that is essential in this regard. It initiates LC emigration from the epidermis and attracts LCs/DDCs to draining nodes by interacting with an N-terminal epitope of the CD44 molecule.[170] The entry into and active transport of cutaneous DCs within lymphatic vessels appears to be mediated by MCPs binding to CCR2 and by secondary lymphoid-organ chemokine/CCL21 produced by lymphatic endothelial cells of the dermis and binding to CCR7 on maturing LCs and DDCs.[171,172] Interestingly, CCL21 expression is upregulated in irritant and allergic contact dermatitis, which implicates its regulated impact on DC emigration from the skin.[173]

FUNCTIONAL PROPERTIES OF DENDRITIC CELLS Like the other members of the DC family, LCs and DDCs are "professional" APCs, endowed with the unique capacity of stimulating antigen-specific responses in naive, resting T cells. To provide a better understanding of this functional property, the basic principles of antigen uptake, processing, and presentation are briefly reviewed.

GENERAL PRINCIPLES OF ANTIGEN PRESENTATION (Fig. 10-8) Unlike B cells, T cells cannot recognize soluble protein antigen per se; their antigen receptor TCR is designed to see antigen-derived peptides bound to MHC locus–encoded molecules expressed by APCs.[176] For the antigen-specific activation of Th cells, exogenous antigen–derived peptides are usually presented in the context of MHC class II molecules.[177] In this situation, peptides are generated in the endocytic, endosomal/lysosomal pathway and are bound to MHC class II molecules. The resulting MHC-peptide complex is expressed at the APC surface for encounter by the TCR of $CD4^+$ Th cells. In contrast, most $CD8^+$ T cells, destined to become cytotoxic T cells, recognize the endogenous antigen in association with MHC class I molecules.[177] Because most nucleated cells transcribe and express MHC class I genes and gene products, it is evident that many cell types can serve as APCs for MHC class I–restricted antigen presentation and/or as targets for MHC class I–dependent attack by T cells. In the MHC class II–dependent antigen-presentation pathway, DCs, including LCs and DDCs, B cells, and monocytes/macrophages, are the major APC populations.

Major Histocompatibility Complex Class I–Restricted Antigen Presentation[178]. **CLASSIC MAJOR HISTOCOMPATIBILITY COMPLEX CLASS I PRESENTATION PATHWAY.** Immediately after their biosynthesis, MHC class I heavy and light (β_2-microglobulin) chains are inserted





▲ **FIGURE 10-8** Antigen-processing pathways. The intracellular antigen-processing pathways for major histocompatibility complex (MHC) class I, MHC class II, and CD1 presentation are shown. The MHC class I pathway involves the processing of cytoplasmic proteins, whereas the MHC class II pathway involves the processing of exogenous proteins. The CD1 pathway regulates the processing and presentation of self-glycosphingolipids and bacterial lipoglycans. DN T cell = double-negative ($CD4^-/CD8^-$) T cell; ER = endoplasmic reticulum; MIIC = MHC class II lysosomal peptide-loading compartment; NKT cell = natural killer T cell; TAP = transporter associated with antigen processing; TCR = T-cell receptor.

into the membranes of the endoplasmic reticulum. The third subunit of the functional MHC class I complex is the peptide itself. The major sources of peptides for MHC class I loading are cytosolic proteins, which can be targeted for their rapid destruction through the catalytic attachment of ubiquitin. Cytosolic proteinaceous material undergoes enzymatic digestion by the proteasome to yield short peptide chains of 8 to 12 amino acids, an appropriate length for MHC class I binding. In its basic conformation, the proteasome is a constitutively active "factory" for self-peptides. IFN-γ, by replacing or adding certain proteasomal subunits, induces "immunoproteasomes," presumably to fine-tune the degradation activity and specificity to the demands of the immune response. The processed peptides are translocated to the endoplasmic reticulum by the transporter associated with antigen processing (TAP), an MHC-encoded dimeric peptide transporter. With the aid of chaperons (calnexin, calreticulin, tapasin), MHC class I molecules are loaded with peptides, released from the endoplasmic reticulum, and transported to the cell surface. Several infectious agents with relevance to skin biology have adopted strategies to subvert MHC class I presentation, and thus the surveillance of cell integrity, by interfering with defined molecular targets. Important examples of such interference are the inhibition of proteasomal function by the Epstein-Barr virus–encoded EBNA-1 protein, the competition for peptide-TAP interactions by a herpes simplex virus protein, and the retention or destruction of MHC class I molecules by adenovirus- and human cytomegalovirus-encoded products.

Alternative Major Histocompatibility Complex Class I Presentation Pathways (Cross-Presentation). Under certain conditions, exogenous antigen can reach the MHC class I presentation pathway. Significant evidence for this cross-presentation first came from in vivo experiments in mice demonstrating that viral, tumor, and MHC antigens can be transferred from MHC-mismatched donor cells to host bone marrow–derived APCs to elicit antigen-specific cytotoxic T-cell responses that are restricted to self MHC molecules.[179] In vitro studies have now defined that exosomes (i.e., small secretory vesicles of approximately 100 nm in diameter secreted by various cell types, including

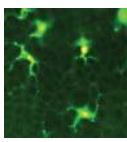
tumor cells), heat shock proteins, immune complexes, and apoptotic cells (taken up via CD36 and αvβ3 or αvβ5 integrins) can all serve as vehicles for the delivery of antigen to DCs in a manner that permits the cross-presentation of antigen. In all in vitro systems in which a direct comparison has been made, DCs, including LCs, but not monocytes/macrophages, were capable of cross-presentation.[180,181] Three distinct pathways are currently exploited by which antigen can access MHC class I molecules of DCs: (1) a recycling pathway for MHC class I in which antigen is loaded in the endosome; (2) a pathway by which retrograde transport of the antigen from the endosome to the endoplasmic reticulum facilitates entry into the classic MHC class I antigen presentation pathway; and (3) an endosome to the cytosol transport pathway, which again allows antigen processing via the classic MHC class I antigen presentation pathway.

Major Histocompatibility Complex Class II–Restricted Antigen Presentation[177]. MHC class II molecules predominantly bind peptides within endosomal/lysosomal compartments. Sampling peptides in these sub-cellular organelles allow class II molecules to associate with a broad array of peptides derived from proteins targeted for degradation after internalization by fluid phase or receptor-mediated endocytosis, macropinocytosis, or phagocytosis. One of the striking structural differences between MHC class I and class II molecules is the conformation of their peptide-binding grooves. Whereas MHC class I molecules have binding pockets to accommodate the charged termini of peptides and thus selectively associate with short peptides, the binding sites of MHC class II molecules are open at both ends. Thus, MHC class II molecules bind peptides with preferred lengths of 15 to 22 amino acids but can also associate with longer moieties.

Newly synthesized MHC class II α and β subunits assemble in a stoichiometric complex with trimers of the type II transmembrane glycoprotein invariant chain (Ii). The association with Ii contributes in at least three different ways to the function of class II molecules: (1) Ii assembly promotes the proper folding of class II molecules in the endoplasmic reticulum; (2) the abluminal portion of Ii contains signal sequences that facilitate the export of MHC class II–Ii complexes through the Golgi system to endosomes/lysosomes; and (3) Ii prevents class II molecules from premature loading by peptides intended for binding to MHC class I molecules in the endoplasmic reticulum. The segment of Ii functioning as a competitor for peptide binding to class II is termed *class II–associated Ii peptide* (CLIP; residues 81 to 104 of Ii). Once the nascent MHC class IIα/β–Ii trimers arrive in the endosomal/lysosomal system, Ii is subject to proteolysis by acid hydrolases. The last proteolytic step, the generation of CLIP, is catalyzed by cathepsin S in DCs, by cathepsin L in thymic epithelial cells, and by cathepsin F in macrophages. On HLA-DM–chaperoned exchange of CLIP for exogenous antigen-derived peptide, fully assembled class II molecules are exported to the cell surface and acquire a stable conformation. Depending on the cell type and the activation status of a cell, the half-life of class II–peptide complexes varies from a few hours to days. It is particularly long (more than 100 hours) on DCs that have matured into potent immunostimulatory cells of lymphoid organs on encounter with an inflammatory stimulus in nonlymphoid tissues. The very long retention of class II–peptide complexes on mature DCs ensures that only those peptides generated at sites of inflammation will be displayed in lymphoid organs for T-cell priming. Cytokines have long been known to regulate antigen presentation by DCs. In fact, proinflammatory (TNF-α, IL-1, IFN-γ) and anti-inflammatory (IL-10, TGF-β1) cytokines regulate presentation in MHC class II molecules in an antagonistic fashion. Mechanistically, regulatory effects include the synthesis of MHC components and proteases, and the regulation of endolysosomal acidification.[182,183]

CD1-Dependent Antigen Presentation[184]. Besides peptides, self-glycosphingolipids and bacterial lipoglycans may also act as T cell–stimulatory ligands. Molecules that bind and present these moieties belong to the family of nonpolymorphic, MHC class I– and II–related CD1 proteins. In the skin, members of the CD1 family are expressed mainly by LCs and DDCs (see Development, Maintenance, and Fate of Skin Dendritic Cells). The CD1 isoforms CD1a, CD1b, CD1c, and CD1d sample both recycling endosomes of the early endocytic system and late endosomes and lysosomes to which lipid antigens are delivered. Unlike in the MHC class II pathway, antigen loading in the CD1 pathway occurs in a vacuolar acidification-independent fashion. T cells expressing a Vα24-containing canonic TCR, NKT cells, and $CD4^-/CD8^-$ T cells include the most prominent subsets of CD1-restricted T cells. CD1-restricted T cells play important roles in host defense against microbial infections. Accordingly, human subjects infected with *M. tuberculosis* showed stronger responses to CD1c-mediated presentation of a microbial lipid antigen than control subjects, and activation of CD1d-restricted NKT cells with a synthetic glycolipid antigen resulted in improved immune responses to several infectious pathogens. Thus, the CD1 pathway of antigen presentation and glycolipid-specific T cells may provide protection during bacterial and parasite infection, probably by the secretion of pro-inflammatory cytokines, the direct killing of infected target cells, and B-cell help for Ig production.

Compelling evidence exists that LCs and other skin DCs, as members of the family of professional APCs, play a pivotal role in the induction of adaptive immune responses against pathogens and neoantigens introduced into and/or generated in the skin (immunosurveillance). This is best illustrated by the early observation that LC-containing, but not LC-depleted, epidermal cell suspensions pulse-exposed to either soluble protein antigens or haptens elicit a genetically restricted, antigen-specific, proliferative in vitro response in naive T cells.[185] Although these observations imply that the LC/DC system is indispensable for the occurrence of antigen-specific skin immunity, it is equally clear that LCs/DCs as they occur in their tissue residence are poorly, if at all, stimulatory for naive T cells. Inaba et al.[186] found that freshly isolated LCs ("immature" LCs) can present soluble antigen to primed MHC class II–restricted T cells but are only weak stimulators of naive, allogeneic T cells. In contrast, LCs purified from epidermal cell suspensions after a culture period of 72 hours or LCs purified from freshly isolated murine epidermal cells and cultured for 72 hours in the presence of GM-CSF and IL-1 ("mature" LC) are extremely potent stimulators of primary T cell–proliferative responses to alloantigens,[186] soluble protein antigens,[187] and haptens.[187] The strong immunostimulatory potential of mature LCs for resting T cells does not mean that they are superior to freshly isolated, immature LCs in every functional aspect. In fact, immature LCs far excel cytokine-activated LCs in their capacity to take up and process native protein antigens.[188] Accordingly, immature rather than mature LCs/DCs ex-



press antigen uptake receptors. Mature LCs, although fully capable of presenting pre-processed peptides, have lost their capacity to process and present native protein antigens.[188] This cytokine-induced/culture-induced switch from the processing/peptide loading to the presentation mode is a highly regulated LC/DC function attributable to fundamental molecular changes in protein synthesis and vesicle trafficking. LCs in their immature state display MHC class II antigens in lysosomal peptide-loading compartments (MIIC) and, to a much lesser extent, on the cell surface. When LCs mature in situ, MHC class II molecules are transferred to the plasma membrane. Likewise, MHC class I surface expression is upregulated during the process of DC maturation.

The display of MHC-peptide complexes on the DC surface delivers the "first signal" to T cells—that is, the triggering of the TCR by the APC-bound peptide-MHC complex. Although this event may be sufficient to induce the proliferation of primed T cells, it is insufficient for the productive activation of naive T cells. The occurrence of the latter requires the receipt of "second signals," which can be delivered by professional APCs. In fact, antigen-specific T cells that encounter MHC-expressing cells that cannot deliver second signals (e.g., MHC class II–induced keratinocytes, endothelial cells, fibroblasts) enter a state of anergy.[189] Second signals also determine the magnitude and quality of primary and secondary T-cell responses. In skin DCs, as well as in DCs from other locations, co-stimulatory molecules that deliver second signals are upregulated during maturation induced by surface receptors triggered by ligands secreted or presented by other somatic cells or, alternatively, by microbial products (danger or competence signals). Second signals include secreted cytokines and membrane-bound co-stimulators, the best defined of which are the two members of the B7 family, B7.1/CD80 and B7.2/CD86. LCs/DCs in situ do not express or express only minute amounts of these co-stimulatory molecules, but greatly upregulate these moieties during maturation. Other co-stimulatory molecules include the ICAM-1 that binds to LFA-1, and LFA-3, the ligand of T cell–expressed CD2. Other important ligand-receptor pairs that positively affect T-cell activation by DCs include heat-stable antigen (CD24)/CD24L, CD40/CD40L, CD70/CD27L, OX40 (CD134)/OX40L, and receptor activator of nuclear factor κB (RANK)/RANKL.

THE SKIN—INITIATION SITE AND TARGET OF IMMUNE RESPONSES (Fig. 10-9)

In 1983, Wayne Streilein coined the term *skin-associated lymphoid tissues*[191] to describe a functionally interactive circuit of cells and tissues (dendritic APCs, cytokine-producing keratinocytes, and skin-homing T cells originating in skin-draining peripheral lymph nodes) that provide the skin with unique immunosurveillance mechanisms for the successful prevention of or combat against cancer and infectious diseases. These cells and tissues also secure the homeostasis of the host by preventing the development or downregulating the expression of exaggerated tissue-destructive immune responses against per se innocuous moieties such as autoantigens and certain allergens.

Critical to the understanding of this yin-yang situation was the observation that, under homeostatic conditions, the overwhelming majority of antigen-presenting DCs are in an immature state that allows them to efficiently take up antigen with the help of specific receptor sites (e.g., Langerin, macrophage mannose receptor, C-type lectin receptor DEC-205, low-affinity IgG receptor CD32/FcγRII, high-affinity IgE receptor FcεRI, the thrombospondin receptor CD36, DC-SIGN), but does not endow them with immunostimulatory properties for naive resting T cells. On the delivery of danger signals,[164] however, DCs undergo a phenotypic and functional metamorphosis that enables them to elicit productive and, under optimal circumstances, protective primary immune responses.

It was originally assumed that the induction of antigen-specific non-responsiveness occurs when antigens are presented in the context of non-dendritic APCs (nonprofessional APCs). The early observation that the application of hapten to LC-deficient skin or mucosa results in hapten-specific tolerance[192] points in this direction.

More recent evidence now suggests that DCs/LCs themselves can actively induce immune tolerance. In vitro, immature DCs preferentially activate Treg cells.[193] In vivo, in the steady state, DCs induce tolerance to specific antigens targeted to these cells.[166,194,195] Mechanisms responsible for the tolerance-inducing property of nonactivated DCs, although not entirely understood, include (1) a reduced expression of MHC-antigen complexes[196] and co-stimulatory molecules[197] on the cell surface; (2) the secretion of immunosuppressive cytokines such as IL-10,[198] which fits well to the finding of Treg induction by UV-irradiated, IL-10–producing Treg cells[199]; (3) the expression of immunoinhibitory enzymes such as indoleamine 2,3-dioxygenase[200]; (4) the receipt of signals interfering with the maturation and migration of DCs, for example, neuropeptides such as CGRP[201] and vasoactive intestinal peptide,[202] the engagement of the CD47/SHPS-1 signal transduction cascade,[203] and others.

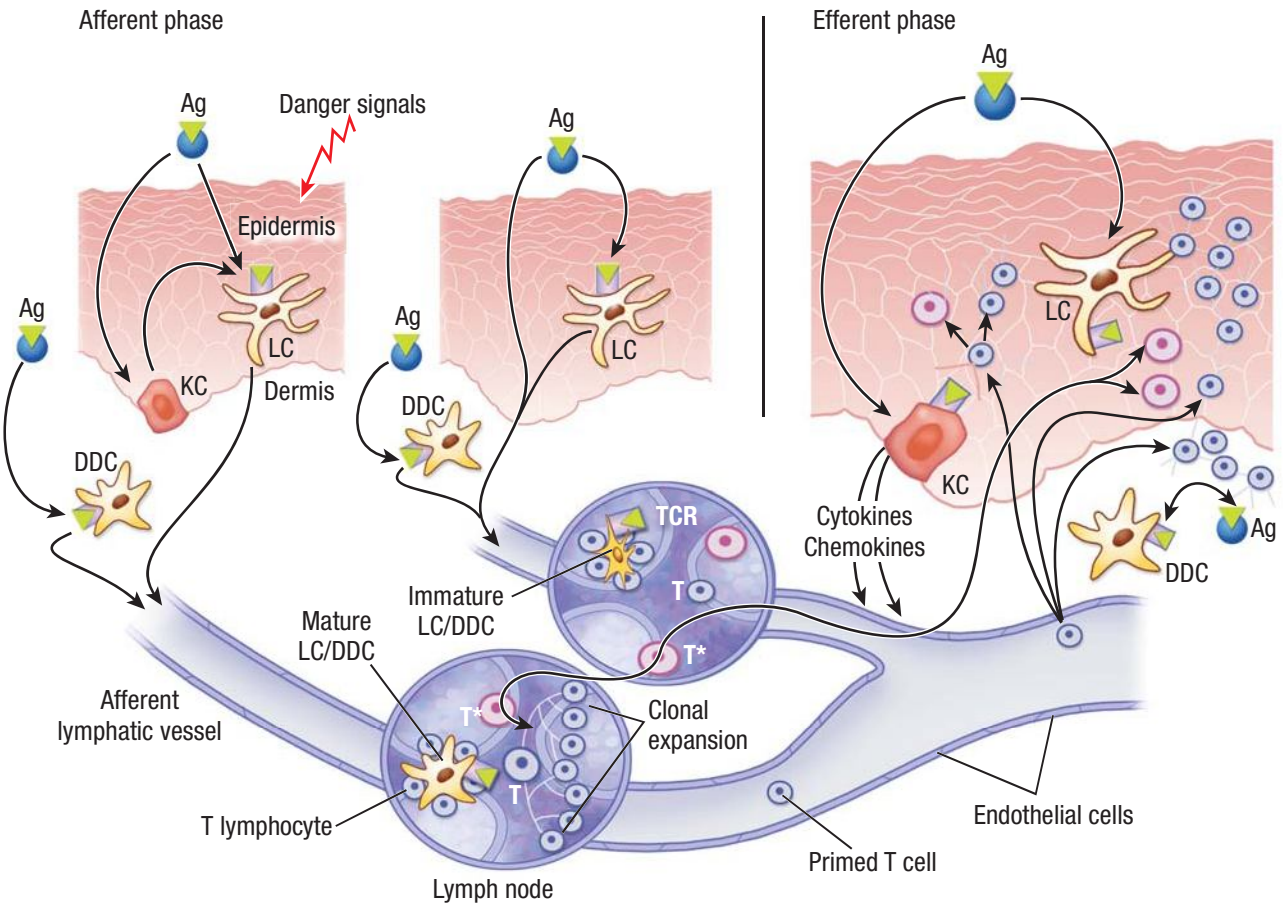
It appears that these different factors are not equally operative in all situations. LCs, for example, can activate self-antigen–specific CD8 T cells in the steady state, which leads to chronic skin disease,[204] and, at the same time, LCs are dispensable for[205] or can even downregulate[206] the induction of CHS.

Perturbation of tissue homoeostasis (i.e., the delivery of a danger signal) initiates a series of molecular events that allow peripheral DCs to rapidly migrate to secondary lymphoid organs, a journey during which they mature into potent immunostimulatory cells capable of sensitizing unprimed lymphocytes for productive responses. This can be well exemplified by a rather simple manipulation: culture of explanted skin for which hypoxia apparently suffices to trigger migration and maturation of cutaneous DCs.[167] Another example is the topical application of contact sensitizers (e.g., dinitrofluorobenzene), which leads to the activation of certain protein tyrosine kinases, the modification of cellular content and structure of intracytoplasmic organelles (increase in coated pits and vesicles, endosomes and lysosomes, Birbeck granules), and increased in situ motility of these cells.[207]

It appears that cytokines, released as a consequence of physicochemical or infection-associated tissue perturbation (e.g., keratinocyte-derived GM-CSF, TNF-α, IL-1) and/or ligation of CD40 molecules on DC/LC surfaces, provide the critical signal for the induction of LC maturation. But how do skin cells recognize a danger signal and translate it into increased cytokine production?

One biologically relevant pathway is certainly the maturation signal that is delivered to DCs/LCs by the uptake of necrotic cells. The fact that LCs are capable of cross-presentation[181,180] could make this an important mechanism in the generation of a protective antitumor immune response.

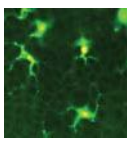
Successful defense against invading microorganisms involves the recognition of pathogen-associated molecular



▲ **FIGURE 10-9** The mechanisms operative in the initiation, expression, and downregulation of cutaneous immune responses. Induction of productive T-cell immunity via the skin: The epicutaneous and/or intracutaneous de novo appearance of antigens (i.e., pathogens such as microorganisms and haptens) results in the elicitation of productive antigen-specific immunity when "danger signals" (i.e., bacterial DNA rich in unmethylated cytosine-phosphate-guanine repeats and other Toll-like receptor ligands) are present at the time of antigenic exposure. The receipt of danger signals leads to tissue perturbation, as evidenced by the increased secretion of granulocyte-macrophage colony-stimulating factor, tumor necrosis factor-α, and interleukin 1 (IL-1) by keratinocytes (KCs) and other skin cells. Antigen-presenting cells (APCs) [Langerhans cells (LCs), dermal dendritic cells (DDCs)] that pick up the antigen, process it, and re-express it as a peptide–major histocompatibility complex (MHC) product on the surface are also profoundly affected by danger signals or danger signal–induced cytokines. The alterations of LCs/DDCs include the increased expression of MHC antigens, co-stimulatory molecules, and cytokines (IL-1β, IL-6, IL-12), as well as the enhanced emigration of these cells from the skin to the paracortical areas of the draining lymph nodes. At this site, the skin-derived dendritic cells (DCs) provide activation stimuli to the naive resting T cells surrounding them. This occurs in an antigen-specific fashion and thus results in the expansion of the respective clone(s). These primed T cells begin to express skin-homing receptors (e.g., CLA) as well as receptors for various chemoattractants that promote their attachment to dermal microvascular endothelial cells of inflamed skin and, ultimately, their entry into this tissue. Elicitation of T cell–mediated tissue inflammation and pathogen defense: On receipt of a renewed antigenic stimulus by cutaneous APCs (LCs, DDCs), the skin-homing primed T cells expand locally and display the effector functions needed for the elimination, or at least the attack, of the pathogen. Alternatively, primed T cells may encounter the antigen on the surface of nonprofessional APCs (e.g., MHC class II–bearing KCs), a situation that conceivably results in a state of clonal T-cell anergy. Downregulation and prevention of cutaneous T-cell immunity: In the absence of danger signals (tissue homeostasis), antigen-loaded LCs/DDCs also leave the cutaneous compartment and migrate toward the draining lymph node. These cells or, alternatively, resident lymph node DCs that had picked up antigenic moieties from afferent lymphatics present this antigen in a nonproductive fashion—that is, they induce antigen-specific T-cell unresponsiveness or allow the responding T cell(s) to differentiate into immunosuppressive T regulatory cells. The latter may limit antigen-driven clonal T-cell expansion during primary immune reactions in lymph nodes and during secondary immune reactions at the level of the peripheral tissue. Such events can result in the downregulation of both desired (antitumor, antimicrobial) and undesired (hapten-specific, autoreactive) immune responses. Ag = antigen; T = T naive cell; T* = anergic T cell; TCR = T-cell receptor.

patterns through members of the TLR protein family, 11 members of which have been classified so far (see earlier). Evidence now exists that human LCs express messenger RNA encoding TLR1, TLR2, TLR3, TLR5, TLR6, and TLR10.[208] Ligands of TLR1, TLR2, and TLR6 include lipoproteins from *M. tuberculosis*, *B. burgdorferi*, *T. pallidum*, mycobacterial lipoarabinomannan, peptidoglycan, zymosan, and glycophosphatidyl inositol anchors from *T. pallidum* and *T. cruzi* lipoproteins. Whereas TLR5 detects bacterial flagellin, TLR3 is associated with the recognition of viral double-stranded RNA. LCs mount a particularly robust antiviral response to TLR3 agonists,[209] which implies that natural or synthetic ligands for TLR3 might prove useful in the treatment of viral skin infections.

For immunotherapeutic purposes, particular attention has also focussed on TLR7, TLR8, and TLR9, which are intracellular receptors for nucleic acids. TLR7 and TLR8 are engaged by viral single-stranded RNA and by synthetic small molecules mimicking features of nucleic



acids, such as imiquimod and R-848. TLR9, on the other hand, recognizes oligodeoxynucleotides (ODNs) containing unmethylated CpG motifs (CpG ODN), which are underrepresented in mammalian genomes but abundant in viral and bacterial DNA. Both TLR7 and TLR9 ligands have profound effects on the skin's immune system. Imiquimod and the other imidazoquinolines induce strong inflammation and, ultimately, regression of viral acanthomas and other superficial skin neoplasms.[210] CpG ODNs promote LC migration[211] and promote the development of Th1 responses.[212] It is still not clear how the topical application of TLR7 and TLR8 ligands could elicit such a robust inflammatory response, because the respective receptors are predominantly expressed on pDCs, which are the main producers of type I IFNs and are virtually absent in normal human skin.[213] The demonstration of TLR7 on suprabasal keratinocytes[208] could indicate that these cells, rather than LCs or DDCs, are the prime skin targets of topical imidazoquinolines and, by triggering the production of pro-inflammatory cytokines and chemokines in these cells, are responsible for the influx of different types of leukocytes, including plasmacytoid and myeloid inflammatory-type DCs. The role of these latter cells in the immune response has yet to be clarified. Evidence exists that inflammatory-type myeloid DCs skew the immune response in a Th1 direction[163] and that pDCs, depending on their state of activation, favor the activation of Th2 and Treg cells, respectively. When topical imiquimod treatment (see Chap. 221) results in the regression and, ultimately, resolution of skin neoplasms, these inflammatory-type DCs are abundantly present around regressing tumor cell islands[214] and can express molecules of the lytic machinery such as perforin, granzyme B, and TNF-related apoptosis-inducing ligand, which suggests their cytotoxic potential.

The induction of skin cell injury and/or demise by cells of the innate immune system should not detract from the fact that adaptive mechanisms are responsible for most of the desired immune reactions in the skin (i.e., the elimination of pathogenic microorganisms and neoplastic cells) as well as for immune-mediated injury of the skin. Examples of the latter are bullous diseases such as pemphigus and bullous pemphigoid. Although these entities are mediated by autoantibodies, other skin diseases are apparently the result of exaggerated and/or misdirected T-cell reactions.

The skin immune system is also affected by various immunomodulating compounds applied to or introduced into the skin. The efficacy of imidazoquinolines and CpG oligonucleotides in cutaneous neoplasms has already been discussed, and one would predict that a more selective targeting of LCs/DDCs will increase their efficacy, tolerability, and safety.

Corticosteroids, the most frequently used immunoinhibitory and anti-inflammatory substances in dermatology, have a profound influence on the phenotype and function of cutaneous leukocytes at both the topical and systemic levels. After topical application of betamethasone valerate for only a few days, apoptotic events are clearly visible in the epidermal LC population, and on continuation of this treatment the epidermis can be essentially depleted of these cells. The so-called *inflammatory-type DCs* (i.e., inflammatory dendritic epidermal cells and pDCs) are similarly susceptible to corticosteroids, which is one of the reasons for the excellent efficacy of topical corticosteroids in treating acute dermatitis/eczema.[220]

The effects of the topical calcineurin inhibitors tacrolimus and pimecrolimus are more selective. Their application to the skin of patients with atopic dermatitis leads to an apoptosis-induced depletion of T cells and to a gradual disappearance of inflammatory-type DCs but leaves the epidermal LC population essentially unaltered.[220] Time will tell whether the differential effects of topical corticosteroids and calcineurin inhibitors on the skin immune system will have an influence on the long-term safety of these compounds.

The entire field of topical immunomodulation is now advancing rapidly because of (1) an increasingly better understanding of the skin's immune function and, as a consequence, the identification of promising drug targets; (2) new computer-assisted methods of drug design; and (3) new technologies that allow for a better penetration of a given compound into the skin and its guidance to the desired target. These developments are heralding a new golden era of skin-based immunotherapy, and the skills of a well-trained dermatologist are required to use the therapy for the maximum benefit of patients.

CHAPTER 11

Cytokines

Ifor R. Williams
Benjamin E. Rich
Thomas S. Kupper

THE CONCEPT OF CYTOKINES

When cells and tissues in complex organisms need to communicate over distances greater than one cell diameter, soluble factors must be employed. A subset of these factors is most important when produced or released transiently under emergent conditions. When faced with an infection- or injury-related challenge, the host must orchestrate a complex and carefully choreographed series of steps. It must mobilize certain circulating white blood cells precisely to the relevant injured area (but not elsewhere) and guide other leukocytes involved in host defense, particularly T and B cells, to specialized lymphatic tissue remote from the infectious lesion but sufficiently close to contain antigens from the relevant pathogen. After a limited period of time in this setting (i.e., lymph node), antibodies produced by B cells, and effector memory T cells, can be released into the circulation and will localize at the site of infection. Soluble factors produced by resident tissue cells at the site of injury, by leukocytes and platelets that are recruited to the site of injury, and by memory T cells ultimately recruited to the area, all conspire to generate an evolving and effective response to a challenge to host defense. Most important, the level of this response must be appropriate to the challenge and the duration of the response must be transient; that is, long enough to decisively eliminate the pathogen, but short enough to minimize damage to healthy host tissues. Much of the cell-to-cell communication involved in the coordination of this response is accomplished by cytokines.

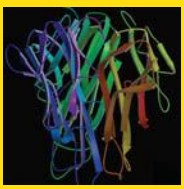
General features of cytokines are their pleiotropism and redundancy. Before the advent of a systematic nomenclature for cytokines, most newly identified cytokines were named according to the biologic assay that was being used to isolate and characterize the active molecule (e.g., T-cell growth factor for the molecule that was later renamed *interleukin 2*, or IL-2). Very often, independent groups studying quite disparate bioactivities isolated the same molecule, which revealed the pleiotropic effects of these cytokines. For example, before being termed *interleukin 1*, this cytokine had been variously known as *endogenous pyrogen*, *lymphocyte-activating factor*, and *leukocytic endogenous mediator*. Many cytokines have a wide range of activities, causing multiple effects in responsive cells and a different set of effects in each type of cell capable of responding. The redundancy of cytokines typically means that in any single bioassay (such as induction of T-cell proliferation), multiple cytokines will display activity. In addition, the absence of a single cytokine (such as in mice with targeted mutations in cytokine genes) can often be largely or even completely compensated for by other cytokines with overlapping biologic effects.

CLASSIFICATIONS OF CYTOKINES

Primary and Secondary Cytokines

A simple concept that continues to be extremely useful for discussion of cytokine function is the concept of "primary" and "secondary" cytokines.[5] Primary cytokines are those cytokines that can, by themselves, initiate all the events required to bring about leukocyte infiltration in tissues. IL-1 (both α and β forms) and tumor necrosis factor (TNF; includes both TNF-α and TNF-β) function as primary cytokines, as do certain other cytokines that signal through receptors that trigger the nuclear factor κB (NF-κB) pathway. IL-1 and TNF are able to induce cell adhesion molecule expression on endothelial cells [selectins as well as immunoglobulin superfamily members such as intercellular adhesion molecule 1 (ICAM-1) and vascular cellular adhesion molecule 1 (VCAM-1)], to stimulate a variety of cells to produce a host of additional cytokines, and to induce expression of chemokines that provide a chemotactic gradient allowing the directed migration of specific leukocyte subsets into a site of inflammation (see Chapter 12). Primary cytokines can be viewed as part of the innate immune system (see Chap. 10), and in fact share signaling pathways with the so-called *Toll-like receptors (TLRs)*, a family of receptors that recognize molecular patterns characteristically associated with microbial products.[6] Although other cytokines sometimes have potent inflammatory activity, they do not duplicate this full repertoire of activities. Many qualify as secondary cytokines whose production is induced after stimulation by IL-1 and/or TNF family molecules. The term *secondary* does not imply that they are less important or less active than primary cytokines; rather, it indicates that their spectrum of activity is more restricted.

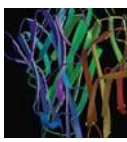
CYTOKINES AT A GLANCE

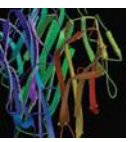


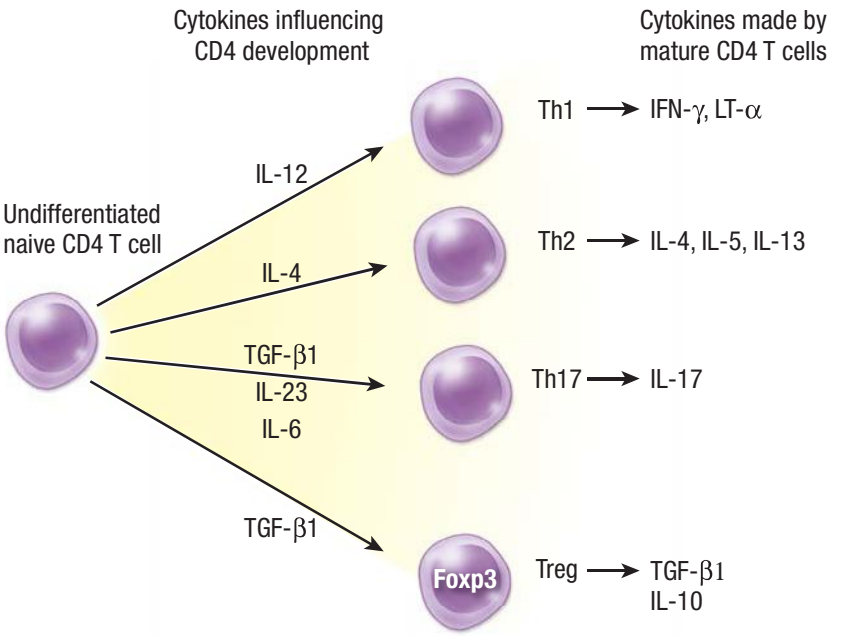
- Cytokines are polypeptide mediators that function in communication between hematopoietic cells and other cell types.
- Cytokines often have multiple biologic activities (pleiotropism) and overlapping biologic effects (redundancy).
- Primary cytokines, such as interleukin 1 and tumor necrosis factor-α, are sufficient on their own to trigger leukocyte influx into tissue.
- Most cytokines signal through either the nuclear factor κB or the Jak/STAT signaling pathways.
- Cytokine-based therapeutics now in use include recombinant cytokines, inhibitory monoclonal antibodies, fusion proteins composed of cytokine receptors and immunoglobulin chains, topical immunomodulators such as imiquimod, and cytokine fusion toxins.

T-Cell Subsets Distinguished by Pattern of Cytokine Production

Another valuable concept that has withstood the test of time is the assignment of many T cell–derived cytokines into groups based on the specific helper T-cell subsets that produce them (Fig. 11-1). The original two helper T-cell subsets were termed *Th1* and *Th2*. Commitment to one of these two patterns of cytokine secretion also occurs with CD8 cytotoxic T cells and γ/δ T cells. Dominance of type 1 or type 2 cytokines in a T-cell immune response has profound consequences for the outcome of immune responses to certain pathogens and extrinsic proteins capable of serving as allergens.[7] Nearly two decades after the original description of the Th1 and Th2 subsets, strong evidence has emerged that there are other function-







▲ **FIGURE 11-1** Cytokines control the development of specific CD4 helper T-cell subsets. The cytokine milieu at the time of activation of naive undifferentiated CD4 T cells has a profound influence on the ultimate pattern of cytokine secretion adopted by fully differentiated T cells. Subsets of effector CD4 T cells with defined patterns of cytokine secretion include T helper 1 (Th1), Th2, and Th17 cells. Regulatory CD4 T cells (Treg cells) express the FoxP3 transcription factor, and their effects are mediated in part by their production of transforming growth factor-β1 (TGF-β1) and/or interleukin 10 (IL-10). IFN = interferon; LT = lymphotoxin. (Adapted from Tato CM, O'Shea JJ: What does it mean to be just 17? *Nature* **441**:166, 2006.)

ally significant patterns of cytokine secretion by T cells. The Th17 subset is distinguished by production of a high level of IL-17, a member of a family of related cytokines (the other members are IL-17B through F) that had not yet been identified when the Th1 and Th2 subsets were first described. Th17 cells promote inflammation, and there is consistent evidence from human autoimmune diseases and mouse models of these diseases that IL-17–producing cells are critical effectors in autoimmune disease.[8] Another subset of T cells known as *regulatory T cells* (or *Treg cells* for short) has emerged as a crucial subset involved in the maintenance of peripheral self-tolerance.[9] Two of the most distinctive features of Treg cells are their expression of the FoxP3 transcription factor and production of transforming growth factor-β (TGF-β), a cytokine that appears to be required for Treg cells to limit the excess activity of the pro-inflammatory T-cell subsets.[10] IL-10 may also be required for the activity of Treg cells. Not only do each of these T-cell subsets exhibit distinctive patterns of cytokine production, cytokines are key factors in influencing the differentiation of naive T cells into these subsets. IL-12 is the key Th1-promoting factor, IL-4 is required for Th2 differentiation, and both IL-23 and TGF-β are involved in promoting Th17 development.

Structural Classification of Cytokines

Not all useful classifications of cytokines are based solely on analysis of cytokine function. Structural biologists, aided by improved methods of generating homogenous preparations of proteins and establishment of new analytical methods (e.g., solution magnetic resonance spectroscopy) that complement the classical x-ray crystallography technique, have determined the three-dimensional structure of many cytokines. These efforts have led to the identification of groups of cytokines that fold to generate similar three-dimensional structures and bind to groups of cytokine receptors that also share similar structural features. For example, most of the cytokine ligands that bind to receptors of the hematopoietin cytokine receptor family are members of the four-helix bundle group of proteins. Four-helix bundle proteins have a shared tertiary architecture consisting of four antiparallel α-helical stretches separated by short connecting loops. The normal existence of some cytokines as oligomers rather than monomers was discovered in part as the result of structural investigations. For example, interferon-γ (IFN-γ) is a four-helix bundle cytokine that exists naturally as a noncovalent dimer. The bivalency of the dimer enables this ligand to bind and oligomerize two IFN-γ receptor complexes, thereby facilitating signal transduction. TNF-α and TNF-β are both trimers that are composed almost exclusively of β-sheets folded into a "jelly roll" structural motif. Ligand-induced trimerization of receptors in the TNF receptor family is involved in the initiation of signaling.

SIGNAL TRANSDUCTION PATHWAYS SHARED BY CYTOKINES

To accomplish their effects, cytokines must first bind with specificity and high affinity to receptors on the cell surfaces of responding cells. Many aspects of the pleiotropism and redundancy manifested by cytokines can be understood through an appreciation of shared mechanisms of signal transduction mediated by cell surface receptors for cytokines. In the early years of the cytokine biology era, the emphasis of most investigative work was the purification and eventual cloning of new cytokines and a description of their functional capabilities, both in vitro and in vivo. Most of the cytokine receptors have now been cloned, and many of the signaling cascades initiated by cytokines have been described in great detail. The vast majority of cytokine receptors can be classified into a relatively small number of families and superfamilies (Table 11-1), the members of which function in an approximately similar fashion. Table 11-2 lists the cytokines of particular relevance for cutaneous biology, including the major sources, responsive cells, features of interest, and clinical relevance of each cytokine. Most cytokines send signals to cells through pathways that are very similar to those used by other cytokines binding to the same class of receptors. Individual cytokines often employ several downstream pathways of signal transduction, which accounts in part for the pleiotropic effects of these molecules. Nevertheless, we propose here that a few major signaling pathways account for most effects attributable to cytokines. Of particularly central importance are the NF-κB pathway and the Jak/STAT pathway, described in the following sections.

Nuclear Factor κB, Inhibitor of κB, and Primary Cytokines

A major mechanism contributing to the extensive overlap between the biologic

TABLE 11-1
Major Families of Cytokine Receptors

Receptor Family	Example	Major Signal Transduction Pathway(s) Leading to Biologic Effects
IL-1 receptor family	IL-1R, type I	NF-κB activation via TRAF6
TNF receptor family	TNFR1	NF-κB activation involving TRAF2 and TRAF5 Apoptosis induction via "death domain" proteins
Hematopoietin receptor family (class I receptors)	IL-2R	Activation of Jak/STAT pathway
IFN/IL-10 receptor family (class II receptors)	IFN-γR	Activation of Jak/STAT pathway
Immunoglobulin superfamily	M-CSF R	Activation of intrinsic tyrosine kinase
TGF-β receptor family	TGF-βR, types I and II	Activation of intrinsic serine/threonine kinase coupled to Smad proteins
Chemokine receptor family	CCR5	Seven transmembrane receptors coupled to G proteins

CCR = CC chemokine receptor; IFN = interferon; IL = interleukin; Jak = Janus kinase; M-CSF = macrophage colony-stimulating factor; NF-κB = nuclear factor κB; STAT = signal transducer and activator of transcription; TGF = transforming growth factor; TNF= tumor necrosis factor; TRAF = tumor necrosis factor receptor–associated factor.

activities of the primary cytokines IL-1 and TNF is the shared use of the NF-κB signal transduction pathway. IL-1 and TNF use completely distinct cell surface receptor and proximal signaling pathways, but these pathways converge at the activation of the NF-κB transcription factor. NF-κB is of central importance in immune and inflammatory processes because a large number of genes that elicit or propagate inflammation have NF-κB recognition sites in their promoters.[11] NF-κB–regulated genes include cytokines, chemokines, adhesion molecules, nitric oxide synthase, cyclooxygenase, and phospholipase A2.

In unstimulated cells, NF-κB heterodimers formed from p65 and p50 subunits are inactive because they are sequestered in the cytoplasm as a result of tight binding to inhibitor proteins in the IκB family (Fig. 11-2). Signal transduction pathways that activate the NF-

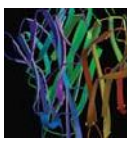


TABLE 11-2
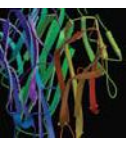
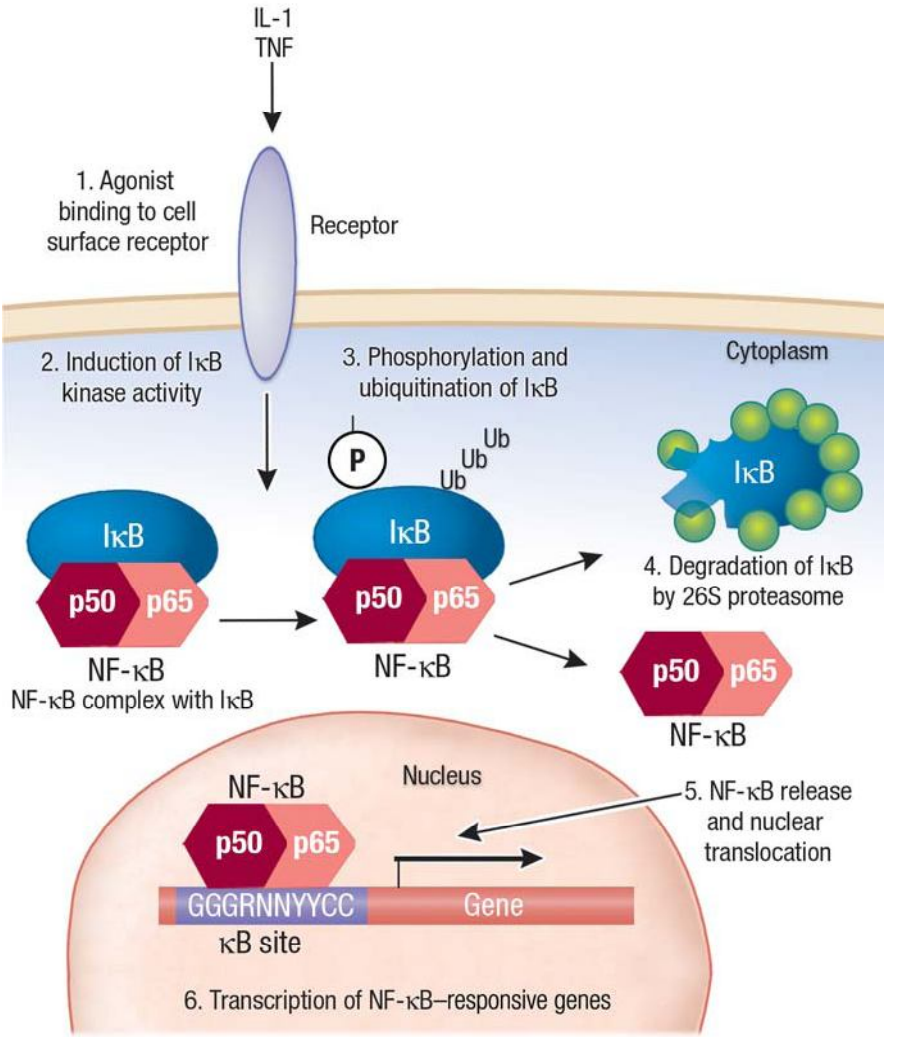
Cytokines of Particular Relevance for Cutaneous Biology

Cytokine	Major Sources	Responsive Cells	Features of Interest	Clinical Relevance
IL-1α	Epithelial cells	Infiltrating leukocytes	Active form stored in keratinocytes	IL-1Ra used to treat rheumatoid arthritis
IL-1β	Myeloid cells	Infiltrating leukocytes	Caspase 1 cleavage required for activation	IL-1Ra used to treat rheumatoid arthritis
IL-2	Activated T cells	Activated T cells, Treg cells	Autocrine factor for activated T cells	IL-2 fusion toxin targets CTCL
IL-4	Activated Th2 cells, NKT cells	Lymphocytes, endothelial cells, keratinocytes	Causes B-cell class switching and Th2 differentiation	—
IL-5	Activated Th2 cells, mast cells	B cells, eosinophils	Regulates eosinophil response to parasites	Anti–IL-5 depletes eosinophils
IL-6	Activated myeloid cells, fibroblasts, endothelial cells	B cells, myeloid cells, hepatocytes	Triggers acute-phase response, promotes immunoglobulin synthesis	—
IL-10	T cells, NK cells	Myeloid and lymphoid cells	Inhibits innate and acquired immune responses	—
IL-12	Activated APCs	Th1 cells	Promotes Th1 differentiation, shares p40 subunit with IL-23	Anti-p40 inhibits Crohn disease and psoriasis
IL-13	Activated Th2 cells	Monocytes, keratinocytes, endothelial cells	Mediates tissue responses to parasites	—
IL-17	Activated Th17 cells	Multiple cell types	Mediates autoimmune diseases	Potential drug target in autoimmune disease
IL-23	Activated dendritic cells	Memory T cells, Th17 cells	Directs Th17 differentiation, mediates autoimmune disease	Anti-p40 inhibits Crohn disease and psoriasis
TNF-α	Activated myeloid, lymphoid, and epithelial cells	Infiltrating leukocytes	Mediates inflammation	Anti–TNF-α effective in psoriasis
IFN-α and IFN-β	Plasmacytoid dendritic cells	Most cell types	Major part of antiviral response	Elicited by topical imiquimod application
IFN-γ	Activated Th1 cells, CD8 T cells, NK cells, dendritic cells	Macrophages, dendritic cells, naive T cells	Macrophage activation, specific isotype switching	IFN-γ used to treat chronic granulomatous disease

APC = antigen-presenting cell; CTCL = cutaneous T-cell lymphoma; IFN = interferon; IL = interleukin; NK = natural killer; NKT = natural killer T cell; Th = T helper; TNF = tumor necrosis factor; Treg = T regulatory.





▲ **FIGURE 11-2** Activation of nuclear factor κB (NF-κB)–regulated genes after signaling by receptors for primary cytokines or by Toll-like receptors (TLRs) engaged by microbial products. Under resting conditions, NF-κB (a heterodimer of p50 and p65 subunits) is tightly bound to an inhibitor called *IκB* that sequesters NF-κB in the cytoplasm. Engagement of one of the TLRs or the signal transducing receptors for interleukin 1 (IL-1) or tumor necrosis factor (TNF) family members leads to induction of IκB kinase activity that phosphorylates IκB on critical serine residues. Phosphorylated IκB becomes a substrate for ubiquitination, which triggers degradation of IκB by the 26S proteasome. Loss of IκB results in release of NF-κB, which permits it to move to the nucleus and activate transcription of genes whose promoters contain κB recognition sites. Ub = ubiquitin.

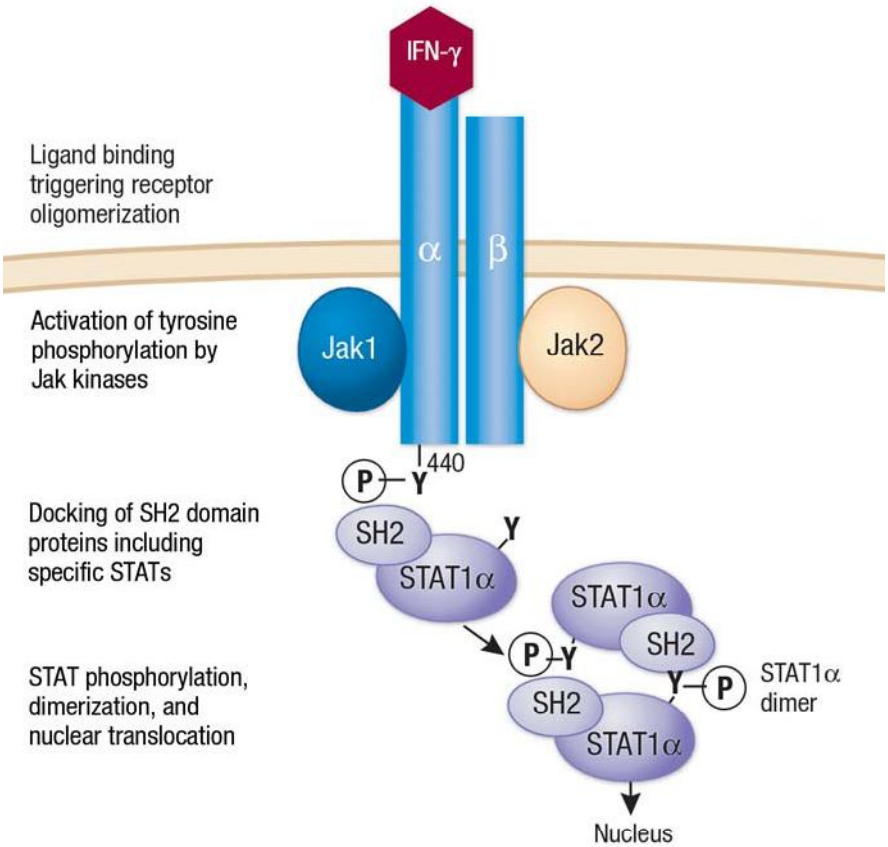
κB system do so through the activation of an IκB kinase (IKK) complex consisting of two kinase subunits (IKKα and IKKβ) and a regulatory subunit (IKKγ). The IKK complex phosphorylates IκBα and IκBβ on specific serine residues, yielding a target for recognition by an E3 ubiquitin ligase complex. The resulting polyubiquitination marks this IκB for rapid degradation by the 26S proteasome complex in the cytoplasm. Once IκB has been degraded, the free NF-κB (which contains a nuclear localization signal) is able to pass into the nucleus and induce expression of NF-κB–sensitive genes. The presence of κB recognition sites in cytokine promoters is very common. Among the genes regulated by NF-κB are IL-1β and TNF-α. This endows IL-1β and TNF-α with the capacity to establish a positive regulatory loop that favors persistent inflammation. Cytokines besides IL-1 and TNF that activate the NF-κB pathway as part of their signal transduction mechanisms include IL-17 and IL-18.

Pro-inflammatory cytokines are not the only stimuli that can activate the NF-κB pathway. Bacterial products (e.g., lipopolysaccharide, or LPS), oxidants, activators of protein kinase C (e.g., phorbol esters), viruses, and ultraviolet (UV) radiation are other stimuli that can stimulate NF-κB activity. TLR4 is a cell surface receptor for the complex of LPS, LPS-binding protein, and CD14. The cytoplasmic domain of TLR4 is similar to that of the interleukin 1 receptor type 1 (IL-1R1) and other IL-1R family members and is known as the *TIR* domain (for Toll/IL-1 receptor).[12] When ligand is bound to a TIR domain–containing receptor, one or more adapter proteins that also contain TIR domains are recruited to the complex. MyD88 was the first of these adapters to be identified; the other known adapters are TIRAP (TIR domain–containing adapter protein), TRIF (TIR domain–containing adapter inducing IFN-β), and TRAM (TRIF-related adapter molecule).[13] Engagement of the adapter, in turn, activates one or more of the IL-1R–associated kinases (IRAK1 to IRAK4), which then signal through TRAF6, a member of the TRAF (TNF receptor–associated factor) family, and TAK1 (TGF-β–activated kinase) to activate the IKK complex.[14]

Jak/STAT Pathway

A major breakthrough in the analysis of cytokine-mediated signal transduction was the identification of a common cell surface to nucleus pathway used by the majority of cytokines. This Jak/STAT pathway was first elucidated through careful analysis of signaling initiated by IFN receptors (Fig. 11-3) but was subsequently shown to play a role in signaling by all cytokines that bind to members of the hematopoietin receptor family.[15] The Jak/STAT pathway operates through the sequential action of a family of four nonreceptor tyrosine kinases (the Jaks or *Ja*nus family *k*inases) and a series of latent cytosolic transcription factors known as *STATs* (*s*ignal *t*ransducers and *a*ctivators of *t*ranscription). The cytoplasmic portions of many cytokine receptor chains are noncovalently associated with one of the four Jaks [Jak1, Jak2, Jak3, and tyrosine kinase 2 (Tyk2)].

The activity of the Jak kinases is upregulated after stimulation of the cytokine receptor. Ligand binding to the cytokine receptors leads to the association of two or more distinct cytokine receptor subunits and brings the associated Jak kinases into close proximity with each other. This promotes cross-phosphorylation or autophosphorylation reactions that in turn fully activate the kinases. Tyrosines in the cytoplasmic tail of the cytokine receptor as well as tyrosines on other associated and newly recruited proteins are also phosphory-



▲ **FIGURE 11-3** Participation of Jak (Janus kinase) and STAT (signal transducer and activator of transcription) proteins in interferon-γ (IFN-γ) signaling. Binding of human IFN-γ (a dimer) to its receptor brings about oligomerization of receptor complexes composed of α and β chains. The nonreceptor protein tyrosine kinases Jak1 and Jak2 are activated and phosphorylate critical tyrosine residues in the receptor such as the tyrosine at position 440 of the α chain (Y^{440}). STAT1α molecules are recruited to the IFN-γ receptor based on the affinity of their Src homology 2 (SH2) domains for the phosphopeptide sequence around Y^{440}. Receptor-associated STAT1α molecules then dimerize through reciprocal SH2-phosphotyrosine interactions. The resulting STAT1α dimers translocate to the nucleus and stimulate transcription of IFN-γ–regulated genes.

lated. A subset of the newly phosphorylated tyrosines can then serve as docking points for attachment of additional signaling proteins bearing Src homology 2 (SH2) domains. Cytoplasmic STATs possess SH2 domains and are recruited to the phosphorylated cytokine receptors via this interaction. Homodimeric or heterodimeric STAT proteins are phosphorylated by the Jak kinases and subsequently translocate to the nucleus. In the nucleus they bind recognition sequences in DNA and stimulate transcription of specific genes, often in cooperation with other transcription factors. The same STAT molecules can be involved in signaling by multiple different cytokines. The specificity of the response in these instances may depend on the formation of complexes involving STATs and other transcription factors that then selectively act on a specific set of genes.

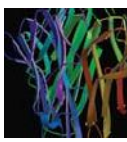
INTERLEUKIN 1 FAMILY OF CYTOKINES (INTERLEUKINS 1α, 1β, 18, 33)

IL-1 is the prototype of a cytokine that has been discovered many times in many different biologic assays. Distinct genes encode the α and β forms of human IL-1, with only 26 percent homology at the amino acid level. Both IL-1s are translated as 31-kd molecules that lack a signal peptide, and both reside in the cytoplasm. This form of IL-1α is biologically active, but 31-kd IL-1β must be cleaved by caspase 1 (initially termed *interleukin-1β–converting enzyme*) to generate an active molecule.

In general, IL-1β appears to be the dominant form of IL-1 produced by monocytes, macrophages, Langerhans cells, and dendritic cells, whereas IL-1α predominates in epithelial cells, including keratinocytes. This is likely to relate to the fact that epithelial IL-1α is stored in the cytoplasm of cells that comprise an interface with the external environment. Such cells, when injured, release biologically active 31-kd IL-1α and, by doing so, can initiate inflammation.[5] If uninjured, however, these cells will differentiate and ultimately release their IL-1 contents into the environment. Leukocytes, including dendritic and Langerhans cells, carry their cargo of IL-1 inside the body, where its unregulated release could cause significant tissue damage. Thus, biologically active IL-1β release from cells is controlled at several levels: IL-1β gene transcription, caspase 1 gene transcription, and availability of the adapter proteins ASC and Ipaf that interact with caspase 1 in the inflammasome to allow the generation of mature IL-1β.[16] The role of IL-1β in the migration of Langerhans cells from the epidermis during the initiation of contact hypersensitivity is a pivotal event in the egress of Langerhans cells from the epidermis and the generation of successful sensitization. Studies of mice deficient in IL-1α and IL-1β genes suggest that both molecules are important in contact hypersensitivity but that IL-1α is more critical.

Active forms of IL-1 bind to the IL-1R1 or type 1 IL-1 receptor.[12] This is the sole signal-transducing receptor for IL-1, and its cytoplasmic domain has little homology with other cytokine receptors, showing greatest homology with the *Toll* gene product identified in *Drosophila*. A second cell surface protein, the IL-1R accessory protein, or IL-1RAcP, must associate with IL-1R1 for signaling to occur. When IL-1 engages the IL-1R1/IL-1RAcP complex, recruitment of the MyD88 adapter occurs, followed by interactions with one or more of the IRAKs. These kinases in turn associate with TRAF6. Stepwise activation and recruitment of additional signaling molecules culminate in the induction of IKK activity. The net result is the activation of a series of NF-κB–regulated genes.

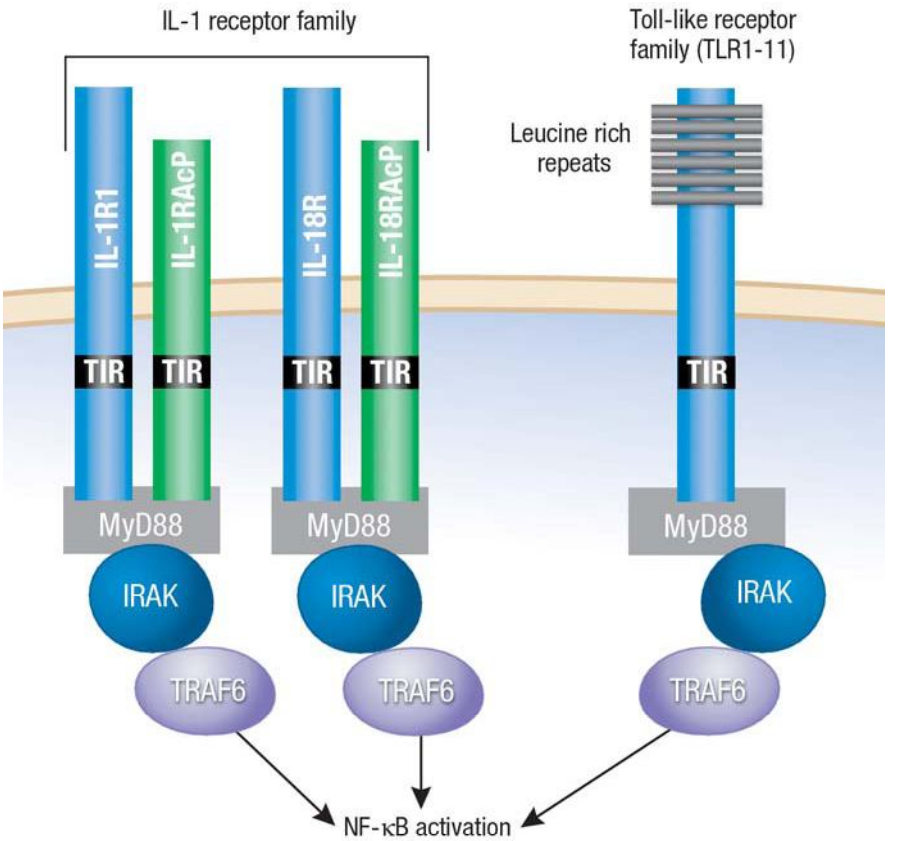
A molecule known as the *IL-1 receptor antagonist*, or IL-1ra, can bind to IL-1R1 but does not induce signaling through the receptor. This IL-1ra exists in three alternatively spliced forms, and an isoform produced in monocytes is the only ligand for the IL-1R1 that both contains a signal peptide and is secreted from cells. Two other isoforms of IL-1ra, both lacking signal peptides, are contained within epithelial cells. The function of IL-1ra seems to be as a pure antagonist of IL-1 ligand binding to IL-1R1, and binding of IL-1ra to IL-1R1 does not in-



duce the mobilization of IL-1RAcP. Consequently, although both IL-1α/β and IL-1ra bind with equivalent affinities to IL-1R1, the association of IL-1R1 with IL-1RAcP increases the affinity for IL-1α/β manyfold while not affecting the affinity for IL-1ra. This is consistent with the observation that a vast molar excess of IL-1ra is required to fully antagonize the effects of IL-1. The biologic role of IL-1ra is likely to be in the quenching of IL-1–mediated inflammatory responses, and mice deficient in IL-1ra show exaggerated and persistent inflammatory responses.

A second means of antagonizing IL-1 activity occurs via expression of a second receptor for IL-1, IL-1R2. This receptor has a short cytoplasmic domain and serves to bind IL-1α/β efficiently, but not IL-1ra. This 68-kd receptor can be cleaved from the cell surface by an unknown protease and released as a stable, soluble 45-kd molecule that retains avid IL-1–binding function. By binding the functional ligands for IL-1R1, IL-1R2 serves to inhibit IL-1–mediated responses. It is likely that IL-1R2 inhibits IL-1 activity in another way, that is, by associating with IL-1RAcP at the cell surface and removing and sequestering it from the pool available to associate with IL-1R1. Thus, soluble IL-1R2 binds to free IL-1, whereas cell surface IL-1R2 sequesters IL-1RAcP. Expression of IL-1R2 can be upregulated by a number of stimuli, including corticosteroids and IL-4. However, IL-1R2 can also be induced by inflammatory cytokines, including IFN-γ and IL-1, probably as a compensatory signal designed to limit the scale and duration of the inflammatory response. Production of IL-1R2 serves to make the producing cell and surrounding cells resistant to IL-1–mediated activation. Interestingly, some of the most efficient IL-1–producing cells are also the best producers of the IL-1R2.

IL-18 was first identified based on its capacity to induce IFN-γ. One name initially proposed for this cytokine was IL-1γ, because of its homology with IL-1α and IL-1β. Like IL-1β, it is translated as an inactive precursor molecule of 23 kd and is cleaved to an active 18-kd species by caspase 1. It is produced by multiple cell types in skin, including keratinocytes, Langerhans cells, and monocytes. IL-18 induces proliferation, cytotoxicity, and cytokine production by Th1 and natural killer (NK) cells, mostly synergistically with IL-12. The IL-18 receptor bears striking similarity to the IL-1 receptor.[12] The binding chain (IL-18R) is an IL-1R1 homolog, originally cloned as IL-1Rrp1. IL-18R alone is a low-affinity receptor that must recruit IL-18RAcP (a homolog of IL-1RAcP). As for IL-1, both chains of the IL-18 receptor are required for signal transduction. Although there is no IL-18 homolog of IL-1ra, a molecule known as *IL-18–binding protein* binds to soluble mature IL-18 and prevents it from binding to the IL-18R complex.



▲ **FIGURE 11-4** The interleukin 1 receptor (IL-1R) family and Toll-like receptors (TLRs) use a common intracellular signaling pathway. Receptors for cytokines in the IL-1 family (typified by the IL-1 and IL-18 receptors) share a common signaling domain with the TLRs (TLR1 to TLR11) called the *Toll/IL-1 receptor (TIR)* domain. The TIR domain receptors interact with TIR domain–containing adapter proteins such as MyD88 that couple ligand binding to activation of IL-1R–associated kinase (IRAK) and ultimately activation of nuclear factor κB (NF-κB). IL-1RAcP = IL-1R accessory protein; TRAF = tumor necrosis factor receptor–associated factor.

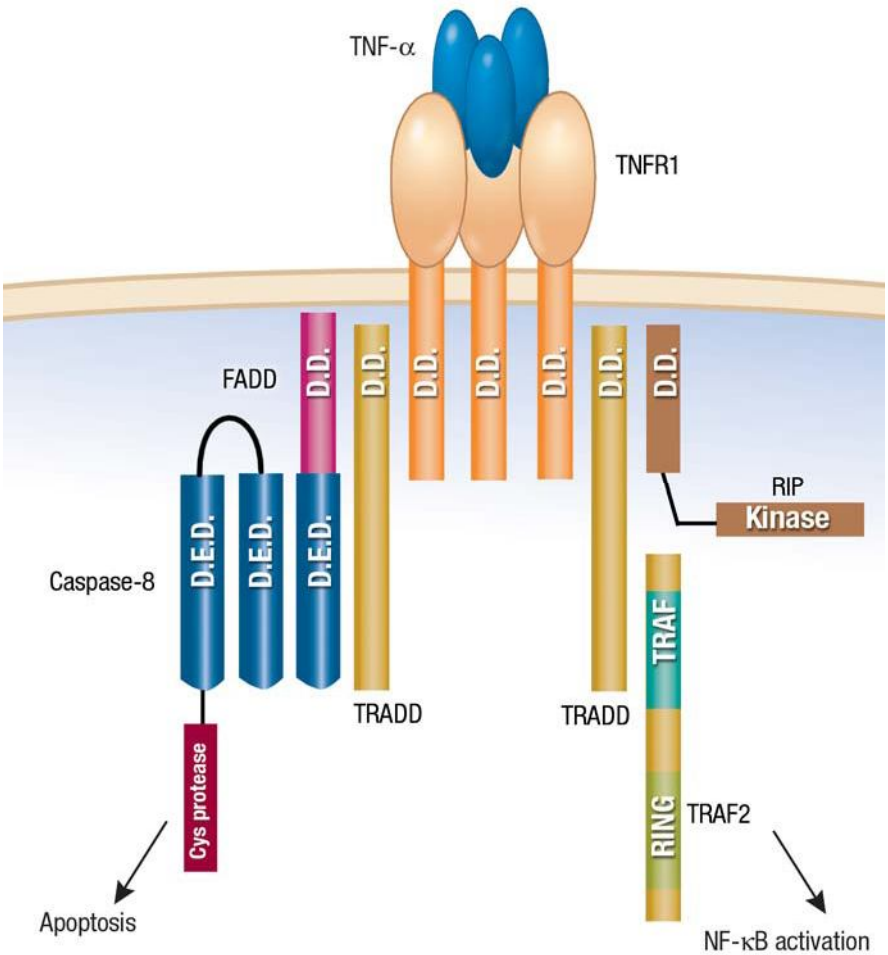
More recently, it has become clear that there is a family of receptors homologous to the IL-1R1 and IL-18R molecules,[12] having in common a TIR motif (Fig. 11-4). All of these share analogous signaling pathways initiated by the MyD88 adapter molecule. One of these receptors, originally known as *ST2*, was initially characterized as a gene expressed by Th2 cells, but not by Th1 cells. The description of a natural ligand for ST2 designated IL-33 has added a new member to the IL-1 family that shares characteristic features of other cytokines in the family, such as a requirement for processing by caspase 1 to release a mature form of the ligand. IL-33 stimulation of Th2 cells promotes their production of the characteristic Th2 cytokines IL-4, IL-5, and IL-10. IL-1R1, IL-18R, IL-33R (ST2), the TLRs, and their ligands are all best viewed as elements of the innate immune system that signal the presence of danger or injury to the host.[17]

When IL-1 produced by epidermis was originally identified, it was noted that both intact epidermis and stratum corneum contained significant IL-1 activity, which led to the concept that epidermis was a shield of sequestered IL-1 surrounding the host, waiting to be released on injury. More recently, it was observed that high levels of the IL-1ra co-exist within keratinocytes; however, repeated experiments show that in virtually all cases, the amount of IL-1 present is sufficient to overcome any potential for inhibition mediated by IL-1ra. Studies have now shown that mechanical stress to keratinocytes permits the release of large amounts of IL-1 in the absence of cell

death. Release of IL-1 induces expression of endothelial adhesion molecules, including E-selectin, ICAM-1, and VCAM-1, as well as chemotactic and activating chemokines. This attracts not only monocytes and granulocytes but a specific sub-population of memory T cells that bear cutaneous lymphocyte antigen on their cell surface. Memory T cells positive for cutaneous lymphocyte antigen are abundant in inflamed skin, comprising the majority of T cells present. Therefore, any injury to the skin, no matter how trivial, releases IL-1 and attracts this population of memory T cells. If they encounter their antigen in this microenvironment, their activation and subsequent cytokine production will amplify the inflammatory response. This has been proposed as the basis of the clinical observation of inflammation in response to trauma, known as the *Koebner reaction*.

TUMOR NECROSIS FACTOR: THE OTHER PRIMARY CYTOKINE

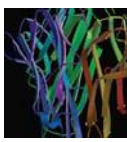
TNF-α is the prototype for a family of related signaling molecules that mediate their biologic effects through a family of related receptor molecules. TNF-α was initially cloned on the basis of its ability to mediate two interesting biologic effects: (1) hemorrhagic necrosis of malignant tumors, and (2) inflammation-associated cachexia. Although TNF-α exerts many of its biologically important effects as a soluble mediator, newly synthesized TNF-α exists as a transmembrane protein on the cell surface. A specific metalloproteinase known as *TNF-α–converting enzyme (TACE)* is responsible for most TNF-α release by T cells and myeloid cells. The closest cousin of TNF-α is TNF-β, also known as *lymphotoxin α (LT-α)*. Other related molecules in the TNF family include lymphotoxin β (LT-β), which combines with LT-α to form the LT-α1β2 heterotrimer; Fas ligand (FasL); TNF-related apoptosis-inducing ligand (TRAIL); TNF-related activation-induced cytokine (TRANCE); and CD40 ligand (CD154). Although some of these other TNF family members have not been traditionally regarded as cytokines, their structure (all are type II membrane proteins with an intracellular N-terminus and an extracellular C-terminus) and signaling mechanisms are closely related to those of TNF. The soluble forms of TNF-α, LT-α, and FasL are homotrimers, and the predominant form of LT-β is the membrane-bound LT-α1β2 heterotrimer. Trimerization of TNF receptor family members by their trimeric ligands appears to be required for initiation of signaling and expression of biologic activity.



▲ **FIGURE 11-5** Two contrasting outcomes of signaling through tumor necrosis factor receptor 1 (TNFR1). Engagement of TNFR1 by trimeric tumor necrosis factor-α (TNF-α) can trigger apoptosis and/or nuclear factor κB (NF-κB) activation. Both processes involve the adapter protein TNFR-associated death domain (TRADD), which associates with TNFR1 via interactions between "death domains" (D.D.) on both proteins. For NF-κB activation, TNFR–associated factor 2 (TRAF2) and receptor-interacting protein (RIP) are required. Induction of apoptosis occurs when the death domain–containing protein Fas-associated death domain protein (FADD) associates with TRADD. FADD also contains a "death effector domain" (D.E.D.) that interacts with caspase 8 to initiate the apoptotic process. Cys = cysteine. (Adapted from Yuan J: Transducing signals of life and death. *Curr Opin Cell Biol* **9**:247, 1997; and Nagata S: Apoptosis by death factor. *Cell* **88**:355, 1997.)

The initial characterization of TNF receptors led to the discovery of two receptor proteins capable of binding TNF-α with high affinity. The p55 receptor for TNF (TNFR1) is responsible for most biologic activities of TNF, but the p75 TNF receptor (TNFR2) is also capable of transducing signals (unlike IL-1R2, which acts solely as a biologic sink for IL-1). TNFR1 and TNFR2 have substantial stretches of close homology and are both present on most types of cells. Nevertheless, there are some notable differences between the two TNFRs.

Unlike cytokine receptors from several of the other large families, TNF signaling does not involve the Jak/STAT pathway. TNF-α evokes two types of responses in cells: (1) pro-inflammatory effects, and (2) induction of apoptotic cell death (Fig. 11-5). The pro-inflammatory effects of TNF-α, which include upregulation of adhesion molecule expression and induction of secondary cytokines and chemokines, stem in large part from activation of NF-κB and can be transduced through both TNFR1 and TNFR2. Induction of apoptosis by signaling through TNFR1 depends on a region known as a *death domain* that is absent in TNFR2, as well as interactions with additional proteins with death domains within the TNFR1 signaling complex. Signaling initiated by ligand bind-



ing to TNFR1, Fas, or other death domain–containing receptors in the TNF family eventually leads to activation of caspase 8 or 10 and the nuclear changes and DNA fragmentation characteristic of apoptosis.

At least two TNFR family members (TNFR1 and the LT-β receptor) also contribute to the normal anatomic development of the lymphoid system. Mice deficient in TNF-α lack germinal centers and follicular dendritic cells. TNFR1 mutant mice show the same abnormalities plus an absence of Peyer's patches. Mice with null mutations in LT-α or LT-β have further abnormalities in lymphoid organogenesis and fail to develop peripheral lymph nodes.

TNF-α is an important mediator of cutaneous inflammation, and its expression is induced in the course of almost all inflammatory responses in skin. Normal human keratinocytes and keratinocyte cell lines produce substantial amounts of TNF-α after stimulation with LPS or UV light. Cutaneous inflammation stimulated by irritants and contact sensitizers is associated with strong induction of TNF-α production by keratinocytes. Exposure to TNF-α causes Langerhans cells to migrate to draining lymph nodes, which allows for sensitization of naive T cells. One molecular mechanism that may contribute to TNF-α–induced migration of Langerhans cells toward lymph nodes is reduced expression of the E-cadherin adhesion molecule after exposure to TNF-α. Induction of CC chemokine receptor 7 on both epidermal and dermal antigen-presenting cells correlates with movement into the draining lymphatics. The predominant TNFR expressed by keratinocytes is TNFR1. Autocrine signaling loops involving keratinocyte-derived TNF-α and TNFR1 lead to keratinocyte production of a variety of TNF-inducible secondary cytokines.

The central role of TNF-α in inflammatory diseases, including rheumatoid arthritis and psoriasis, has become evident from clinical studies. Clinical drugs that target the TNF pathway include the humanized anti–TNF-α antibody infliximab, the human anti–TNF-α antibody adalumimab, and the soluble TNF receptor etanercept. Drugs in this class are U.S. Food and Drug Administration (FDA) approved for the treatment of several autoimmune and inflammatory diseases, including Crohn disease and rheumatoid arthritis. All of these anti-TNF drugs are also FDA approved for the treatment of psoriatic arthritis, and etanercept is approved for use in treating chronic plaque psoriasis (see Chap. 235). This class of drugs also has the potential to be valuable in the treatment of other inflammatory dermatoses. Paradoxically, they are not effective against all autoimmune diseases—multiple sclerosis appears to worsen slightly after treatment with these agents. The TNF antagonists are powerful immunomodulating drugs, and appropriate caution is required in their use. Cases of cutaneous T-cell lymphoma initially thought to represent psoriasis have rapidly progressed to fulminant disease after treatment with TNF antagonists. TNF antagonists can also allow the escape of latent mycobacterial infections from immune control, with a potentially lethal outcome for the patient.

LIGANDS OF THE CLASS I (HEMATOPOIETIN RECEPTOR) FAMILY OF CYTOKINE RECEPTORS

The hematopoietin receptor family (also known as the *class I cytokine receptor family*) is the largest of the cytokine receptor families and comprises a number of structurally related type I membrane-bound glycoproteins. The cytoplasmic domains of these receptors associate with nonreceptor tyrosine kinase molecules, including the Jak kinases and src family kinases. After ligand binding and receptor oligomerization, these associated nonreceptor tyrosine kinases phosphorylate intracellular substrates, which leads to signal transduction. Most of the multiple-chain receptors in the hematopoietin receptor family consist of a cytokine-specific α chain subunit paired with one or more shared receptor subunits. Five shared receptor subunits have been described to date: the common γ chain (γ_c), the common β chain shared between the IL-2 and IL-15 receptors; a distinct common β chain shared between the granulocyte-macrophage colony stimulating factor (GM-CSF), IL-3, and IL-5 receptors; the IL-12Rβ2 chain shared by the IL-12 and IL-23 receptors; and finally the glycoprotein 130 (gp130) molecule, which participates in signaling by IL-6 and related cytokines.

Cytokines with Receptors That Include the γ_c Chain

The receptor complexes using the γ_c chain are the IL-2, IL-4, IL-7, IL-9, IL-13, IL-15, and IL-21 receptors. Two of these receptors, IL-2R and IL-15R, also use the IL-2Rβ_c chain. The γ_c chain is physically associated with Jak3, and activation of Jak3 is critical to most signaling initiated through this subset of cytokine receptors.[18]

INTERLEUKIN 2 AND INTERLEUKIN 15 IL-2 and IL-15 can each activate NK cells and stimulate proliferation of activated T cells. IL-2 is a product of activated T cells, and IL-2R is largely restricted to lymphoid cells. The IL-15 gene is expressed by nonlymphoid tissues, and its transcription is induced by UVB radiation in keratinocytes and fibroblasts and by LPS in monocytes and dendritic cells. Multiple isoforms of IL-15Rα are found in various hematopoietic and non-hematopoietic cells. The IL-2R and IL-15R complexes of lymphocytes incorporate up to three receptor chains, whereas most other cytokine receptor complexes have two. The affinities of IL-2R and IL-15R for their respective ligands can be regulated, and to some extent, IL-2 and IL-15 compete with each other. The highest-affinity receptor complexes for each ligand (approximately 10^{-11} *M*) consist of the IL-2Rβ_c and γ_c chains, as well as their respective α chains (IL-2Rα, also known as CD25, and IL-15Rα). γ_c and IL-2Rβ_c without the α chains form a functional lower-affinity receptor for either ligand (10^{-8} to 10^{-10} *M*). Although both ligands transmit signals through the γ_c chain, those signals elicit overlapping but distinct responses in various cells. Activation of naive CD4 T cells by T-cell receptor and co-stimulatory molecules induces expression of IL-2, IL-2Rα, and IL-2Rβ_c, which leads to vigorous proliferation. Prolonged stimulation of T-cell receptor and IL-2R leads to expression of FasL and activation-induced cell death. Although IL-2 signaling facilitates the death of CD4 T cells in response to sustained exposure to antigen, IL-15 inhibits IL-2–mediated activation-induced cell death as it stimulates growth. Similarly, IL-15 promotes proliferation of memory CD8 T cells, whereas IL-2 inhibits it. IL-15 is also involved in the homeostatic survival of memory CD8 T cells, NK cells, and NK T cells. These contrasting biologic roles are illustrated by mice deficient in IL-2 or IL-2Rα, which develop autoimmune disorders, and mice deficient in IL-15 or IL-15Rα, which have lymphopenia and immune deficiencies. Thus IL-15 appears to have an important role in promoting effector functions of antigen-specific T cells, whereas IL-2 is involved in reining in autoreactive T cells.[19]

INTERLEUKIN 4 AND INTERLEUKIN 13 IL-4 and IL-13 are products of activated Th2 cells that share limited structural homology (approximately 30 percent) and overlapping but distinct biologic activities. A specific receptor for IL-4, which does not bind IL-13, is found on T cells and NK cells. It consists of IL-4Rα (CD124) and γ_c and transmits signals via Jak1 and Jak3. A second receptor complex that can bind either IL-4 or IL-13 is found on keratinocytes, endothelial cells, and other nonhematopoietic cells. It consists of IL-13Rα1 (CD213a1) and IL-4Rα and transmits signals via Jak1 and Jak2. These receptors are expressed at low levels in resting cells, and their expression is increased by various activating signals. Curiously, exposure of monocytes to IL-4 or IL-13 suppresses expression of IL-4Rα and IL-13Rα1, whereas the opposite effect is observed in keratinocytes. Both signal transduction pathways appear to converge with the activation of STAT6, which is both necessary and sufficient to drive Th2 differentiation. Another cell surface molecule homologous to IL-13Rα1, termed *IL-13Rα2* (CD213a2), binds specifically to IL-13 but is not known to transmit any signals.[20]

The biologic effects of engagement of the IL-4 receptor vary depending on the specific cell type, but most pertain to its principal role as a growth and differentiation factor for Th2 cells. Exposure of naive T cells to IL-4 stimulates them to proliferate and differentiate into Th2 cells, which produce more IL-4, which in turn leads to autocrine stimulation that prolongs Th2 responses. Thus the expression of IL-4 early in the immune response can initiate a cascade of Th2 cell development that results in a predominately Th2 response. The genes encoding IL-4 and IL-13 are located in a cluster with IL-5 which undergoes structural changes during Th2 differentiation that are associated with increased expression. Although naive T cells can make low levels of IL-4 when activated, IL-4 is also produced by activated NK T cells. Mast cells and basophils also release preformed IL-4 from secretory granules in response to FcεRI-mediated signals. A prominent activity of IL-4 is the stimulation of class switching of the immunoglobulin genes of B cells. As critical factors in Th2 differentiation and effector function, IL-4 and IL-13 are mediators of atopic immunity. In addition to controlling the behavior of effector cells they also act directly on resident tissue cells, such as in inflammatory airway reactions.[21]

INTERLEUKIN 9 AND INTERLEUKIN 21 IL-9 is a product of activated Th2 cells that acts as an autocrine growth factor as well as a mediator of inflammation.[22] It is also produced by mast cells in response to IL-10 or stem cell factor. It stimulates proliferation of T and B cells and promotes expression of immunoglobulin E by B cells. It also exerts pro-inflammatory effects on mast cells and eosinophils. IL-9–deficient mice exhibit deficits in mast cell and goblet cell differentiation. IL-21 is also a product of Th2 T cells that signals through a receptor composed of a specific α chain (IL-21R) homologous to the IL-4R α chain and γ_c.[23] Absence of an intact IL-21 receptor is associated with impaired Th2 responses.[24] IL-9 and IL-21 can be grouped together with IL-4 and IL-13 as cytokines that function as effectors of allergic inflammatory processes and may play an important role in asthma and allergic disorders.

INTERLEUKIN 7 Mutations abrogating the function of IL-7, IL-7Rα (CD127), γ_c, or Jak3 in mice or humans cause profound immunodeficiency as a result of T- and NK-cell depletion.[18] This is principally due to the indispensable role of IL-7 in promoting the expansion of lymphocytes and regulating the rearrangement of their antigen receptor genes. IL-7 is a potent mitogen and survival factor for immature lymphocytes in the bone marrow and thymus. The second function of IL-7 is as a modifier of effector cell functions in the reactive phase of certain immune responses. IL-7 transmits activating signals to mature T cells and certain activated B cells. Like IL-2, IL-7 has been shown to stimulate proliferation of cytolytic T cells and lymphokine-activated killer cells in vitro and to enhance their activities in vivo. Monocytes exposed to IL-7 release IL-6, IL-1α, IL-1β, and TNF-α and exhibit enhanced tumoricidal activity in vitro. IL-7 is a particularly significant cytokine for lymphocytes in the skin and other epithelial tissues. It is expressed by keratinocytes in a regulated fashion, and this expression is thought to be part of a reciprocal signaling dialog between dendritic epidermal T cells and keratinocytes in murine skin. Keratinocytes release IL-7 in response to IFN-γ, and dendritic epidermal T cells secrete IFN-γ in response to IL-7.

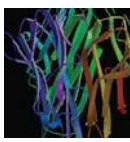
An IL-7–related cytokine using one chain of the IL-7 receptor as part of its receptor is thymic stromal lymphopoietin (TSLP). TSLP was originally identified as a novel cytokine produced by a thymic stromal cell line that could act as a growth factor for B- and T-lineage cells. The TSLP receptor consists of the IL-7 receptor α chain and a second receptor chain homologous to but distinct from the γ_c chain. TSLP has attracted interest because of its ability to prime dendritic cells to become stronger stimulators of Th2 cells. This activity may permit TSLP to foster the development of some types of allergic diseases.[25]

Cytokines with Receptors Using the Interleukin 3 Receptor β Chain

The receptors for IL-3, IL-5, and GM-CSF consist of unique cytokine-specific α chains paired with a common β chain known as *IL-3Rβ* or β_c (CD131). Each of these factors acts on subsets of early hematopoietic cells.[26] IL-3, which was previously known as *multi-lineage colony-stimulating factor*, is principally a product of $CD4^+$ T cells and causes proliferation, differentiation, and colony formation of various myeloid cells from bone marrow. IL-5 is a product of Th2 $CD4^+$ cells and activated mast cells that conveys signals to B cells and eosinophils. IL-5 has a co-stimulatory effect on B cells in that it enhances their proliferation and immunoglobulin expression when they encounter their cognate antigen. In conjunction with an eosinophil-attracting chemokine known as *eotaxin*, IL-5 plays a central role in the accumulation of eosinophils that accompanies parasitic infections and some cutaneous inflammatory processes. IL-5 appears to be required to generate a pool of eosinophil precursors in bone marrow that can be rapidly mobilized to the blood, whereas eotaxin's role is focused on recruitment of these eosinophils from blood into specific tissue sites. GM-CSF is a growth factor for myeloid progenitors produced by activated T cells, phagocytes, keratinocytes, fibroblasts, and vascular endothelial cells. In addition to its role in early hematopoiesis, GM-CSF has potent effects on macrophages and dendritic cells. In vitro culture of fresh Langerhans cells in the presence of GM-CSF promotes their transformation into mature dendritic cells with maximal immunostimulatory potential for naive T cells. The effects of GM-CSF on dendritic cells probably account for the dramatic ability of GM-CSF to evoke therapeutic antitumor immunity when tumor cells are engineered to express it.[27]

Interleukin 6 and Other Cytokines with Receptors Using Glycoprotein 130

Receptors for a group of cytokines including IL-6, IL-11, IL-27, leukemia inhibitory factor, oncostatin M, ciliary



neurotrophic factor, and cardiotrophin-1 interact with a hematopoietin receptor family member, gp130, that does not appear to interact with any ligand by itself. The gp130 molecule is recruited into signaling complexes with other receptor chains when they engage their cognate ligands.

IL-6 is the most thoroughly characterized of the cytokines that use gp130 for signaling and serves as a paradigm for discussion of the biologic effects of this family of cytokines. IL-6 is yet another example of a highly pleiotropic cytokine with multiple effects. A series of different names (including *IFN-β2, B-cell stimulatory factor 2, plasmacytoma growth factor, cytotoxic T cell differentiation factor,* and *hepatocyte-stimulating factor*) were used for IL-6 before it was recognized that a single molecular species accounts for all of these activities. IL-6 acts on a wide variety of cells of hematopoietic origin. IL-6 stimulates immunoglobulin secretion by B cells and has mitogenic effects on B lineage cells and plasmacytomas. IL-6 also promotes maturation of megakaryocytes and differentiation of myeloid cells. Not only does it participate in hematopoietic development and reactive immune responses, but IL-6 is also a central mediator of the systemic acute-phase response. Increases in circulating IL-6 levels stimulate hepatocytes to synthesize and release acute-phase proteins.

There are two distinct signal transduction pathways triggered by IL-6. The first of these is mediated by the gp130 molecule when it dimerizes on engagement by the complex of IL-6 and IL-6Rα. Homodimerization of gp130 and its associated Jak kinases (Jak1, Jak2, Tyk2) leads to activation of STAT3. A second pathway of gp130 signal transduction involves Ras and the mitogen-activated protein kinase cascade and results in phosphorylation and activation of a transcription factor originally designated *nuclear factor of IL-6*.

IL-6 is an important cytokine for skin and is subject to dysregulation in several human diseases, including some with skin manifestations. IL-6 is produced in a regulated fashion by keratinocytes, fibroblasts, and vascular endothelial cells as well as by leukocytes infiltrating the skin. IL-6 can stimulate the proliferation of human keratinocytes under some conditions. Psoriasis is one of several inflammatory skin diseases in which elevated expression of IL-6 has been described. Human herpesvirus 8 produces a viral homolog of IL-6 that may be involved in the pathogenesis of human herpesvirus 8–associated diseases, including Kaposi sarcoma and body cavity–based lymphomas.

The other cytokines using gp130 as a signal transducer have diverse bioactivities. IL-11 inhibits production of inflammatory cytokines and has shown some therapeutic activity in patients with psoriasis. Exogenous IL-11 also stimulates platelet production and has been used to treat thrombocytopenia occurring after chemotherapy. IL-27 is discussed in the next section with the IL-12 family of cytokines.

Interleukin 12, Interleukin 23, and Interleukin 27: Pivotal Cytokines for T Helper 1 and T Helper 17 Responses

IL-12 is different from most other cytokines in that its active form is a heterodimer of two proteins, p35 and p40. IL-12 is principally a product of antigen-presenting cells such as dendritic cells, monocytes, macrophages, and certain B cells in response to bacterial components, GM-CSF, and IFN-γ. Activated keratinocytes are an additional source of IL-12 in skin. Human keratinocytes constitutively make the p35 subunit, whereas expression of the p40 subunit can be induced by stimuli including contact allergens, phorbol esters, and UV radiation.

IL-12 is a critical immunoregulatory cytokine that is central to the initiation and maintenance of Th1 responses. Th1 responses that are dependent on IL-12 provide protective immunity to intracellular bacterial pathogens. IL-12 also has stimulatory effects on NK cells, promoting their proliferation, cytotoxic function, and the production of cytokines, including IFN-γ. IL-12 has been shown to be active in stimulating protective antitumor immunity in a number of animal models.[27]

Two chains that are part of the cell surface receptor for IL-12 have been cloned. Both are homologous to other β chains in the hematopoietin receptor family and are designated β1 and β2. The β1 chain is associated with Tyk2 and the β2 chain interacts directly with Jak2. The signaling component of the IL-12R is the β2 chain. The β2 chain is expressed in Th1 but not Th2 cells and appears to be critical for commitment of T cells to production of type 1 cytokines. IL-12 signaling induces the phosphorylation of STAT1, STAT3, and STAT4, but it is STAT4 that is essential for induction of a Th1 response.

IL-23 is a heterodimeric cytokine in the IL-12 family that consists of the p40 chain of IL-12 in association with a distinct p19 chain. IL-23 has overlapping activities with IL-12 but also induces proliferation of memory T cells. Interest in IL-23 has been sparked by the observation that IL-23 is involved in the induction of T cells producing IL-17 (Th17 subset).[28] The IL-23 receptor consists of two chains: the IL-12Rβ1 chain that forms part of the IL-12 receptor and a specific IL-23 receptor encoded by a gene located near the IL-12Rβ2 gene.[29]

The newest member of the IL-12 family is IL-27. IL-27 is also a heterodimer and consists of a subunit called *EBI3* that is homologous to IL-12 p40 and a second subunit known as *p28* that is homologous to IL-12 p35. IL-27 plays a role in the early induction of the Th1 response.[30] The IL-27 receptor consists of a receptor called *WSX-1* that associates with the shared signal-transducing molecule gp130.[31]

The IL-12 family of cytokines has emerged as a promising new target for anti-cytokine pharmacotherapy. The approach that has been developed the furthest to date is targeting both IL-12 and IL-23 with monoclonal antibodies directed against the common p40 subunit. An anti–human p40 monoclonal antibody (CNTO 1275) was reported to show beneficial effects in phase I trials in psoriasis patients.[32] A similar therapeutic antibody (ABT-784) has demonstrated efficacy in Crohn disease.[33] The development of anti-p40 therapies is several years behind anti–TNF-α drugs, but p40 is an attractive target for future drug development efforts for some types of immune-mediated diseases.

LIGANDS OF THE CLASS II FAMILY OF CYTOKINE RECEPTORS

A second major class of cytokine receptors with common features includes two types of receptors for IFNs, IL-10R, and the receptors for additional IL-10–related cytokines including IL-19, IL-20, IL-22, and IL-24.

Interferons: Prototypes of Cytokines Signaling Through a Jak/STAT Pathway

IFNs were one of the first families of cytokines to be characterized in detail. The IFNs were initially subdivided into three classes: IFN-α (the leukocyte IFNs), IFN-β (fibroblast IFN), and IFN-γ

(immune IFN). The α and β IFNs are collectively called *type I IFNs*, and all of these molecules signal through the same two-chain receptor (the IFN-αβ receptor).[34] The second IFN receptor is a distinct two-chain receptor specific for IFN-γ. Both of these IFN receptors are present on many cell types within skin as well as in other tissues. Each of the chains comprising the two IFN receptors is associated with one of the Jak kinases (Tyk2 and Jak1 for the IFN-αβR and Jak1 and Jak2 for the IFN-γR). Only in the presence of both chains and two functional Jak kinases will effective signal transduction occur after IFN binding. A new class of IFNs known as *IFN-λ* or *type III IFNs* has now been identified that has a low degree of homology with both type I IFNs and IL-10.[35] The current members of this class are IL-28A, IL-28B, and IL-29. Although the effects of these cytokines are similar to those of the type I IFNs, they are less potent. These type III IFNs use a shared receptor that consists of the β chain of the IL-10 receptor associated with an IL-28 receptor α chain.

Viruses, double-stranded RNA, and bacterial products are among the stimuli that elicit release of the type I IFNs from cells. Plasmacytoid dendritic cells have emerged as a particularly potent cellular source of type I IFNs. Many of the effects of the type I IFNs directly or indirectly increase host resistance to the spread of viral infection. Additional effects mediated through IFN-αβR are increased expression of major histocompatibility complex (MHC) class I molecules and stimulation of NK cell activity. Not only does it have well-known antiviral effects, but IFN-α also can modulate T-cell responses by favoring the development of a Th1 type of T-cell response. Finally, the type I IFNs also inhibit the proliferation of a variety of cell types, which provides a rationale for their use in the treatment of some types of cancer. Forms of IFN-α enjoy considerable use clinically for indications ranging from hairy cell leukemia, various cutaneous malignancies, and papillomavirus infections (see Chap. 196). Some of the same conditions that respond to therapy with type I IFNs also respond to topical immunomodulatory agents like imiquimod. This synthetic imidazoquinoline drug is an agonist for the TLR7 receptor, whose natural ligand is single-stranded RNA. Imiquimod stimulation of cells expressing TLR7 elicits local release of large amounts of type I IFNs from plasmacytoid dendritic cells, which can trigger clinically useful antiviral and tumor inhibitory effects against genital warts, superficial basal cell carcinoma, and actinic keratoses. Resiquimod is a related synthetic compound that activates both TLR7 and TLR8, eliciting a slightly different spectrum of cytokines.[36]

Production of IFN-γ is restricted to NK cells, CD8 T cells, and Th1 CD4 T cells. Th1 cells produce IFN-γ after engagement of the T-cell receptor, and IL-12 can provide a strong co-stimulatory signal for T-cell IFN-γ production. NK cells produce IFN-γ in response to cytokines released by macrophages, including TNF-α, IL-12, and IL-18. IFN-γ has antiviral activity, but it is a less potent mediator than the type I IFNs for induction of these effects. The major physiologic role of IFN-γ is its capacity to modulate immune responses. IFN-γ induces synthesis of multiple proteins that play essential roles in antigen presentation to T cells, including MHC class I and class II glycoproteins, invariant chain, the Lmp2 and Lmp7 components of the proteasome, and the TAP1 and TAP2 intracellular peptide transporters. These changes increase the efficiency of antigen presentation to CD4 and CD8 T cells. IFN-γ is also required for activation of macrophages to their full antimicrobial potential, enabling them to eliminate microorganisms capable of intracellular growth. Like type I IFNs, IFN-γ also has strong antiproliferative effects on some cell types. Finally, IFN-γ is also an inducer of selected chemokines (CXC chemokine ligands 9 to 11) and an inducer of endothelial cell adhesion molecules (e.g., ICAM-1 and VCAM-1). Because of the breadth of IFN-γ's activities, it comes the closest of the T-cell cytokines to behaving as a primary cytokine.

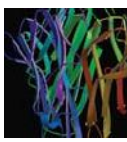
Interleukin 10: An "Anti-Inflammatory" Cytokine

IL-10 is one of several cytokines that primarily exert regulatory rather than stimulatory effects on immune responses.[37] IL-10 was first identified as a cytokine produced by Th2 T cells that inhibited cytokine production after activation of T cells by antigen and antigen-presenting cells. IL-10 exerts its action through a cell surface receptor found on macrophages, dendritic cells, neutrophils, B cells, T cells, and NK cells. The ligand-binding chain of the receptor is homologous to the receptors for IFN-α/β and IFN-γ, and signaling events mediated through the IL-10 receptor use a Jak/STAT pathway. IL-10 binding to its receptor activates the Jak1 and Tyk2 kinases and leads to the activation of STAT1 and STAT3. The effects of IL-10 on antigen-presenting cells such as monocytes, macrophages, and dendritic cells include inhibition of expression of class II MHC and co-stimulatory molecules (e.g., B7-1, B7-2) and decreased production of T cell–stimulating cytokines (e.g., IL-1, IL-6, and IL-12). At least four viral genomes harbor viral homologues of IL-10 that transmit similar signals by binding to the IL-10R.

A major source of IL-10 within skin is epidermal keratinocytes. Keratinocyte IL-10 production is upregulated after activation; one of the best-characterized activating stimuli for keratinocytes is UV irradiation. UV radiation–induced keratinocyte IL-10 production leads to local and systemic effects on immunity. Some of the well-documented immunosuppressive effects that occur after UV light exposure are the result of the liberation of keratinocyte-derived IL-10 into the systemic circulation. IL-10 also plays a dampening role in other types of cutaneous immune and inflammatory responses, because the absence of IL-10 predisposes mice to exaggerated irritant and contact sensitivity responses.

Novel Interleukin 10–Related Cytokines: Interleukins 19, 20, 22, and 24

A series of cytokines related to IL-10 have been identified and shown to engage a number of receptor complexes with shared chains.[38] IL-19, IL-20, and IL-24 transmit signals via a complex consisting of IL-20Rα and IL-20Rβ. Transgenic mice overexpressing IL-20 develop severe cutaneous inflammation and altered epidermal proliferation and differentiation. Expression of the IL-20R chains is strongly induced when they are triggered, and they are only detected on keratinocytes, endothelial cells, and certain monocytes in association with inflammatory conditions such as psoriasis.[39] IL-22 activates a receptor consisting of IL-22R and IL-10Rβ, whereas IL-20 and IL-24 also engage a complex incorporating IL-20Rβ and IL-22R.[40,41] The profound effects of IL-20 expression in transgenic mice and the association of IL-20R expression with psoriasis point toward a significant role for these cytokines in the epidermal changes associated with cutaneous inflammation.



TRANSFORMING GROWTH FACTOR-β FAMILY AND ITS RECEPTORS

TGF-β1 was first isolated as a secreted product of virally transformed tumor cells capable of inducing normal cells in vitro to show phenotypic characteristics associated with transformation. Over 30 additional members of the TGF-β family have now been identified. They can be grouped into several families: the prototypic TGF-βs (TGF-β1 to TGF-β3), the bone morphogenetic proteins, the growth/differentiation factors, and the activins. The TGF name for this family of molecules is somewhat of a misnomer, because TGF-β has antiproliferative rather than proliferative effects on most cell types. Many of the TGF-β family members play an important role in development, influencing the differentiation of uncommitted cells into specific lineages. TGF-β family members are made as precursor proteins that are biologically inactive until a large pro-domain is cleaved. Monomers of the mature domain of TGF-β family members are disulfide linked to form dimers that strongly resist denaturation.

Participation of at least two cell surface receptors (type I and type II) with serine/threonine kinase activity is required for biologic effects of TGF-β.[42] Ligand binding by the type II receptor (the true ligand-binding receptor) is associated with the formation of complexes of type I and type II receptors. This allows the type II receptor to phosphorylate and activate the type I receptor, a "transducer" molecule that is responsible for downstream signal transduction. Downstream signal transmission from the membrane-bound receptors in the TGF-β receptor family to the nucleus is primarily mediated by a family of cytoplasmic Smad proteins that translocate to the nucleus and regulate transcription of target genes.

TGF-β has a profound influence on several types of immune and inflammatory processes. An immunoregulatory role for TGF-β1 was identified in part through analysis of TGF-β1 knockout mice that develop a wasting disease at 20 days of age associated with a mixed inflammatory cell infiltrate involving many internal organs. This phenotype is now appreciated to be a result in part of the compromised development of regulatory T cells when TGF-β1 is not available. Development of cells in the dendritic cell lineage is also perturbed in the TGF-β1–deficient mice, as evidenced by an absence of epidermal Langerhans cells and specific sub-populations of lymph node dendritic cells. A combination of effects of TGF-β on fibroblast function make it one of the most fibrogenic of all cytokines studied.[43] TGF-β–treated fibroblasts display enhanced production of collagen and other extracellular matrix molecules. In addition, TGF-β inhibits the production of metalloproteinases by fibroblasts and stimulates the production of inhibitors of the same metalloproteinases (tissue inhibitors of metalloproteinase, or TIMPs). TGF-β effects on fibroblasts may be important in promoting wound healing.

CHEMOKINES: SECONDARY CYTOKINES CENTRAL TO LEUKOCYTE MOBILIZATION

Chemokines are a large superfamily of small cytokines that have two major functions. First, they guide leukocytes via chemotactic gradients in tissue. Typically, this is to bring an effector cell to where its activities are required. Second, a subset of chemokines has the capacity to increase the binding of leukocytes via their integrins to ligands at the endothelial cell surface, which facilitates firm adhesion and extravasation of leukocytes in tissue. The activities of this important class of cytokines are sufficiently complex that they are the subject of a separate chapter (Chap. 12).

CYTOKINE NETWORK—THERAPEUTIC IMPLICATIONS AND APPLICATIONS

This chapter has attempted to bring some degree of order and logic to the analysis of a field of human biology that continues to grow at a rapid rate. Although many things may change in the world of cytokines, certain key concepts have stood the test of time. Principal among them is the idea that cytokines are emergency molecules, designed to be released locally and transiently in tissue microenvironments. When cytokines are released persistently, the result is typically chronic disease. One potential way to treat such diseases is with cytokine antagonists or other drugs that target cytokines or cytokine-mediated pathways.

Cytokines and cytokine antagonists are being used therapeutically by clinicians, and development of additional agents continues. With certain notable exceptions, systemic cytokine therapy has been disappointing and is often accompanied by substantial morbidity. In contrast, local and transient administration of cytokines may yield more promising results. An example of this approach is the transduction of tumor cells to express factors such as GM-CSF (GVAX vaccines) or IL-12 family members to enhance antitumor immune responses.[44] Conversely, agents that specifically block cytokine activity are also being developed. Antibodies and TNF receptor–Fc fusion proteins are FDA-approved antagonists of TNF-α activity that are highly effective at inducing durable remissions in psoriasis (see Chaps. 18, 235, and 236). Antibodies against the p40 subunit shared by IL-12 and IL-23 are also active in treating psoriasis. Anakinra is a formulation of recombinant IL-1Ra approved by the FDA as adjunct therapy or second-line monotherapy for the treatment of adult rheumatoid arthritis and has been shown to be very effective in patients with neonatal-onset multisystemic inflammatory disease (see Chap. 134). Other cytokines that have predominantly anti-inflammatory effects, such as IL-10 and IL-11, show some inhibitory activity in psoriasis, but are not currently being developed further for this indication. A class of pharmacologic agents that inhibits the production of multiple T cell–derived cytokines is the calcineurin inhibitors. Tacrolimus and pimecrolimus both bind to the immunophilin FK-506 binding protein-12 (FKBP-12), producing complexes that bind to calcineurin, a calcium-dependent phosphatase that acts on proteins in the nuclear factor of activated T cells' family to promote their nuclear translocation and activation of cytokine genes (including IL-2, IL-4, and IFN-γ)[45] (see Chap. 221). Finally, fusion toxins linked to cytokines, such as the IL-2 fusion protein denileukin diftitox, exploit the cellular specificity of certain cytokine-receptor interactions to kill target cells (see Chap. 235). Denileukin diftitox is FDA approved for the treatment of cutaneous T-cell lymphoma and has also shown therapeutic activity in psoriasis.[46] Each of the aforementioned approaches is still relatively new and open to considerable future development. An understanding of cytokines by clinicians of the future is likely to be central to effective patient care.

CHAPTER 12

Chemokines

Sam T. Hwang

The skin is an organ in which the migration, influx, and egress of leukocytes occurs in both homeostatic and inflammatory processes. Chemokines and their receptors are accepted as vital mediators of cellular trafficking. Since the discovery of the first chemoattractant cytokine, or chemokine, in 1977, 50 additional new chemokines and 17 chemokine receptors have been discovered. Most chemokines are small proteins with molecular weights in the 8 to 10 kd range and are synthesized constitutively in some cells and can be induced in many cell types by cytokines. Initially associated only with recruitment of leukocyte subsets to inflammatory sites,[1] it has become clear that chemokines play roles in angiogenesis, neural development, cancer metastasis, hematopoiesis, and infectious diseases. This chapter focuses primarily on the function of chemokines in inflammatory conditions, but also touches on the role of these molecules in other settings as well.

STRUCTURE OF CHEMOKINES

Chemokines are grouped into four subfamilies based on the spacing of amino acids between the first two cysteines. The CXC chemokines (also called *α-chemokines*) show a C-X-C motif with one nonconserved amino acid between the two cysteines. The other major subfamily of chemokines (called β-chemokines) lacks the additional amino acid and is termed the *CC subfamily*. The two remaining subfamilies contain only one member each: the C subfamily is represented by lymphotactin, and fractalkine is the only member of the CXXXC (or CX3C) subfamily. Chemokines can also be assigned to one of two broad and, perhaps, overlapping functional groups. One group [e.g., regulated on activation normal T-cell expressed and secreted (RANTES), macrophage inflammatory protein 1α/β, liver and activation-regulated chemokine (LARC)] mediates the attraction and recruitment of immune cells to sites of active inflammation, whereas others [e.g., secondary lymphoid-organ chemokine (SLC) and stromal cell–derived factor-1 (SDF-1)] appear to play a role in constitutive or homeostatic migration pathways.[2]

The complexity and redundancy in the nomenclature of chemokines have led to the proposal for a systematic nomenclature for chemokines based on the type of chemokine (C, CXC, CX3C, or CC) and a number based on the order of discovery as proposed by Zlotnik and Yoshie.[2] For example, SDF-1, a CXC chemokine, has the systematic name CXCL12. Because both nomenclatures are still in wide use, the original names (abbreviated in most cases) as well as systematic names are used interchangeably throughout the chapter. Table 12-1 provides a list of chemokine receptors of interest in skin that are discussed in this chapter as well as the major chemokine ligands that bind to them.

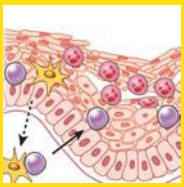
Chemokines are highly conserved and have similar secondary and tertiary structure. Based on crystallography studies, a disordered amino terminus followed by three conserved antiparallel β-pleated sheets is a common structural feature of chemokines. Fractalkine is unique in that the chemokine domain sits atop a mucin-like stalk tethered to the plasma membrane via a transmembrane domain and short cytoplasmic tail.[3] Although CXC and CC chemokines form multimeric structures under conditions required for structural studies, these associations may be relevant only when chemokines associate with cell-surface components such as glycosaminoglycans (GAGs) or proteoglycans. Because most chemokines have a net positive charge, these proteins tend to bind to negatively charged carbohydrates present on GAGs. Indeed, the ability of positively charged chemokines to bind to GAGs is thought to enable chemokines to preferentially associate with the lumenal surface of blood vessels despite the presence of shear forces from the blood that would otherwise wash the chemokines away.

CHEMOKINE RECEPTORS AND SIGNAL TRANSDUCTION

Chemokine receptors are seven transmembrane spanning membrane proteins that couple to intracellular heterotrimeric G proteins containing α, β, and γ subunits.[2] They represent a part of a large family of G protein coupled receptors (GPCRs), including rhodopsin, that have critical biologic functions. Leukocytes express several Gα protein subtypes: s, i, and q, whereas the β and γ subunits each have 5 and 11 known subtypes, respectively. This complexity in the formation of the heterotrimeric G protein may account for specificity in the action of certain chemokine receptors. Normally, G proteins are inactive when guanosine diphosphate (GDP) is bound, but they are activated when the GDP is exchanged for guanosine triphosphate (GTP) (Fig. 12-1). After binding to ligand, chemokine receptors rapidly associate with G proteins, which in turn increases the exchange of GTP for GDP. Pertussis toxin is a commonly used inhibitor of GPCR that irreversibly adenosine diphosphate-ribosylates Gα subunits of the α_i class and subsequently prevents most chemokine receptor–mediated signaling.

Activation of G proteins leads to the dissociation of the Gα and Gβγ subunits (see Fig. 12-1). The Gα subunit has been observed to activate protein tyrosine kinases and mitogen activated protein kinase, leading to cytoskeletal changes and gene transcription. The Gα subunit retains GTP, which is slowly hydrolyzed by the guanosine triphosphatase (GTPase) activity of this subunit. This GTPase activity is both positively and negatively regulated by GTPase-activating proteins

CHEMOKINES AT A GLANCE



- Chemokines and their receptors are vital mediators of cellular trafficking.
- Most chemokines are small proteins with molecular weights in the 8- to 10-kd range.
- Chemokines are synthesized constitutively in some cells and can be induced in many cell types by cytokines.
- Chemokines play roles in inflammation, angiogenesis, neural development, cancer metastasis, hematopoiesis, and infectious disease.
- In skin, chemokines play important roles in atopic dermatitis, psoriasis, melanoma, melanoma metastasis, and some viral (including retroviral) infections.
- Promising therapeutic applications of chemokines include the prevention of T-cell arrest on activated endothelium or blocking infection of T cells by human immunodeficiency virus 1 using CC chemokine receptor 5 analogues.

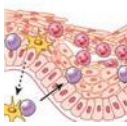


TABLE 12-1
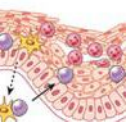
Chemokine Receptors in Skin Biology

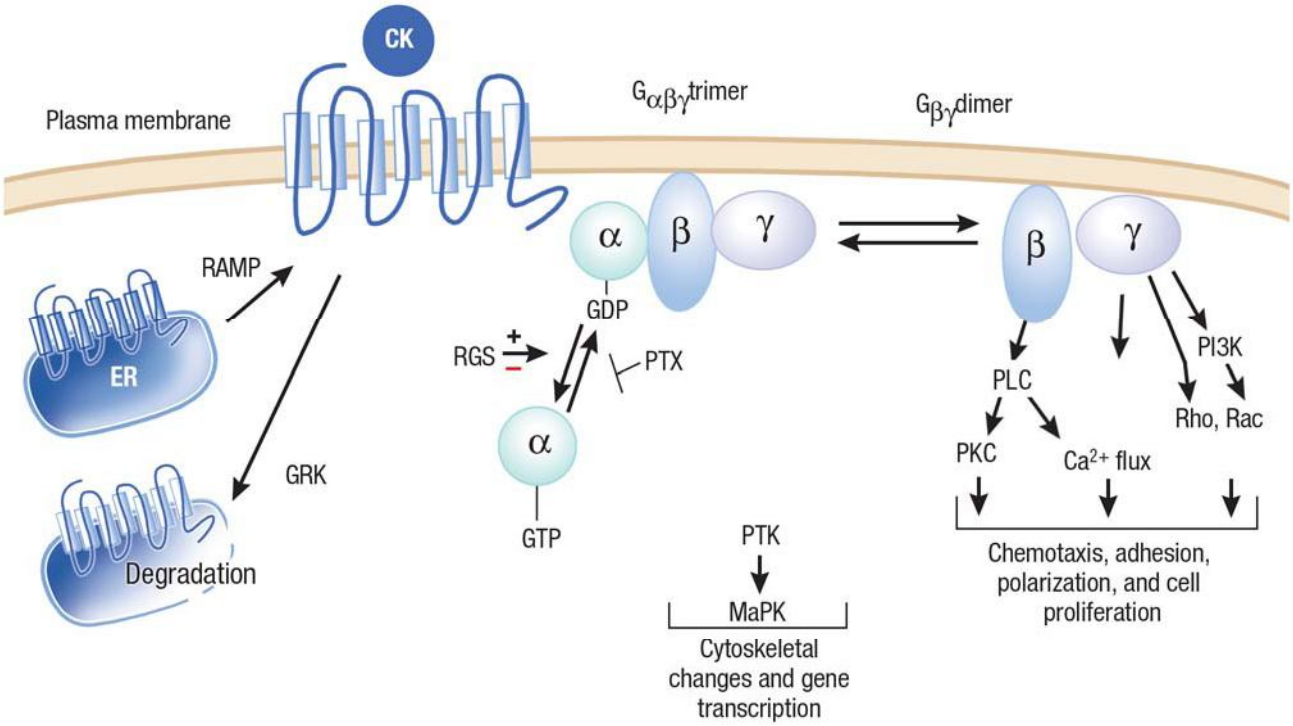
Chemokine Receptor (CCR)	Chemokine Ligand (CCL)	Expression Pattern	Comments	References
CCR1	MIP-1α (CCL3), RANTES (CCL5), MCP-3 (CCL7)	T, Mo, DCs, NK, B	Migration of DCs and Mo; strongly upregulated in T by IL-2	82
CCR2	MCP-1 (CCL2), -3, -4 (CCL13)	T, Mo	Migration of T to inflamed sites; replenish Langerhans cell precursors in epidermis; involved in skin fibrosis via MCP-1	32, 63, 82
CCR3	Eotaxin (CCL11) > RANTES, MCP-2 (CCL8), 3, 4	Eosinophils, basophils, Th2, NK	Migration of Th2, T, and "allergic" immune cells	22, 91
CCR4	TARC (CCL17), macrophage-derived chemokine (CCL22)	T (benign and malignant)	Expression in Th2 > Th1 cells; highly expressed on CLA+ memory T; TARC expression by keratinocytes may be important in atopic dermatitis; may guide trafficking of malignant as well as benign inflammatory T	10, 21, 44, 78, 92
CCR5	RANTES, MIP-1α,β (CCL3, 4)	T, Mo, DCs	Marker for Th1 cells; migration to acutely inflamed sites; may be involved in transmigration of T through endothelium; major HIV-1 fusion co-receptor	14, 82
CCR6	Liver and activation-regulated chemokine (CCL20)	T, DCs, B	Expressed by memory, not naive, T; possibly involved in arrest of memory T to activated endothelium and recruitment of T to epidermis in psoriasis	54, 55, 93
CCR7	Secondary lymphoid-organ chemokine (CCL21), Epstein-Barr virus–induced molecule-1 ligand chemokine (CCL19)	T, DCs, B, melanoma cells	Critical for migration of naive T and "central memory" T to secondary lymphoid organs; required for mature DCs to enter lymphatics and localize to lymph nodes; facilitates nodal metastasis	15, 34, 38, 74, 94
CCR9	Thymus-expressed chemokine (CCL25)	T, melanoma cells	Associated with melanoma small bowel metastases	75
CCR10	CTACK (CCL27)	T (benign and malignant), melanoma cells	Preferential response of CLA^+ T to CTACK in vitro; may be involved in T (benign as well as malignant) homing to epidermis, where CTACK is expressed; survival of melanoma in skin	9, 27, 76, 80
CXCR1, 2	IL-8 (CXCL8), MGSA/GRO α (CXCL1), ENA-78 (CXCL5)	Neutrophils, NK, En, melanoma cells	Recruitment of neutrophils (e.g., epidermis in psoriasis); may be involved in angiogenesis; melanoma growth factor	61, 96, 97
CXCR3	Interferon-inducible protein 10 (CXCL10), monokine induced by interferon-γ (CXCL9), interferon-inducible T cell α chemoattractant (CXCL11)	T	Marker for Th1 cells and may be involved in T recruitment to epidermis in cutaneous T-cell lymphoma; induces arrest of activated T on stimulated endothelium	18, 26
CXCR4	Stromal cell–derived factor-1α,β (CXCL12)	T, DCs, En, melanoma cells	Major HIV-1 fusion co-receptor; involved in vascular formation; involved in melanoma metastasis	73, 82
CX3CR1	Fractalkine (CX3CL1)	T, Mo, mast cells, NK	May be involved in adhesion on activated T, Mo, and NK cells to activated endothelium	3, 97

B = B cells; CLA = cutaneous lymphocyte–associated antigen; CTACK = cutaneous T cell–attracting chemokine; DCs = dendritic cells; En = endothelial cells; HIV-1 = human immunodeficiency virus 1; IL = interleukin; MCP = macrophage chemoattractant protein; MIP = macrophage inflammatory protein; Mo = monocytes; NK = natural killer cells; RANTES = regulated on activation normal T-cell expressed and secreted; T = T cells; TARC = thymus and activation-regulated chemokine; Th = T helper.



(also known as *regulator of G protein signaling proteins*). The Gβγ dimer initiates critical signaling events in regard to chemotaxis and cell adhesion. It activates phospholipase C,[4] leading to formation of diacylglycerol and inositol triphosphate [$Ins(1,4,5)P_3$]. $Ins(1,4,5)P_3$ stimulates Ca^{2+} entry into the cytosol, which along with diacylglycerol, activates protein kinase C isoforms. Although the Gβγ subunits have been shown to be critical for chemotaxis, the $G\alpha_i$ subunit has no known role in chemotactic migration. There is also evidence that binding of chemokine receptors results in the activation of other intracellular effectors including Ras and Rho, phosphatidylinositol-3-kinase.[5]

RhoA and protein kinase C appear to play a role in integrin affinity changes, whereas phosphatidylinositol-3-kinase may be critical for changes in the avidity state of lymphocyte function–associated antigen 1. Other proteins have been found that regulate the synthesis, expression, or degradation of GPCRs. For example, receptor-activity-modifying proteins act as chaperones of seven transmembrane spanning receptors and regulate surface expression as well as



▲ **FIGURE 12-1** Chemokine receptor–mediated signaling pathways. the ligand specificity of chemokine receptors (see Fig. 12-1). Importantly, after chemokine receptors are exposed to appropriate ligands, they are frequently internalized, leading to an inability of the chemokine receptor to mediate further signaling. This downregulation of chemokine function, which has been termed *desensitization*, occurs because of phosphorylation of Ser/Thr residues in the C-terminal tail by proteins termed *GPCR kinases* and subsequent internalization of the receptor (see Fig. 12-1). Desensitization may be an important mechanism for regulating the function of chemokine receptors by inhibiting cell migration as leukocytes arrive at the primary site of inflammation.

CHEMOKINES AND CUTANEOUS LEUKOCYTE TRAFFICKING

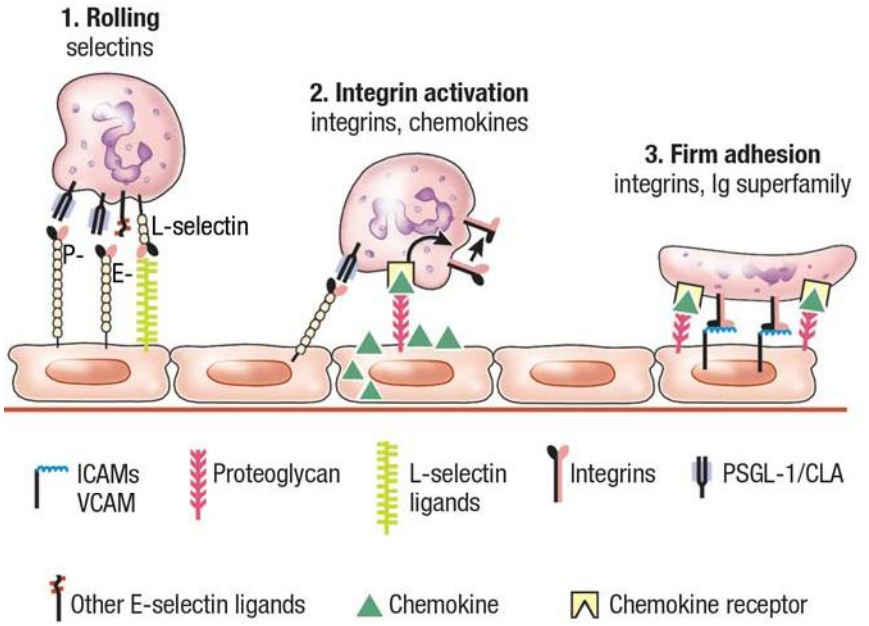
Generally speaking, chemokines are thought to play at least three different roles in the recruitment of host defense cells, predominantly leukocytes, to sites of inflammation.[6] First, they provide the signal or signals required to cause leukocytes to come to a complete stop (i.e., arrest) in blood vessels at inflamed sites such as skin. Second, chemokines have been shown to have a role in the transmigration of leukocytes from the lumenal side of the blood vessel to the ablumenal side. Third, chemokines attract leukocytes to sites of inflammation in the dermis or epidermis after transmigration. Keratinocytes and endothelial cells are a rich source of chemokines when stimulated by appropriate cytokines. In addition, chemokines and their receptors are known to play critical roles in the emigration of resident skin dendritic cells (DCs) [i.e., Langerhans cells (LCs) and dermal DCs] from the skin to draining lymph nodes (LNs) via afferent lymphatic vessels, a process that is essential for the development of acquired immune responses (see Chap. 10).

This section is divided into three subsections. The first introduces basic concepts of how all leukocytes arrest in inflamed blood vessels before transmigration by introducing the multistep model of leukocyte recruitment. The second details mechanisms of T-cell migration, and the final subsection focuses on the mechanisms by which chemokines mediate the physiologic migration of DCs from the skin to regional LNs.

Multistep Model of Leukocyte Recruitment

For leukocytes to adhere and migrate to peripheral tissues, they must overcome the pushing force of the vascular blood stream as they bind to activated endothelial cells at local sites of inflammation. According to the multistep or cascade model of leukocyte recruitment (Fig. 12-2), one set of homologous adhesion molecules termed *selectins* mediates the transient attachment of leukocytes to endothelial cells while another set of adhesion molecules termed *integrins* and their receptors (immunoglobulin superfamily members) mediates stronger binding (i.e., arrest) and transmigration.[7] The selectins (E-, L-, and P-selectin) are members of a larger family of carbohydrate-binding proteins termed *lectins*. The selectins bind their respective carbohydrate ligands located on protein scaffolds and thus mediate the transient binding or "rolling" of leukocytes on endothelial cells.

The skin-associated vascular selectin known as *E-selectin* is upregulated on endothelial cells by inflammatory cytokines such as tumor necrosis factor (TNF)-α and binds to sialyl Lewis X–based carbohydrates. E-selectin ligands form distinct epitopes known as the *cutaneous lymphocyte–associated antigen* (CLA). CLA is expressed by 10 percent to 40 percent of memory T cells and has been suggested as a marker for skin-homing T cells.[8] At least two chemokine receptors [CC chemokine receptor 10 (CCR10) and CCR4] show preferential expression in CLA^+ memory T



▲ **FIGURE 12-2** Multistep model of leukocyte recruitment. Leukocytes, pushed by the blood stream, first transiently bind or "roll" on the surface of activated endothelial cells via rapid interactions with P-, E-, or L-selectin. Chemokines are secreted by endothelial cells and bind to proteoglycans that present the chemokine molecules to chemokine receptors on the surface of the leukocyte. After chemokine receptor ligation, intracellular signaling events lead to a change in the conformation of integrins and changes in their distribution on the plasma membrane, resulting in integrin activation. These changes result in high affinity/avidity binding of integrins to endothelial cell intercellular adhesion molecules (ICAMs) and vascular cell adhesion molecule (VCAM)-1 in a step termed *firm adhesion*, which is then followed by transmigration of the leukocyte between endothelial cells and into tissue. CLA = cutaneous lymphocyte–associated antigen; Ig = immunoglobulin; PSGL-1 = P-selectin glycoprotein ligand 1.

cells.[9,10] Whereas E-selectin is likely to be an important component of skin-selective homing, there is also evidence to suggest that L-selectin is involved in T-cell migration to skin.[11,12]

In the second phase of this model, leukocyte integrins such as those of the β_2 family must be "turned on" or activated from their resting state to bind to their counter-receptors such as intercellular adhesion molecule 1 that are expressed by endothelial cells. A vast array of data suggest that the binding of chemokines to leukocyte chemokine receptors plays a critical role in activating both β_1 and β_2 integrins.[5,13] Activation of chemokine receptors leads to a complex signaling cascade (see Fig. 12-1) that causes a conformational change in individual integrins that leads to increases in the affinity and avidity of individual leukocyte integrins for their ligands. Furthermore, later steps of migration (i.e., transmigration or diapedesis) have been shown to be dependent on chemokines as well in selective cases.[14] In the case of neutrophils, their ability to roll on inflamed blood vessels likely depends on their expression of L-selectin and E-selectin ligands whereas their arrest on activated endothelia likely depends on their expression of CXCR1 and CXCR2 as described below for wound healing (see Chap. 163). Integrin activation via chemokine-mediated signals appears to be more complex in T cells, which appear to use multiple chemokine receptors, and is described in more detail in the following section.

Chemokine-Mediated Migration of T Cells

Antigen-inexperienced T cells are termed *naive* and can be identified by expression three cell surface proteins: CD45RA (an isoform of the pan-leukocyte marker), L-selectin, and the chemokine receptor CCR7. These T cells migrate efficiently to secondary LNs, where they may make contact with antigen-bearing DCs from the periphery. Once activated by DCs presenting antigen, T cells then express CD45RO, are termed *memory* T cells, and appear to express a variety of adhesion molecules and chemokine receptors which facilitate their extravasation from blood vessels to inflamed peripheral tissue. A specific subset of $CCR7^-$, L-$selectin^-$ memory T cells, has been proposed to represent an effector memory T-cell subset that is ready for rapid deployment at peripheral sites in terms of their cytotoxic activity and ability to mobilize cytokines.[15]

Although chemokines are both secreted and soluble, the net positive charge on most chemokines allows them to bind to negatively charged proteoglycans such as heparin sulfate that are present on the lumenal surface of endothelial cells, thus allowing them to be presented to T cells as they roll along the lumenal surface (see Fig. 12-2). After ligand binding, chemokine receptors send intracellular signals that lead to increases in the affinity and avidity of T-cell integrins such as lymphocyte function–associated antigen 1 and very late antigen 4 for their endothelial receptors intercellular adhesion molecule 1 and vascular cell adhesion molecule-1, respectively.[16] Only a few chemokine receptors (CXCR4, CCR7, CCR4, and CCR6) are expressed at sufficient levels on resting peripheral blood T cells to mediate this transition. With activation and interleukin (IL)-2 stimulation, increased numbers of chemokine receptors (e.g., CXCR3) are expressed on activated T cells, making them more likely to respond to other chemokines. In several different systems, inhibition of specific chemokines produced by endothelial cells or chemokine receptors found on T cells dramatically influences T-cell arrest in vivo and in vitro.[17]

CXCR3 serves as a receptor for chemokine ligands Mig (monokine induced by interferon-γ), interferon-inducible protein 10 (IP-10), and interferon-inducible T cell α chemoattractant. All three of these chemokines are distinguished from other chemokines by being highly upregulated by interferon-γ. Resting T cells do not express functional levels of CXCR3, but upregulate this receptor with activation and cytokines such as IL-2. Once expressed on T cells, CXCR3 is capable of mediating arrest of memory T cells on activated endothelial cells.[18] The expression of its chemokine ligands is strongly influenced by the cytokine interferon-γ, which synergistically works with proinflammatory cytokines such as TNF-α to increase expression of these ligands by activated endothelial cells[18] and epithelial cells.

In general, activation of T cells by cytokines such as IL-2 is associated with the enhanced expression of CCR1, CCR2, CCR5, and CXCR3. Just as T helper 1 (Th1) and Th2 (T cell) subsets have different functional roles, it might

have been predicted that these two subsets of T cells would express different chemokine receptors. Indeed, CCR4[19–21] and CCR3[22] are associated with Th2 cells in vitro, whereas Th1 cells are associated with CCR5 and CXCR3.[23]

In some instances, chemokine receptors may be regarded as functional markers that identify Th1- versus Th2-type lymphocytes while also promoting their recruitment to inflammatory sites characterized by "allergic" or "cell-mediated" immunity, respectively. When T cells are activated in vitro in the presence of Th1-promoting cytokines, CXCR3 and CCR5 appear to be highly expressed, whereas in the presence of Th2-promoting cytokines, CCR4, CCR8, and CCR3 expression predominates. In rheumatoid arthritis, a Th1-predominant disease, many infiltrating T cells express CCR5 and CXCR3[24] whereas, in atopic disease, CCR4 expressing T cells may be more frequent.[21] There is likely to be overlap as demonstrated under some conditions in which both Th1 and Th2 type T cells can express CCR4.[20]

The epidermis is a particularly rich source of chemokines, including RANTES, macrophage chemoattractant protein-1 (MCP-1), IP-10, IL-8, LARC, and thymus and activation-regulated chemokine (TARC), which likely contribute to epidermal T-cell migration. Keratinocytes from patients with distinctive skin diseases appear to express unique chemokine expression profiles. For instance, keratinocytes derived from patients with atopic dermatis (see Chap. 14) synthesized messenger RNA for RANTES at considerably earlier time points in response to IL-4 and TNF-α in comparison to unaffected and psoriatic patients.[25] Keratinocytes derived from psoriatic patients (see Chap. 18) synthesized higher levels of IP-10 with cytokine stimulation as well as higher constitutive levels of IL-8,[25] a chemokine known to recruit neutrophils. IL-8 may contribute to the large numbers of neutrophils that localize to the suprabasal and cornified layers of the epidermis in psoriasis. IP-10 may serve to recruit activated T cells of the Th1 helper phenotype to the epidermis and has been postulated to have a role in the recruitment of malignant T cells to the skin in cutaneous T-cell lymphomas.[26]

Cutaneous T cell–attracting chemokine (CTACK)/CC chemokine ligand 27 (CCL27) is selectively and constitutively expressed in the epidermis, and its expression is only marginally increased under inflammatory conditions.[27] Interestingly, CTACK has been reported to preferentially attract CLA$^+$ memory T cells in vitro[27] and has been demonstrated to play a role in the recruitment and function of skin-homing T cells in inflammatory disease models.[28,29]

Chemokines in the Trafficking of Dendritic Cells from Skin to Regional Lymph Nodes

Antigen-presenting cells, including DCs of the skin, are critical initiators of immune responses and their trafficking patterns are thought to influence immunologic outcomes. Their mission includes taking up antigen at sites of infection or injury and bringing these antigens to regional LNs where they both present antigen and regulate the responses of T and B cells. Skin-resident DCs are initially derived from hematopoietic bone marrow progenitors[30] and migrate to skin during the late prenatal and newborn periods of life. Under resting (steady state) conditions, homeostatic production by keratinocytes of CXCL14 (receptor unknown) may be involved in attracting CD14$^+$ DC precursors to the basal layer of the epidermis.[31] Under inflammatory conditions, when skin-resident DC and LC leave the skin in large numbers, keratinocytes release a variety of chemokines, including CCL2 and CCL7 (via CCR2)[32] and CCL20 (via CCR6),[33] which may attract monocyte-like DC precursors to the epidermis to replenish the LC population.

When activated by inflammatory cytokines (e.g., TNF-α, and IL-1β), lipopolysaccharide, or injury, skin DCs, including LCs, leave the epidermis, enter afferent lymphatic vessels, and migrate to draining regional LNs where they encounter both naive and memory T cells. Chemokines guide the DC on this journey. Activated DC specifically upregulate expression of CCR7, which binds to secondary lymphoid tissue chemokine (SLC/CCL21), a chemokine expressed constitutively by lymphatic endothelial cells (see eFig. 12-2.1 in on-line edition).[34,35] SLC guides DCs into dermal lymphatic vessels and helps retain them in SLC-rich regional draining LNs (Fig. 12-3).[36]

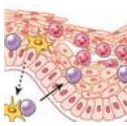
Interestingly, naive T cells also strongly express CCR7 and use this receptor to arrest on high endothelial venules.[37] The importance of the CCR7 pathway is demonstrated by LCs from CCR7 knockout mouse that demonstrate poor migration from the skin to regional LNs[38] and by the observation that antibodies to SLC block migration of DCs from the periphery to LNs.[34] Thus, CCR7 and its ligands facilitate the recruitment of at least two different kinds of cells—naive T cells and DCs—to the LNs through two different routes under both inflammatory[38] and resting conditions.[36]

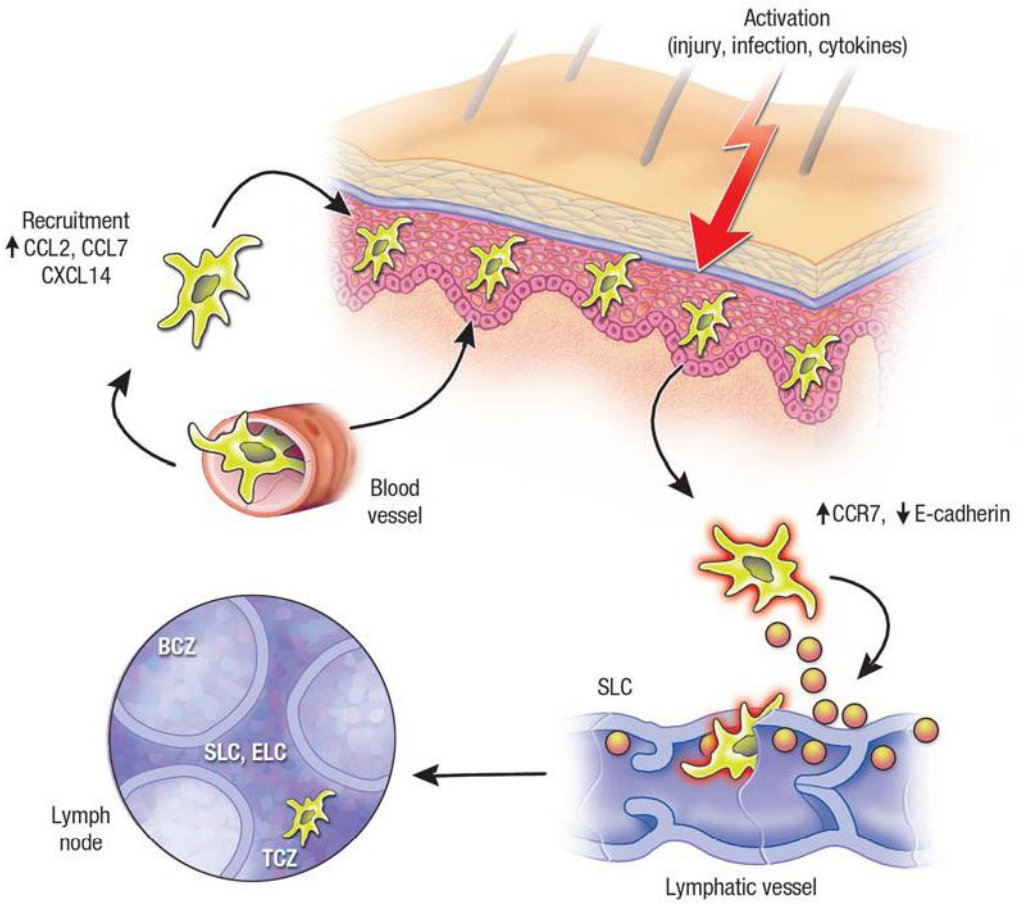
After DCs reach the LN, they must interact with T cells to form a so-called *immunologic synapse* that is critical for T-cell activation. Activated DCs secrete a number of chemokines, including macrophage-derived chemokine,[39] which attracts T cells to the vicinity of DCs and promotes adhesion between the two cell types.[40,41] CCR5 (via CCL3/4) has also been identified as mediating recruitment of naive CD8$^+$ T cells to aggregates of antigen-specific CD4$^+$ T cells and DCs.[42] Therefore, chemokines orchestrate a complex series of migration patterns, bringing both DCs and T cells to the confines of the LN, where expression of chemokines by DCs themselves appears to be a direct signal for binding of the T cell (see Fig. 12-3).

CHEMOKINES IN DISEASE

Atopic Dermatitis (See Chap. 14)

Atopic dermatitis is a prototypical Th2-mediated, allergic skin disease (see Chap. 14) in which chemokines may play pathogenic roles.[43] The mechanism of lymphocyte homing to skin in the setting of atopic dermatitis has been elucidated by clinical data from humans as well as experimental data in the NC/Nga mouse model of atopic dermatitis, which suggest that the Th2-associated chemokine receptor, CCR4, in conjunction with its ligand, TARC/CCL17, may play a role in recruiting T cells to atopic skin. In human patients with atopic dermatitis, CLA$^+$CCR4$^+$ lymphocytes were found to be increased in the peripheral blood of atopic dermatitis patients compared to controls.[21] Moreover, serum levels of TARC in atopic dermatitis patients were 10-fold higher than concentrations found in unaffected individuals and correlated with disease severity, whereas psoriatics showed only a minimal elevation of TARC in the serum.[44] Interestingly, another chemokine, CCL18, whose receptor is currently unknown, is produced by LC (as well as other antigen-presenting cells) and shows selective expression in atopic skin relative to psoriatic skin. Similar to TARC, CCL18 at-





◀ FIGURE 12-3 Trafficking of epidermal Langerhans cells (LCs) to regional lymph nodes. LCs are activated by a variety of stimuli, including injury, infectious agents, and cytokines such as interleukin-1β and tumor necrosis factor-α. Having sampled antigens, the activated LCs downregulate E-cadherin and strongly upregulate CC chemokine receptor 7 (CCR7). Sensing the CCR7-ligand, secondary lymphoid-organ chemokine (SLC; ●), produced by lymphatic endothelial cells, the LCs migrate into lymphatic vessels, passively flow to the lymph nodes, and stop in the T-cell zones (TCZs) that are rich in two CCR7 ligands, SLC and Epstein-Barr virus–induced molecule-1 ligand chemokine (ELC). Note that chemokines also contribute to the recruitment of LCs under both resting and inflammatory conditions. BCZ = B-cell zone; CCL = CC chemokine ligand; CXCL = CXC chemokine ligand.

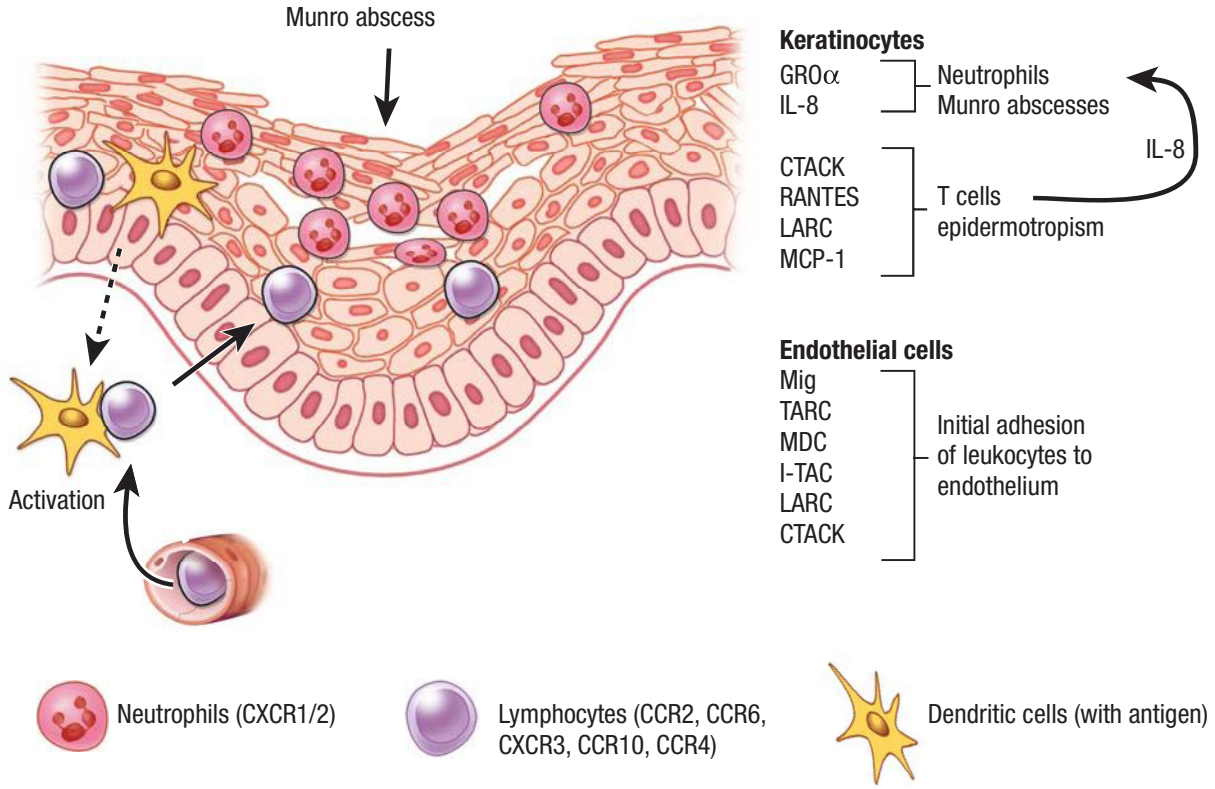
tracts CLA$^+$ memory T cells.[45] Perhaps of physiologic consequence, CCL18 expression is elicited in volunteer skin after topical challenge with dust mite allergen and staphylococcal superantigen.[46]

The recruitment of eosinophils to skin is a frequently observed finding in allergic skin diseases, including atopic dermatitis and cutaneous drug reactions, and likely is mediated by chemokines. Eotaxin/CCL11 was initially isolated from the bronchoalveolar fluid of guinea pigs after experimental allergic inflammation and binds primarily to CCR3, a receptor expressed by eosinophils,[47] basophils, and Th2 cells.[22] Injection of eotaxin into the skin promotes the recruitment of eosinophils whereas anti-eotaxin antibodies delay the dermal recruitment of eosinophils in the late-phase allergic reaction in mouse skin.[48] Immunoreactivity and messenger RNA expression of eotaxin and CCR3 are both increased in lesional skin and serum of patients with atopic dermatitis, but not in nonatopic controls.[49,50] Eotaxin has also been shown to increase proliferation of CCR3-expressing keratinocytes in vitro.[51] Finally, expression of eotaxin (and RANTES) by dermal endothelial cells has been correlated with the appearance of eosinophils in the dermis in patients with onchocerciasis that experience allergic reactions after treatment with ivermectin.[52] These observations suggest that production of eotaxin and CCR3 may contribute to the recruitment of eosinophils and Th2 lymphocytes in addition to stimulating keratinocyte proliferation.

Psoriasis (See Chap. 18)

Psoriasis, an inflammatory skin disorder characterized by thickened, pruritic plaques, does not have a clear etiology, although it is considered a Th1-mediated, autoimmune disease. As shown in Fig. 12-4 and reviewed by others,[53] there are multiple potential trafficking pathways that may be mediated by chemokines in psoriasis. Chemokines, including LARC/CCL20[54] and TARC/CCL17,[10] that are expressed by vascular endothelial cells mediate the arrest of effector memory T cells on endothelial cells.[55] In addition, both CCL17 and CCL20 can be synthesized by keratinocytes, possibly contributing to T-cell migration to the epidermis. Although the CCL17 receptor, CCR4, has been associated with Th2-type T cells,[19] there is also evidence suggesting that Th1-type T cells can express this receptor.[20]

Neutrophils found in the epidermis of psoriatic skin are likely to be attracted there by high levels of IL-8, which would act via CXCR1 and CXCR2. In addition to attracting neutrophils, IL-8 is an ELR$^+$ CXC chemokine that is known to be angiogenic, and it may also attract endothelial cells. This may lead to the formation of the long tortuous capillary blood vessels in the papillary dermis that are characteristic of psoriasis. Moreover, keratinocytes also express CXCR2 and thus may be auto-regulated by the expression of CXCR2 ligands in the skin. Of note, an IL-8/CXCL8–producing population of memory T cells that express CCR6 has been isolated from patients with acute generalized exanthematous pustulosis, a condition induced most commonly by drugs (e.g., aminopenicillins) and characterized by small intraepidermal or subcorneal sterile pustules (see Chap. 40).[56] Similar T cells have been isolated from patients with Behçet disease and pustular psoriasis.[57] It is possible that this subpopulation of T cells contributes to neutrophil accumulation in the stratum corneum (Munro abscesses) in psoriasis and other inflammatory skin disorders characterized by neutrophil-rich infiltrates in the absence of frank infection.



▲ FIGURE 12-4 Possible sites of actions of chemokines in psoriasis. Chemokines attract both neutrophils (to form Munro abscesses) and lymphocytes via attachment to endothelial cells and then migrate to the epidermis (epidermotropism). Specific chemokines tend to attract either neutrophils or lymphocytes, but generally not both. A newly identified subset of T cells can secrete interleukin-8 and attract neutrophils in conditions such as acute generalized exanthematous pustulosis.[58] Dendritic cells may also secrete chemokines, attract T cells, and stimulate conjugate formation that activates T cells. CCR = CC chemokine receptor; CTACK = cutaneous T cell–attracting chemokine; CXCR = CXC chemokine receptor; IL-8 = interleukin 8; I-TAC = interferon-inducible T cell α chemoattractant; LARC = liver and activation-regulated chemokine; MCP-1 = macrophage chemoattractant protein-1; MDC = macrophage-derived chemokine; Mig = monokine induced by interferon-γ; RANTES = regulated on activation normal T-cell expressed and secreted; TARC = thymus and activation-regulated chemokine.

Although the aforementioned chemokines have been shown to be expressed in psoriatic epidermis, they may also be found in a variety of skin diseases, including cutaneous T-cell lymphoma and atopic dermatitis. It is becoming apparent that multiple, rather than single, chemokines and their receptors likely contribute to the fine-tuning of T-cell migration in the skin.

Cancer

Chemokines may play a role in tumor formation and immunity in several distinct ways, including the control of angiogenesis and the induction of tumor immune responses.[58] CXC chemokines that express a three amino acid motif consisting of glu-leu-arg (ELR) immediately preceding the CXC signature are angiogenic, whereas most non-ELR CXC chemokines, except SDF-1, are angiostatic. Interestingly, it is not clear that ELR⁻ chemokines actually bind to chemokine receptors to reduce angiogenesis. It has been proposed that they act by displacing growth factors from proteoglycans. In any event, the balance between ELR⁺ versus ELR⁻ chemokines is thought to contribute to the complex regulation of angiogenesis at tumor sites. IL-8, a prototypical ELR⁺ chemokine, can be secreted by melanoma cells and has been detected in conjunction with metastatic dissemination of this cancer.[59] IL-8 may also act as an autocrine growth factor for melanoma[60] as well as several other types of cancer. Although CXCR1 and CXCR2 bind IL-8 in common, several other ELR⁺ CXC chemokines, including growth regulated oncogene α and epithelial-neutrophil–activating peptide-78, bind primarily to CXCR2. CXCR2 appears, in most instances, to be associated with both the angiogenic and growth regulatory properties of tumors.[61]

Tumors, including melanoma, have long been known to secrete chemokines that can attract a variety of leukocytes. The question arises as to why this is not deleterious to the tumor itself. Breast cancers, for instance, are known to secrete MCP-1, a chemokine that attracts macrophages through CCR2. Higher tissue levels of MCP-1 correlate with increasing numbers of macrophages within the tissue. Although chemokines secreted by tumor cells do lead to recruitment of immune cells, this does not necessarily lead to increased clearance of the tumor.[62]

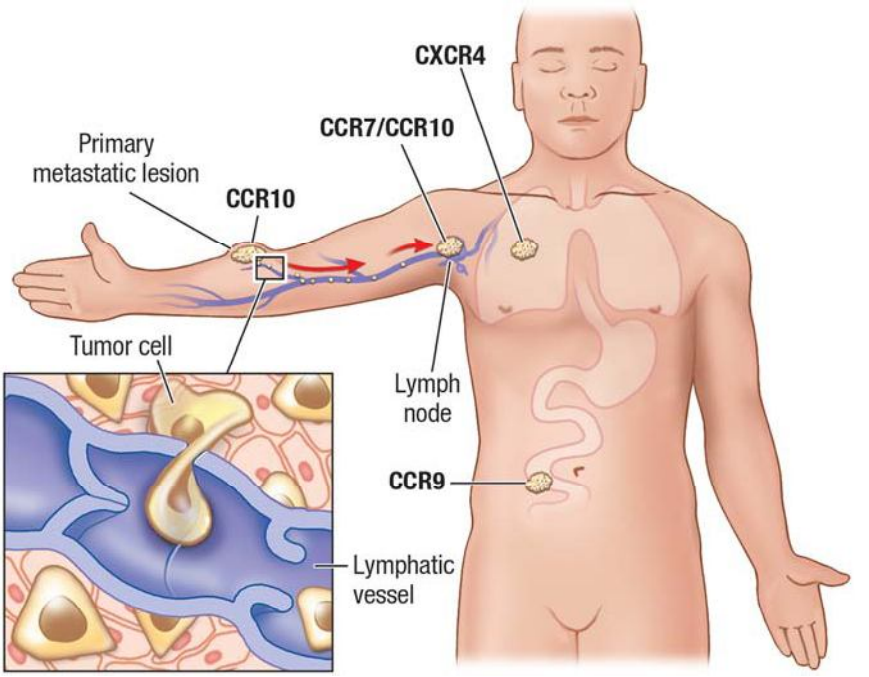
Inflammatory cells such as macrophages may actually play a critical role in cancer invasion and metastasis. First, MCP-1 may increase expression of macrophage IL-4 through an autocrine feedback loop and possibly skew the immune response from Th1 to Th2. Interestingly, MCP-1–deficient mice show markedly reduced dermal fibrosis after dermal challenge with bleomycin, a finding of possible relevance to the pathogenesis of conditions such as scleroderma.[63] Secondly, macrophages may promote tumor invasion and metastasis.[64] The antitumor effects of specific chemokines may occur by a variety of mechanisms. ELR⁻ CXCR3 ligands such as IP-10 are potently anti-angiogenic and may act as downstream effectors of IL-12–induced, natural killer cell–dependent angiostasis.[65] Of note, some cancer cells can synthesize

LARC, attracting immature DCs that express CCR6.[66] Experimentally, LARC has been transduced into murine tumors, where it attracts DCs in mice and suppresses tumor growth in experimental systems.[67] Last, chemokines produced by tumor cells may attract $CD4^+CD25^+$ T regulatory cells that suppress host anti-tumor cytolytic T cells.[68]

Tumor metastasis is the most common source of mortality and morbidity in cancer. With skin cancers such as melanoma, there is a propensity for specific sites such as brain, lung, and liver, as well as distant skin sites. Cancers may also metastasize via afferent lymphatics and eventually reach regional draining LNs. The discovery of nodal metastasis often portends a poor prognosis for the patient. In fact, the presence of nodal metastases is one of the most powerful negative predictors of survival in melanoma.[69]

Chemokines may play an important role in the site-specific metastases of cancers of the breast and of melanoma (Fig. 12-5).[70] Human breast cancer as well as melanoma lines expressed the chemokine receptors CXCR4 and CCR7, whereas normal breast epithelial cells and melanocytes do not appear to express these receptors.[71] CXCR4 is expressed in over 23 different solid and hematopoietic cancers. Broad expression of this receptor may be due to its regulation by hypoxia, a condition common to growing tumors, via the hypoxia inducible factor-1α transcription factor.[72] In several different animals of breast cancer[71] and melanoma metastasis,[73] inhibition of CXCR4 with antibodies or peptides resulted in dramatically reduced metastases to distant organs. Expression of CCR7 by cancer cells, including gastric carcinoma and melanoma, appears to be critical for invasion of afferent lymphatics and LN metastasis. CCR7-transfected B16 murine melanoma cells were found to metastasize with much higher efficiency to regional LNs compared to control B16 cells after inoculation into the footpad of mice.[74] CCR9 may also play a role in melanoma metastasis to the small bowel, which shows high expression of the CCR9 ligand, CCL25.[75]

CCR10 is highly expressed by melanoma primary tumors[76] and is correlated with nodal metastasis in melanoma patients[77] and in experimental animal models (see eFig. 12-5.1 in online edition).[76] Engagement of CCR10 by CTACK results in activation (via phosphorylation) of the phosphatidylinositol 3-kinase and Akt signaling pathways, leading to anti-apoptotic effects in melanoma cells.[76] Because CTACK is constitutively produced by keratinocytes, it may act as a survival factor for both primary as well as secondary (metastatic) melanoma tumors that express CCR10. In fact, CCR10-activated melanoma cells become resistant to killing by melanoma antigen-specific T cells.[76] Interestingly, CCR4[78] and CCR10[79,80] have been implicated in the trafficking and/or survival of malignant T (lymphoma) cells to skin. Thus, a limited number of specific chemokine receptors appear to play distinct, nonredundant roles, in facilitating cancer progression and metastasis (summarized in Fig. 12-5).



▲ **FIGURE 12-5** Chemokine receptors in melanoma progression and metastasis. Chemokine receptors play distinct roles in melanoma metastasis.[71] CC chemokine receptor 10 (CCR10) may enhance survival of primary melanoma tumors and skin metastases. CCR7, CCR10, and, possibly, CXC chemokine receptor 4 (CXCR4) may contribute to lymph node metastasis. CXCR4 appears to be involved in primary tumor development and metastasis at distant organ sites such as the lungs. CCR9 has been implicated in melanoma small bowel metastasis in patients.

Infectious Diseases

Although chemokines and chemokine receptors may have evolved as a host response to infectious agents, recent data suggest infectious organisms may have co-opted chemokine- or chemokine receptor–like molecules to their own advantage in selected instances. A variety of microorganisms express chemokine receptors, including US28 by cytomegalovirus (see Chap. 193) and Kaposi sarcoma herpesvirus (or human herpesvirus-8) GPCR. In the case of Kaposi sarcoma herpesvirus GPCR, this receptor is able to promiscuously bind several chemokines. More important, it is constitutively active and may work as a growth promoter in Kaposi sarcoma (see Chap. 128).[81]

Human immunodeficiency virus 1 (HIV-1), the causative agent of acquired immunodeficiency syndrome, is an enveloped retrovirus that enters cells via receptor-dependent membrane fusion (see Chap. 198). CD4 is the primary fusion receptor for all strains of HIV-1 and binds to HIV-1 proteins, gp120 and gp41. However, different strains of HIV-1 have emerged that preferentially use CXCR4 (T-tropic) or CCR5 (M-tropic) or either chemokine receptor as a co-receptor for entry. Although other chemokine co-receptors can potentially serve as co-receptors, most clinical HIV-1 strains are primarily dual-tropic for either CCR5 or CXCR4.[82]

The discovery of a 32–base pair deletion (Δ32) in CCR5 in some individuals that leads to low levels of CCR5 expression in T cells and DCs and correlates with a dramatic resistance to HIV-1 infection demonstrated a clear role for CCR5 in the pathogenesis of HIV-1 in-

fection.[83] Interestingly, the frequency of Δ32 mutations in humans is surprisingly high, and the complete absence of CCR5 in homozygotes has only been associated with a more clinically severe form of sarcoidosis. Otherwise, these individuals are healthy. In fact, there is an association of less severe autoimmune disease with this mutation.[84]

LCs reside in large numbers in the genital mucosa and may be one of the first initial targets of HIV-1 infection.[85] Because infected (activated) LCs likely enter dermal lymphatic vessels and then localize to regional LNs, the physiologic migratory pathway of LCs may also coincidentally lead to the transmission of HIV-1 to T cells within secondary lymphoid organs. CCR5 is expressed by immature or resting LCs in the epidermis and is the target of CCR5 analogues of RANTES that block HIV infection,[86] suggesting possible therapeutic strategies in the treatment or prevention of HIV-1 disease.[87] CXCR4 antagonists may also be of clinical utility with T- or dual-tropic viruses.[88]

A newly described autosomal dominant genetic syndrome comprised of warts (human papilloma virus–associated), hypogammaglobulinemia, infections, and myelokathexis is the result of an activating mutation (deletion) in the cytoplasmic tail of the CXCR4 receptor or in yet unidentified downstream regulators of CXCR4 function.[89,90] Bacterial infections are common because myelokathexis is associated with neutropenia and abnormal neutrophil morphology. The nearly universal presence of human papilloma virus infections associated with this syndrome can involve multiple common, as well as genital, wart subtypes (see eFig. 12-5.2 in on-line edition) and suggest a critical role for normal CXCR4 function in immunologic defense against this common human pathogen.

Thus, the skin is rich in cells (keratinocytes, fibroblasts, endothelial cells, and immune cells) that are able to produce chemokines. Chemokines not only orchestrate the migration of inflammatory cells, but also play roles in angiogenesis, cancer metastasis, and cellular proliferation. Other unanticipated biologic roles may ultimately be discovered. Just two of the promising therapeutic applications of chemokines (or molecules that mimic chemokines) may be in (1) preventing undesirable migration into the skin by preventing arrest of T cells or other inflammatory cells on activated endothelium and (2) blocking the infection of DCs and T cells by HIV-1 virus using CCR5 analogues. Signaling pathways are just beginning to be understood, and further work needs to be done to understand the regulation of these receptors, the specificity of intracellular activities, and the mechanism by which chemokine receptors work in the face of multiple chemokines present in many inflammatory sites.

CHAPTER 13

Allergic Contact Dermatitis

David E. Cohen
Sharon E. Jacob

As the primary interface with the environment, the skin is placed in the precarious position of routine exposure and assault from exogenous chemicals and physical agents. Fortunately, most of these exposures result in no clinically apparent disease. However, in some circumstances, a panoply of immunologic events results in the sensitization and subsequent elicitation of allergic contact dermatitis (ACD).

The classic interpretation of the skin as a simple barrier to penetration by exogenous agents underestimates the immunologic capacity of the integument. Modern concepts have divulged the finely orchestrated interplay of host defenses that cope with these onslaughts. In the 1950s, Landsteiner and Chase[1] firmly established ACD as a form of cell-mediated hypersensitivity. It was not until the latter half of the twentieth century, however, that the fundamental role of intact lymphatic systems, cellular elements (Langerhans cells, keratinocytes, and lymphoid cells), and specific cytokines in the sensitization and elicitation phases of ACD became recognized (see Chap. 10).[1]

Today we understand that these complex T-cell–mediated events are specifically and sensitively targeted to one or more chemical entities. When the level of exposure exceeds the thresholds of sensitization and elicitation, immunologic memory of the event is generated. That being said, the frequent lack of an obvious causative culprit or temporal relationship between the allergen and dermatitis leads to an intense detective and analytic exercise of determining and subsequently avoiding the offending chemical entity.

EPIDEMIOLOGY

Much of the epidemiologic data regarding ACD has been extrapolated or inferred from government reports on the prevalence and economic impact of occupational skin diseases. A basic assumption in many studies is that most occupational dermatitis is irritant in nature. More recent evidence, however, suggests that there is a larger proportion of allergic occupational dermatosis than previously thought. Of the 5839 patients patch-tested for contact dermatitis by the North American Contact Dermatitis Group between 1998 and 2000, 1097 (19 percent) were deemed to have occupationally related disease. In this occupational cohort, 60 percent of cases were of allergic and 32 percent were of irritant origin. Of note, the hands were primarily affected in two-thirds of allergic occupational cases and four-fifths of irritant occupational cases[2] (Fig. 13-1; see Chap. 211).

In 2001, 4714 cases of occupational dermatitis were reported to the Bureau

CONTACT DERMATITIS AT A GLANCE

- Allergic contact dermatitis (ACD) is the classic presentation of delayed-type hypersensitivity responses to exogenous agents.
- Over 3700 allergens have been reported to cause ACD in humans.
- ACD may clinically present acutely after allergen exposure and initial sensitization or after elicitation in a previously sensitized individual.
- The acute phase is characterized by the development of erythematous, indurated, scaly plaques, with severe cases demonstrating vesiculation and bullae in exposed areas. Affected sites often mimic the pattern of exposure and may provide insight into the allergen source and elicitor of disease.
- Repeated or continuous exposure of sensitized individual to allergens results in chronic disease, which is usually marked by lichenified erythematous plaques with variable hyperkeratosis, scale, and fissuring.
- The hands, feet, eyelids, and lips, which commonly come in contact with the environment, are likely sites for ACD.
- Histopathologic presentation consists of epidermal spongiosis with a superficial, perivascular, lymphohistiocytic dermal infiltrate.

of Labor Statistics, down 50 percent from the 9472 cases registered just 10 years earlier. The substantial drop over that decade in both the rate and absolute number of cases of occupational dermatitis may reflect improved work conditions and may explain the observed relative decrease in irritant contact dermatitis (ICD) and proportional increase in ACD. It is important to note that the prevalence of ACD in the general population is often extrapolated from the data gleaned from occupational dermatitis studies or from centers and groups that patch-test patients who already have dermatitis.

Because few cross-sectional general population-based studies regarding the prevalence and incidence of ACD have ever been performed, the remainder of available epidemiologic data is generally obtained from retrospective studies reviewing specific body sites of involvement. These data are marred to varying extents by the selection bias inherent in referral to a patch test center and may not be representative of the general population. Nevertheless, such data permit recognition of allergens with high sensitizing potential and strategies for their replacement by substances with low sensitizing potential. Table 13-1 lists many common allergens that elicited positive test results in a group of individuals who were patch-

◀ **FIGURE 13-2** This patient was found to have clinically relevant positive reactions to balsam of Peru and bromonitropropane.

tested by the North American Contact Dermatitis Group.

In two cross-sectional studies, 769 randomly selected 15- to 41-year-old patients from the western part of Copenhagen County, Denmark, were patch-tested in 1990 and 1998 to evaluate the point prevalence of ACD in this population. The rate of positive reactions to at least one allergen was 15.9 percent and 18.6 percent, respectively. Nickel was the most common allergen. Furthermore, the investigators noted a statistically significant increase in allergy to cosmetic agents over the time interval between studies.[3]

These same investigators completed another cross-sectional study in those same years. They randomly patch-tested 567 patients aged 15 to 69 years from western Copenhagen in 1990. In 1998, they re-tested 365 of the same patients in an effort to observe incident cases. Of the individuals who previously had negative patch test results in 1990, 12 percent showed one or more positive patch test results (incident contact allergy). Notably, 6 percent and 8 percent of the re-tested patients who previously had negative patch test results developed incident allergy to nickel and haptens other than nickel, respectively. Female gender, young age, and prior ear piercing (before 1990) were risk factors for the development of nickel allergy.[4]

In a United States–based study, Templet, Hall, and Belsito noted that hand dermatitis was one of the most frequently cited reasons for referral to a patch-testing center. Of the 1034 patients who had been patch-tested over an 8-year period, 32 percent had hand dermatitis; 54 percent were diagnosed with ACD, whereas only 27 percent received a diagnosis of ICD. A gender difference was seen: the peak prevalence in men was in the fifth decade, whereas no specific peak was seen in women.[5]

Another United States–based study found that 17 percent of a U.S. managed care insured population experienced hand dermatitis, with one in six affected patients not seeking medical attention. The effect of chronic hand disease was estimated to increase total medical costs by 25 percent or $70 per month based on medical care delivery and prescription costs.[6]

With the high incidence of hand and face exposure to the environment, one would anticipate a comparable prevalence of hand and face dermatitis. Absolute prevalence data on facial and eyelid dermatitis in the general population is not available, however. Rather, scant prevalence data are available from tertiary care referral centers, which represent only approximately 17 percent of all patch-tested individuals. Of the individuals with eyelid dermatitis referred for patch testing, approximately 50 percent to 75 percent were reported to have at least one positive patch test reaction.[7,8] Few data are available for source-based epidemiology. U.S. population studies of cosmetic allergy prevalence are nearly 20 years old and, given the dynamic nature of product development, no longer provide the data accuracy they once did. One study in India demonstrated a 66 percent rate of positive reactions to cosmetics in patch testing. The allergic individuals tended to be young (mean age, 27.5 years), with dermatitis affecting the face, neck, and scalp. Fragrances, preservatives, and para-phenylenediamine (PPD) were the most common provocative agents.[9]

Age

Although the subject of ACD in pediatric patients has received substantial attention in Europe, it has not enjoyed the same level of attention in North America. Despite this, ample evidence suggests that even young children have rather substantial prevalence rates when they are patch-tested under appropriate conditions[10] (Fig. 13-2). In Italy, of 1094 consecutively patch-tested children, 570 proved to be allergic (52.1 percent). In this cohort of children younger than 12 years of age, the highest sensitization rate was observed in those 7 months to 3 years of age (63.4 percent allergic). Metals, mercury derivatives (thimerosal and metallic mercury), neomycin, wool alcohols, methylchloroisothiazolone-methylisothiazolinone (Kathon CG), and fragrance mix were the most frequent contact allergens. Girls showed a greater propensity for nickel allergy than boys. The neck and antecubital/popliteal fossae were more frequently involved in individuals allergic to nickel and Kathon CG, and sensitization was more frequently seen in atopic than in non-atopic patients.[11]

Clinically, individuals older than 65 years have various defects in the induction and/or elicitation of ACD.[13] In studies of *Rhus* reactivity, younger individuals (18 to 25 years) had a more rapid onset and resolution of the dermatitis than did older persons. When sensitization rates to standard allergens were analyzed as a function of age, incidence rates were found to be significantly lower in individuals older than 70 years.[14] When 1444 elderly subjects with suspected ACD were compared to a control group aged 20 to 40 years, the prevalence of allergic reactivity was found to be significantly lower in the elderly group compared with younger adult patients (40.7 percent vs. 47.8 percent, $p < 0.0001$). The clinical relevance of this difference is debatable, however, and may reflect a need to modify the allergens selected in keeping with age-appropriate exposures or to allow a longer time between patch removal and the delayed reading. Allergens used with greater frequency in this population, such as neomycin, lanolin alcohols, paraben mix, and methyl dibromoglutaronitrile/phenoxyethanol (Euxyl K400) showed a higher sensitization rate in elderly patients than in younger adult patients[15] (Fig. 13-3).

Gender and Race

Gender differences in the development of ACD are largely unknown, because few studies have looked at induction of sensitization in men and women under controlled circumstances. When the human repeat-insult patch-testing method was used to assess induction rates for 10 common allergens, women were found to be more often sensitized to 7 of the

▲ **FIGURE 13-3** Allergic contact dermatitis to aminoglycoside antibiotics. The patient used a neomycin-containing topical antibiotic and a tobramycin-containing eyedrop.

10 allergens studied.[16] In maximization studies that looked at allergens of different potencies, women reacted more frequently to the weakest sensitizers.[17]

The role of race, if any, in the development of ACD to potent allergens such as dinitrochlorobenzene paraphenylenediamine remains controversial.[18,19] Goh found no differences in the incidence of ACD among the indigenous (Malay, Chinese, and Indian) sub-populations in Singapore.[20] Limited studies suggest lower sensitization rates to nickel and neomycin in African Americans than in Caucasians.[14] In addition, erythema evaluation becomes increasingly difficult with ascending order in Fitzpatrick's skin typing, which makes this evaluation variable and requires that greater importance be given to changes in edema and induration. Additional studies evaluating racial influences on immunologic and nonimmunologic (e.g., barrier function) factors and ethnic influences affecting ACD development are needed.

ETIOLOGY AND PATHOGENESIS

ACD represents a delayed (type IV) hypersensitivity reaction to the over 3700 exogenous chemicals that have been described to provoke this reaction.[21] Because this represents a true allergy with immunologic sequelae, only minute quantities of a given chemical are necessary to elicit overt allergic reactions. Evidence dating back to the 1940s indicates that the ability to be sensitized to specific agents has a genetic component. Research has now linked the presence of specific human leukocyte antigen alleles to allergy to nickel, chromium, and cobalt.[22,23]

To mount an immune reaction to an allergen, the individual must be genetically susceptible, have sufficient contact with a sensitizing chemical, and then have repeated contact with the substance later. This is in distinction to ICD, in which no immunologic reaction takes place and the intensity of the reaction is proportional to the dose of the chemical applied (which is directly related to chemical concentration, duration of exposure, and general skin integrity).

Thus ACD is a systemic disease defined by hapten-specific T cell–mediated skin inflammation and characterized by three phases: sensitization, elicitation, and resolution.[24] In the sensitization phase, low-molecular-weight electrophilic or hydrophilic hapten chemicals (usually less than 500 to 1000 d) penetrate the skin and form hapten-protein complexes with epidermal carrier proteins, which produces a complete allergen. These binding proteins are likely cell surface molecules on the Langerhans cell, such as class I and II major histocompatibility complex molecules. For a detailed description of the mechanisms involved in the generation and perpetuation of ACD, see Chap. 10.

The linkage between haptens and epidermal proteins is usually covalent, although metallic haptens may form stable noncovalent linkages with carrier proteins, such as cobalt in vitamin B_{12}.[25] Some of these hapten chemicals are not inherently allergenic (pro-haptens) and must undergo metabolic biotransformation to be able to participate in an allergic response.[26] Because the skin has substantial metabolic capabilities, including many phase I and phase II enzymes, such biotransformation may occur in the skin at the site of contact with the chemical. The importance of the relationship between the carrier and the hapten cannot be underestimated, because potent contact sensitizers, when complexed to nonimmunogenic carriers, can induce tolerance rather than sensitization.

CLINICAL APPROACH

An algorithmic approach to the patient is described in the following sections.

Consideration of the Diagnosis

ACD should be considered in the differential diagnosis of a wide range of eczematous dermatoses (Box 13-1). For example, a patient who has a geometric or pattern-specific dermatitis after an exposure to an exogenous agent should be suspected of having ACD. In addition, the diagnosis should be considered in individuals whose dermatitis is persistent despite appropriate standard therapies. This also pertains to patients with confounding skin disorders, such as atopic dermatitis and psoriasis, who have classic presentations.

Construction of the Exposure Montage

Sensitization and subsequent elicitation of a dermatitis are a direct consequence of exposure to a specific chemical in a susceptible person. There are many variables that factor into the susceptibility of a given individual. For example, an alteration in the inherent skin barrier function or repair mechanism, which may be affected by genetics, age, gender, customs, and psychosocial influences, can increase the predisposition. The geographic location in which the patient resides may also be important, because it may, for example, increase the probability of encountering region-specific botanical allergens. Finally, incidental random exposures must be considered; for instance, a Floridian family's excursion to poison ivy–laden Pennsylvania. Thus, it may be considered that for every chemical there is a predetermined dose (threshold of sensitization) in every person that under optimal circumstances could potentially result in sensitization and the subsequent clinical outcome of ACD.

History Taking

The paradox of patch testing is the deceptive simplicity of application versus the required expertise necessary for allergen selection and interpretation and recognition of clinical significance.[27] Expertise in patch testing starts with obtaining a comprehensive multi-year history from the patient regarding the present illness. An algorithmic approach is again necessary. Information regarding the patient's demographic characteristics, personal and family medical histories, and occupational and home environment, as well as a dermatitis-specific history including prior use of over-the-counter and prescription medications must be obtained (Table 13-2).

Investigation of Exposure Patterns

Patterns of exposure direct the physician to the likely cause(s) of the erup-

Box 13-1

Differential Diagnosis of the Eczematous Dermatoses

DIFFERENTIAL DIAGNOSIS	GEOGRAPHIC-MORPHOLOGIC DISTRIBUTION	DIAGNOSTIC CLUES
Allergic contact dermatitis	Eczematous, scaly edematous plaques with vesiculation	Primary lesions in distribution of contactant; pruritus
Asteotic dermatitis	Crackled parchment-like patches, absent edema and vesiculation	Lower legs
Atopic dermatitis	Eczematous, honey-crusted, scaled plaques; chronic lesions may be lichenified	Flexural areas in children and neck predominance
Autosensitization reaction	Eczematous, poorly defined patches of vesiculation	History of chronic dermatitis or infection with new widespread, less-defined patches
Dyshidrotic eczema	Deep-seated papulovesicles on palmar-plantar surfaces and volar edges	Palm and sole typically dorsal involvement
Irritant contact dermatitis	Sharply demarcated macular erythema, hyperkeratosis, absence of vesiculation	Burning exceeds itching
Mycosis fungoides (patch to plaque stage)	Poorly demarcated, atrophic, scaly pink patches and plaques	Torso predominance
Nummular dermatitis	Coin-shaped, well demarcated plaques with scale and vesiculation; variably exudative	Legs, dorsal hands, extensor surfaces
Psoriasis	Sharply demarcated papulosquamous plaques with no vesiculation	Scalp, retro-auricular area, elbows, knees, genitalia, nails; predominance in areas of trauma (Koebnerization); pustules may be acutely present, particularly on palms and soles; concomitant arthritis
Seborrheic dermatitis	Papulosquamous greasy, scaly plaques	Hair-bearing regions, glabella, and nasolabial folds
Stasis dermatitis	Papulosquamous plaques with dyschromia	Shins and medial surfaces, lower legs, concomitant varicosities

From Rietschel RL: Clues to an accurate diagnosis of contact dermatitis. *Dermatol Ther* **17**:224, 2004.

tion. One must not only consider the potential exposure variables for each patient but also must cross-reference these allergen exposures to arrive at the most likely suspect allergen list for that individual. As a case in point, a patient with a persistent post–hair dye hairline and eyelid dermatitis should be investigated for current use of hair dye products, black henna tattoo preparations, para-aminobenzoic acid–based sunscreens, ester anesthetics, and cross-reacting medications (e.g., hydrochlorothiazide, sulfonylureas, and cyclooxygenase 2 inhibitors). Furthermore, a 2-year-old with concomitant hand and facial dermatitis would more likely be sensitized to balsam of Peru–based fragrances or preservatives in baby washes and diaper balms. It is important to focus on the most likely substances but also to include high-probability alternatives.

Of note, each algorithm is as specific to the patient as the patient's environment is to him or her. Potential new allergens are frequently entering the individual's immediate and global environment. For example, betaine detergent technology was first incorporated into personal care and hygiene products (e.g., low-irritancy baby shampoo) in the late 1960s. In 1983, the first case of cocamidopropyl betaine allergy was noted; since then there has been an upward trend toward its ever-increasing inclusion in personal care products.[28] Almost two decades later, the increasing incidence of cocamidopropyl betaine allergy led to the inclusion of this allergen in comprehensive standard screening trays and the designation of co-

TABLE 13-2
History Taking in Allergic Contact Dermatitis

Demographics and occupational history	Age, gender, race, ethnicity, religion, social aspects (marital status), job title, job description, regular and occasional chemical exposures and sources, location of employment, time at current job, previous occupations
Family medical history	Genetic factors, predispositions
Personal medical history	Drug allergies, concomitant diseases, medications, surgeries
Dermatitis-specific history	Onset, location, temporal associations (waxings/wanings), treatments

camidopropyl betaine as allergen of the year by the American Contact Dermatitis Society. Although there are inherent limitations and biases in the data tracked by the members of tertiary referral groups that report epidemiologic data, the importance of these data cannot be overemphasized, because they also increase awareness of rising chemical allergies previously thought to be rare (e.g., to corticosteroids, gold, and amide anesthetics).

CLINICAL MANIFESTATIONS

Cutaneous Findings

Given the wide array of potential allergens and the inherent uniqueness of every person's skin, it stands to reason that there should be an equally wide variation in the clinical presentation of ACD. However, certain aspects are less variable and tend to follow rather reproducible patterns. In general, once sensitization has been established, acute ACD progresses from erythema to edema to papulovesiculation, with escalating responses (see Figs. 13-2 and 13-3). One exception may be the areas of thin skin with higher absorption coefficients, such as the eyelids, mucosal surfaces, and genitalia. These areas may quickly become edematous, which leads the individual to avoid behaviors or to seek medical attention, and thus the more developed stage may be interrupted. Second, ACD usually occurs in the distribution of the contactant. For example, an arm that has brushed against poison ivy may demonstrate a linear vesicular edematous plaque. In situations in

which the allergen exposure is persistent, however, lichenification and scale predominate. Concurrent with this evolution comes the possibility of more widespread eruptions in non-distinct patterns. Given this, early diagnosis is of utmost importance.

Morphologic Approach

Once a comprehensive history has been obtained, the second step is a complete dermatologic assessment of the patient. This is especially helpful because the patient may be aware of only the most prominent site of dermatitis, and a concurrent dermatitis at a remote site may provide integral clues to the diagnosis. Knowledge of the shape, character, and location of the dermatitis heightens the probability that the culprit allergen will be accurately chosen for testing.

Regional Dermatitis Algorithm

SCALP Despite the great potential for allergen exposure, the scalp remains relatively resistant to allergic dermatitis. Possible reasons for this decreased reactivity may be increased skin thickness, alterations in cellular milieu because of the follicular hair units, variations in vascularity, and dilutional effects of perspiration. Often allergens that are applied the scalp and hair, for example, hair dye (PPD) and shampoos (fragrances, preservatives, and surfactants), may elicit dermatitis in the adjacent areas, such as the hairline, eyelids, and postauricular areas. In the patient with scalp dermatitis, consideration should be given to alternative diagnoses such as seborrheic dermatitis and ICD.

FACE AND EYELIDS The face is always exposed to a great number of potential allergens (see Figs. 13-2 and 13-3). Incidental exposures to aeroallergens can lead to severe consequences, for example, blistering dermatitis after fall burning of leaves accidentally contaminated with poison ivy or chronic photo contact dermatitis from feverfew or other sesquiterpene lactone–containing plants. Furthermore, inadvertent transmission from the hands is frequent to this area, and dermatitis can be seen despite lack of any evidence of allergy on the hands (ectopic contact dermatitis). Because the face is the most likely area to encounter a myriad of grooming tools such as eyelash curlers, makeup sponges, and toothbrushes (rubber additives) and personal hygiene products and cosmetics (fragrances, emulsifiers, preservatives), a wide range of allergens must be considered. Vehicle-based preservatives are a significant source of facial dermatitis.

NECK Like the face, the neck is subject to numerous direct environmental encounters as well as indirect exposure from the hands. Given the repeated insult from a wide variety of fragrance-based chemicals (perfume, eau de toilette, scents), the neck and wrists are especially prone to and may eventually develop a *berloque* dermatitis (*berloque* is French for "trinket-like," and refers to the pendant-like pigmentation seen on the neck and chest). Metal allergy may manifest as chronic dermatitis from exposure to necklaces and jewelry clasps that contain nickel or cobalt.

TORSO The relatively protected condition of the torso alters the list of potential allergen sources. Although it also encounters the fragrances, preservatives, and detergents of daily personal hygiene products (body washes, soaps, lotions), it is also susceptible to textile allergens (dyes and formaldehyde resins.) The most significant textile-associated allergens are the disperse dyes (azoanilines) and urea formaldehyde resins (in wrinkle-resistant, colorfast clothing). Specifically, the heat, humidity, and friction of the body fold (periaxillary and pericrural) areas may contribute to the leaching of the textile resins and dyes and the observed dermatitis accentuation in these areas.[29]

AXILLAE The axillary compartment is subject to many of the same exposures as the trunk, with one major distinction being the use of deodorants and antiperspirants (Fig. 13-4). The formulations of these products use a wide variety of constituents, such as fragrances [balsam of Peru, Lyral (hydroxyisohexyl 3-cyclohexene carboxaldehyde)], preservatives (formaldehyde releasers, parabens), and other excipients (lichen extract, vitamin E, propylene glycol). A commonly observed effect is the sparing of the vault, secondary to the perspirational dilution of the allergens. Furthermore, aerosolized exposure of the allergens may lead to a scattering array pattern with satellite papules.

HANDS AND FEET The high incidence of hand dermatitis (see Epidemiology) is a direct consequence of the fact that the hands are our most important tools in our interactions with the environment. In fact, hand dermatitis can account for as much as 80 percent of the occupationally related skin diseases, especially in certain "wet work" occupations (health care, food handling, cosmetology, etc.).[30] Careful consideration should be given to occupation-specific exposures in the evaluation of hand dermatitis. For example, a construction worker may be sensitized to chromium from cement exposure, whereas a hairdresser may be allergic to paraphenylenediamine (dyes), cocamidopropyl betaine (surfactant-detergent), or glycerol monothioglycolate (permanent wave and straightening solutions).

▲ **FIGURE 13-4** Allergic contact dermatitis to aerosol deodorant. This patient was allergic to Lyral.

The multifactorial etiology of hand dermatitis adds to the complexity of both the diagnosis and treatment (see Fig. 13-1).[31] Co-existent disorders, such as atopy, dyshidrosis, psoriasis, and dermatophytosis, may be encountered in these patients. At times, an underlying endogenous dermatosis may even become unmasked or worsened by a secondary contact dermatitis (either allergic or irritant). For example, cases of iatrogenic contact dermatitis to either the rubber additive in gloves (thiuram, carbamate) or topical therapeutics (preservatives and corticosteroids) may be encountered. Clinical clues that the physician should have a higher index of suspicion of ACD include involvement of the finger web spaces and dorsal hands, and pruritus.

As are the palms, the volar foot surfaces are relatively resistant to development of ACD, and the investigator must consider co-morbidities and the possibility of confounding disorders (psoriasis, dyshidrosis, juvenile plantar dermatosis, etc.) to

comprehensively evaluate the patient with such manifestations. The dorsum of the foot, on the other hand, is frequently involved. Complete evaluation should include testing with the principal allergens generally associated with foot dermatitis, including rubber accelerators (present in rubber-based liners and/or glues), isocyanates (in foam rubber), *p*-tert-butylphenol formaldehyde resin (in glue), potassium dichromate (in tanned leather), antibiotic creams and topical corticosteroids (from prescription and over-the-counter self-treatment), in addition to suspect source component testing using a 8–10 mm punch biopsy swatch of the shoe. Often, extended contact with the shoe component is necessary to elicit a reaction.

Perioral and Perianal Mucosal Exposures

Mucosal ACD, such as aphthae and lingual erosions caused by contact with allergens in toothpaste, is a rare but perhaps under-reported phenomenon. More commonly, patients have persistent perioral dermatitis rather than intra-oral lesions. Flavorants, detergents (cocamidopropyl betaine), and whiteners (peroxides) are frequently encountered in dental hygiene products. Fortunately, only rarely do individuals react to dental amalgam metals (nickel, cobalt, mercury, and gold) with oral lichen planus–like dermatoses, stomatitis, or systematic symptoms. The low reaction rates may reflect a dilutional effect of the mucosal secretions or inherent differences in mucosal immunity. Furthermore, studies have shown that primary mucosal exposure to an allergen may lead to tolerance. For example, the frequency of nickel sensitivity is lower in individuals who undergo orthodontic treatment before ear piercing.[32]

With an increasing number of older persons (older than 65 year of age) in our society, age-associated changes such as mucosal dryness, incontinence, and inability to cleanse properly have resulted in increasing use of genital and perianal hygiene products and exposure to related allergens, such as moistened toilet tissue (methylchloroisothiazolinone and methyldibromoglutaronitrile) and suppositories (fragrances and parabens). Although lower or slower reactivity is reported in the aged population, studies suggest that ACD continues to occur in this population.[33–35] Thus, increased vigilance will be required to discover new allergen associations involving these and other products used by this population.

Paradoxical Dermatoses

The quintessential allergen inducing a paradoxical dermatitis is gold. It is important to note that allergic reactions to gold very rarely involve the contact site of the offending jewelry, such as a watch or a ring. Reactions may be seen on the eyelids, cheeks, or bridge of the nose, however, where gold (e.g., in glasses) has come into contact with a harder metal such as titanium dioxide or zinc oxide in a sunscreen, cosmetic cream, or foundation.[36]

Several other allergens (e.g., lanolin and paraben) are also noted for their paradoxical induction of ACD because they are too weak to elicit a response on intact skin but may give rise to ACD when they are applied to a damaged epidermis (e.g., atopy, stasis dermatitis)—thus the terms *paraben paradox* and *lanolin paradox*.[37] Furthermore, corticosteroids, which were designated the allergens of the year in 2005 by the American Contact Dermatitis Society, because of their intrinsic anti-inflammatory properties, require a delayed patch test reading (at 96 hours) to capture allergic reactions. In cases of treatment-resistant dermatitis or cases in which clinical progression occurs despite the use of increasingly potent corticosteroids, corticosteroid allergy should be suspected. One must be aware of the five structural classes of corticosteroids (A, B, C, D1, and D2; see Chap. 216) and the inherent potential cross-reactivities between the classes.[38]

Systemic Manifestations and Generalized Dermatitis

Systemic contact dermatitis is a relatively uncommon and poorly understood aspect of ACD that highlights the potential for long-lasting immunologic memory in previously sensitized areas of skin. This phenomenon occurs primarily in individuals who are initially sensitized topically to an allergen and then subsequently exposed systemically, which results in a wide array of outcomes, from a recall reaction (dermatitis at the site of original sensitization) to extensive, bizarre-appearing dermatitis and erythroderma.

The more ubiquitous the allergen in nature and the patient's environment, the less obvious the temporal associations will be between the exposures and the dermatitis. One particularly notorious allergen is balsam of Peru, derived from the post-wounding exudates of the bark of the El Salvadoran *Myroxylon pereirae* tree (see Figs. 13-2, 13-5).[39] It is encountered in early infancy in baby washes and diaper salves and again daily in adulthood a wide range of substances from fragranced personal hygiene products to denture adhesives. Furthermore, the balsam itself—or, more typically, modified fractions of it—are frequently used as fragrance and flavoring additives (e.g., in lozenges, cough syrups, children's antibiotic suspensions, and colas). Importantly, because these chemicals (cinnamic acid, cinnamyl cinnamate, benzyl benzoate, benzoic acid, and benzyl alcohol and esterified polymers of coniferyl alcohol) are naturally derived, they have a number of natural cross-reactants (cinnamon, clove, eugenol). In one report special analyses proved that tomatoes contained cinnamic alcohol and coniferyl alcohol, two main allergens in the balsam of Peru mixture.[40] Consumption of these allergens may result in a recall reaction topically at other sites where similar chemicals were previously applied or in a systemic flare (see Fig. 13-5). Of note, 47 percent of patients allergic to balsam of Peru and/or other fragrance agents required dietary modification to control their dermatitis; 18 percent of patients who failed to modify their diets had persistent disease, and only 36 percent improved without some form of dietary modification.[39]

▲ **FIGURE 13-5** Allergic contact dermatitis to fragrances. This patient had a systemic flare reaction.

The metals are a group of frequently encountered ubiquitous allergens (nickel, cobalt, and chromium). They are present in a wide range of metallic objects (jewelry, tweezers, clothing snaps, paperclips, and coins) in addition to unexpected sources such as cigarette smoke, vitamins, water, and foodstuffs.

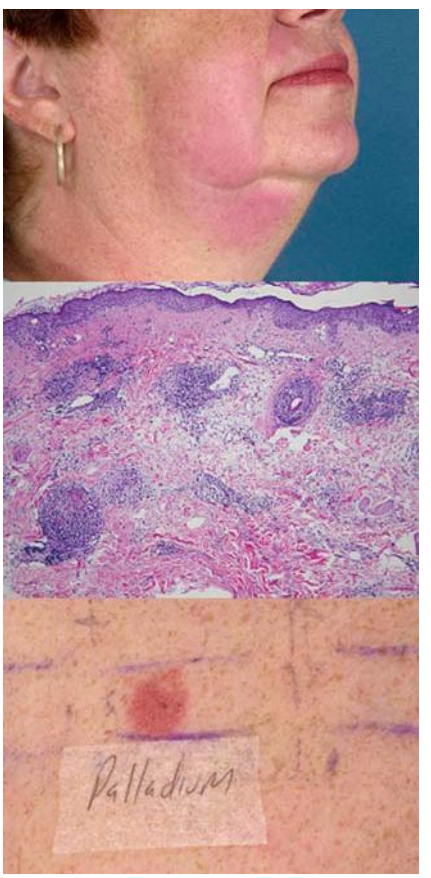
Another frequently and unexpectedly encountered allergen is formalde-

hyde. It has a variety of industrial applications, including in plastics and glues, and is commonly used as a broad-spectrum biocide. Thus sources of exposure can range from insulation materials, shoe glues, paper products, nail hardeners, clothing resins, and cigarette smoke to commonly used personal hygiene products and medical creams. The formaldehyde-releasing preservatives (FRPs) include quaternium-15 (Dowicil), imidazolidinyl urea (Germal I), diazolidinyl urea (Germal II), 2-bromo-2-nitropropane-1,3-diol (Bronopol), dimethylol-dimethyl hydantoin (Glydant), and *tris*-(hydroxy-methyl)-nitro-methane (Tris Nitro). A staggering number of leave on and wash on/wash off cosmetics and creams include these common allergenic preservatives. Of note, some topical steroid preparations contain fairly high amounts of FRPs, and failure to improve warrants patch testing with both corticosteroid and preservatives. Furthermore, corticosteroids containing FRPs should not be used by patients hypersensitive to formaldehyde.[41]

For many patients, the diagnosis of rubber allergy comes with a cumbersome list of substances to avoid, because both natural and synthetic rubber chemicals are ubiquitous. Frequent sites of allergen contact and subsequent reaction are the face (makeup sponges), ear canals (earplugs, ear phones), periocular area (goggles, eyelash curlers), brassiere and/or waistline areas (elasticized undergarments), genital areas (condoms, diaphragms, pessaries), hands (gloves, rubber bands), feet (shoes), and/or joints (orthopedic braces). It is important to note that for every 100 lb of rubber, there are 4 to 5 lb of rubber additives (90 percent of which constitute the accelerators and antidegradants), and these additives are responsible for a majority of the reactions.[42] Sensitization is typical to either the accelerants (thiurams, carbamates, guanidines, and/or benzothiazoles) or the antioxidants (black rubber mix/PPD derivatives) that are found in both natural and synthetic rubber, with thiuram mix (62 percent) and black rubber mix (38 percent) being the most common offenders.[43]

NONECZEMATOUS VARIANTS OF ALLERGIC CONTACT DERMATITIS ACD, like syphilis, is a great mimicker with multiple noneczematous variants, including but not limited to lichenoid contact dermatitis, erythema multiforme (EM), cellulitis-appearing dermal contact hypersensitivity, contact leukoderma, contact purpura, and erythema dyschromicum perstans.[44] Of these, the lichenoid and EM-like variants are most common.

Lichenoid allergic contact reactions are usually secondary to exposure and sensitization to metals, substituted PPD color developers, and flavoring agents. Metals, in particular, have been linked to oral lichen planus. Many drugs can also cause a systemic lichenoid hypersensitivity, the most notorious being the quinine derivatives, hydroxyurea, angiotensin-converting enzyme inhibitors, β blockers, and anti-epileptic agents. EM-like ACD reactions are most frequently seen after contact with exotic woods, common plants, and topical medications. The other noneczematous variants of ACD are quite rare. Of note, most cases of contact leukoderma are due to either post-inflammatory hypopigmentation or direct chemical toxicity (e.g., hydroquinones, catechols, phenols, mercaptoamines).[45] Granulomatous dermatitis has been reported in response to metals, including mercury, chromates, cobalt, beryllium, gold, and palladium (Fig. 13-6).



▲ **FIGURE 13-6** Granulomatous contact dermatitis in a patient with palladium allergy. A palladium-containing dental post was implanted on the affected side just before the onset of the eruption. Improvement was effected by its removal.

ALLERGIC CONTACT URTICARIA Allergic contact urticaria (ACU) represents one of the least common forms of contact dermatitis. ACU is an immunoglobulin E–mediated immediate-type hypersensitivity reaction that is distinct from the T cell–mediated type IV hypersensitivity reaction of ACD. Importantly, ACU has been reported in response to a number or agents that are also capable of eliciting a type IV reaction, for example, bacitracin (antibiotic), mercaptobenzothiazole (rubber accelerator), and colophony (adhesive).

The most notorious allergen to cause ACU worldwide is natural rubber latex. The incidence in the United States is largely unknown; however, estimates suggest that less than 1 percent to 2 percent of the general population is affected.[46] Among hospital workers most likely to be exposed to natural rubber latex gloves, the rate of latex ACU has been reported to range from a low of 5.5 percent[47] to as high as 38 percent.[48] Furthermore, comorbid conditions requiring hospitalizations and medical care in early life, such as moderate to severe atopic dermatitis, spina bifida, or meningomyelocele, predispose to the development of ACU, as does mucosal exposure to latex.

ACU from latex may present as immediate symptoms (such as burning, stinging, or itching with or without localized urticaria on contact with latex proteins) or, with aerosolization exposure, may include disseminated urticaria, allergic rhinitis, and/or anaphylaxis. Latex-allergic patients may also develop a type IV delayed hypersensitivity reaction to nonlatex components of the gloves, usually on the dorsal aspect of the hands; for example, to a rubber additive (thiuram) that may be found in latex, nitrile, and vinyl gloves. In contrast to ACD, ACU in response to latex gloves may present with palmar involvement, which may relate to solubilization of the latex proteins or the lipid content of the hyperkeratotic volar surface caused by normal hidrosis.

Although there are over 250 separate natural rubber latex proteins, only approximately 25 percent show reactivity with immunoglobulin E autoantibodies.[46] As of 2003, the International Union of Immunological Societies Committee on Nomenclature listed 13 *Hevea brasiliensis* (Hev b) protein allergens. Significant advances in DNA technology and cloning have allowed for purification and characterization of these allergens. It is now known that the most important Hev b allergens are Hev b 1 to 3

for children with spina bifida and Hev b 2 and 5 to 7 for health care workers.[46]

A diagnosis of latex allergy should be considered in any patient with a history of urticaria or angioedema when donning condoms or gloves, or inflating balloons. In vitro radioallergosorbent testing and enzyme-linked immunosorbent assay are commercially available and should be performed as the initial diagnostic step. Three in vitro serologic assays have U.S. Food and Drug Administration (FDA) approval for diagnostic purposes: ImmunoCAP (Pharmacia-Upjohn, Uppsala, Sweden), AlaSTAT FEIA (Diagnostic Products Corp., Los Angeles, CA), and HY-TEC EIA (Hycor Biomedical, Inc., Garden Grove, CA).

Although skin prick testing is the gold standard, it should be noted that there is currently no FDA-approved, commercially available, standardized latex allergen preparation. The stability profile and quality controllability of non-ammoniated latex make it the current top candidate for FDA licensure.[46] Currently, extemporaneous extracts or elutes made by soaking high-allergen gloves in water at room temperature are used.[49] In most but not all cases, these crude eluates are sufficient to allow prick test confirmation of ACU. It must be emphasized that in vivo testing can potentiate anaphylactic reactions.

LABORATORY FINDINGS

In Vivo Patch Test

The gold standard method for the diagnosis of ACD remains the patch test. Details on the patch test procedure are beyond the scope of this chapter but may be found in a number of standard texts.[50] It must be noted that only 23 commercially prepared allergens are currently FDA approved in the United States for use in a preloaded system. A perusal of Table 13-1 makes it apparent that nearly half of the top 25 allergens in North America are not available on the commercially made trays in the United States. The T.R.U.E. (Thin-layer Rapid Use Epicutaneous) Test has 2 panel trays. Thus, investigators who intend to fully evaluate their patients must prepare allergen trays with worldwide standardized commercially available allergens and add patient-specific test materials for completeness. Compounding reference texts outlining appropriate allergen concentrations and vehicles are available.[50]

TRUE-POSITIVE AND TRUE-NEGATIVE RESULTS The identification of true-positive reactions with clinical relevance is the primary goal of the patch test and is best achieved with a high pre-test probability.[51] That being said, one major challenge in patch testing is obtaining a true-positive result (true sensitization) with no clinical relevance to the patient's current dermatologic problem and assuming they are related. Attempts to assign relevance to such an allergen may lead to consequences that are cumbersome and distressing to both the physician and the patient. Assigning clinical relevance to a true-positive patch test result requires correlation between the involved areas of skin and the patient's environmental exposures, and notation of significant improvement on avoidance of the allergen or recurrence with its reintroduction.

The North American Contact Dermatitis Group frequently reports their prevalence data with relevance assignments, and continued failure of relevance marks the allergen for removal from the standard screening series. A good example of this is thimerosal. Many patients with positive patch test results to thimerosal have been sensitized by vaccines but are asymptomatic.[52] It should be noted that lack of relevance does not mean the patient is not allergic to the chemical in question, but more specifically that this chemical is not the causal agent for the dermatitis currently being evaluated.

True-negative results are an equally important component of the patch test, because they provide some assurance that a chemical in question is not causing the dermatitis. If a question arises as to whether a true-negative result is truly irrelevant, provocative repeat open application testing can be an invaluable diagnostic tool. The patient is taught to repeatedly apply the commercial product to intact normal skin (same site) several times daily for 1 to 2 weeks to elicit a reaction.

FALSE-POSITIVE AND FALSE-NEGATIVE RESULTS No in vivo test is infallible, and investigative patch testers must always take into consideration the possibility of false-positive and false-negative reactions when performing the patch test.

Because there are more than 3700 potential human allergens, and because of the obvious limitation of the commercially available screening trays such as T.R.U.E. Test (Kabi Pharmacia Service A/S, Hillerod, Denmark) and Allergen Patch Test Kit (Hermal Laboratories, Delmar, NY–American Academy of Dermatology), it stands to reason that a high number of clinically relevant allergens go unidentified. In an analysis of the North American Contact Dermatitis Group data for 1994 to 1996 on 3120 patients[53] it was found that 62 percent had at least one positive reaction to an allergen present on the T.R.U.E. Test, of which 45 percent were relevant to the current dermatitis. In their study of 732 patients over 5.5 years, Cohen et al.[54] found that only 23 percent of patients reacted exclusively to allergen(s) in the Allergen Patch Test standard series, 37 percent reacted to allergens in both the standard series and other supplementary tests, and 40 percent reacted only to supplementary allergens.

In Vitro Tests for Allergic Contact Dermatitis

In vitro and animal tests for the diagnosis of ACD such as the lymphocyte transformation and macrophage migration inhibition tests have been in development for the last decade. One major obstacle in developing in vitro systems is the lack of specificity to detect the antigenic moiety of a particular chemical. Lymphocyte transformation tests performed on blood cells from patients who had a positive patch test reaction to thiuram mix and/or showed sensitization to tetramethylthiuram monosulfide or to tetramethylthiuram monosulfide and tetramethylthiuram disulfide demonstrated significant proliferation of peripheral blood mononuclear cells in response to hapten-protein conjugates, whereas cells from patients with negative patch test reactions to thiuram and control donors with no history of ACD failed to mount a significant response.[58] The local lymph node assay, which uses a mouse model, allows quantitative assessment of the sensitizing potency of allergens.[59] However, patch testing remains the only reliable bioassay to ascertain sensitization to exogenous chemicals.

DIFFERENTIAL DIAGNOSIS

Eczematous Dermatoses

The differential diagnosis of ACD includes a wide range of inflammatory skin disorders (see Box 13-1). The presence of eosinophilic spongiosis and multinucleate dermal dendritic fibrohistiocytic cells is especially suggestive of ACD when encountered in the presence of acanthosis, lymphocytic infiltrate, dermal eosinophils, and hyperkeratosis.[60]

Noneczematous Variants

The pathologic findings of the noneczematous variants of ACD may be nearly identical to those of the diseases they simulate. Lichenoid ACD does have some features that help to distinguish it from idiopathic lichen planus, including a less intense lichenoid infiltrate with more eosinophils and neutrophils, less epidermal hyperplasia with fewer necrotic keratinocytes, and some degree of epidermal spongiosis.[61] In contrast, EM-like ACD has no epidermal spongiosis, and the findings are indistinguishable from those of EM from other causes. Dermal contact hypersensitivity also lacks spongiosis but has the characteristic lymphohistiocytic, perivascular infiltrate that often goes deeper in the dermis (mid-dermal) than eczematous ACD. The histopathologic features of acute allergic contact leukoderma have not been studied. In the best-documented cases, eczematous patch test reactions to PPD subsequently depigmented, at which time the biopsy specimen was indistinguishable from that for chemically induced vitiligo. Allergic contact purpura is pathologically similar to the eczematous variant of ACD but with a capillaritis that results in extravasation of red blood cells.[62] It is difficult to separate from the other pigmented purpuric dermatoses.

In all of the noneczematous and eczematous variants of ACD, patch testing is the only means for accurate diagnosis. The history, physical examination, and/or pathology are usually not diagnostic.

COMPLICATIONS

Complications of Not Patch Testing

In 2004 the American Academy of Dermatology and the Society for Investigative Dermatology determined that 72 million Americans were living with contact dermatitis and that it was the third most common reason for patients to seek consultation with the dermatologist. It accounted for 9.2 million visits that year, at a cost of $1.9 billion.[63] In 1989, Rietschel determined that patch testing the 5.7 million persons estimated to have dermatitis/eczema translated into a positive cost-benefit ratio of $40 million to $90 million per year, when the expense of patch testing was compared with the cost of treatment.[64] Furthermore, Van Der Valk, Devos, and Coenraads reported that patch testing was even more cost effective when the test was performed on patients for whom there was a high index of suspicion for the diagnosis of ACD, because increased likelihood of detecting a clinically relevant allergen correlates with a significantly better clinical outcome.[65]

Complications of Patch Testing

Patient disappointment is a significant problem with patch testing, because there is no guarantee of detection of a clinically relevant allergen or of subsequent skin improvement with avoidance of a given allergen. These outcomes are anticipated and expected, but not guaranteed. Furthermore, there are small risks of causing a flare of the dermatitis and, although remote, of inducing sensitization to one of the allergens. Patients should be made aware that positive test reactions may persist for several weeks, and in the case of gold, sometimes longer. Post-inflammatory hyperpigmentation or hypopigmentation may occur at positive patch test reaction sites.

PROGNOSIS

It is difficult to assess the actual prognosis of ACD, because there is no standardized instrument for such an evaluation. Quality-of-life questionnaires (which measure symptom, emotional, and functional parameters), number of outpatient dermatology visits, and subjective evaluations have all been used. In fact, much of the information on prognosis is extrapolated from data on occupational contact dermatitis, because of the important implications for worker's compensation. It is important to note that these data are subject to selection bias, because most studies are investigating patients who are being evaluated at a tertiary care contact dermatitis referral clinic.[67]

Almost two decades ago, the prognosis for occupational contact dermatitis was relatively poor, with only 30 percent to 50 percent of patients demonstrating improvement.[68] Fortunately, more recent reviews demonstrate that with early intervention and appropriate management over 75 percent of patients recover without permanent impairment.[69] This upward trend toward a positive prognosis may relate to better identification of allergens, improved standardization of the diagnostic tools, increased preventive efforts, and patient education.[70]

Cahill et al. performed an extensive review of the literature to identify common variables that influence prognosis.[71] They specifically looked at the effects of age, sex, atopy, patient knowledge, disease etiology, duration of symptoms, and change of vocation and found no differences related to these factors. Change of work conditions is not always associated with an improved prognosis, because patients may still not appropriately avoid the inducing allergen. Furthermore, change of employment, although it may improve ACD, may have a direct negative impact on quality of life.[72]

Although assessment of the patient's knowledge base is a difficult task, it is generally accepted that greater knowledge correlates with better clinical outcomes. In a follow-up study by Agner, Flyvholm, and Menne, patients diagnosed with formaldehyde allergy were rigorously informed about their diagnosis and the culprit allergen, and given an exposure assessment for their products. At 1- and 5-year post–patch test follow-up, the patients were interviewed and examined by the dermatologist, and given further exposure assessment for their current products. As expected, patients who reported not paying attention to their allergens when buying or using consumer products were exposed to formaldehyde in their current products. Furthermore, patients who reportedly paid attention to avoiding their allergens had statistically fewer flares of their dermatitis.[73]

Use of the Contact Allergen Replacement Database tool allowed for a lower mean counseling time and higher levels of patient satisfaction, although no statistically significant differences were noted on clinical measures of disease activity.[74]

Nielsen et al. performed a cross-sectional study on a random sample of 567 persons (aged 15 to 69 years) and a subsequent repeat patch study on 365 (68 percent) of the original population. Positive patch test results were re-confirmed in 71 percent of the subjects (37 out of 52) 8 years after the baseline study. Nickel provoked the highest frequency of positive reactions at 79 percent (19 out of 24 subjects), whereas cosmetic ingredients produced the lowest frequency, 50 percent (5 out of 10 subjects). Of note, 60 percent (21 out of 35 subjects) had a positive patch test reaction to one or more allergens. This study confirmed the continued need for allergen avoidance to prevent elicitation of ACD.[75] Unfortunately, there are factors that are beyond the ability of the patient to control to become symptom free. These include the nature (ubiquity) of the allergen itself or the inability to

shield the skin from the environment (e.g., the face and hands are always exposed). Reports indicate that sensitization to nickel, chromium, and epoxy are specifically associated with a less favorable prognosis, especially if contact is occupationally related, even when continued exposure ceases.[76,77]

Meding, Wrangsjo, and Jarvholm evaluated the long-term course, occupational relevance, and medico-social implications of hand dermatitis in patients diagnosed through a prior population-based study.[78] Patients were evaluated using two questionnaires, one administered at baseline and one administered 15 years later. Of the patients who completed both questionnaires, 66 percent reported periodic exacerbations of their chronic hand eczema (44 percent of which had been within the previous year), whereas 12 percent experienced continuous symptoms. These findings underscore the overwhelming chronicity of most hand dermatitis cases. Predictive factors for hand eczema severity were also assessed using a logistic regression model.[79] The most important predictive factors for persistence of disease were a history of childhood eczema, a greater extent of eczema involvement at initial presentation, and an age younger than 20 years at onset of the hand eczema. In addition they found that hand dermatitis was associated with considerable alteration of psychosocial function, for example, sleep disturbances (36 percent) and hampered leisure activities (72 percent). In the 3 percent of patients who reported a necessary occupational change secondary to their hand dermatitis, this change did correlate with clinical improvement.

TREATMENT

The fundamental management of patients with ACD relies on both treatment of symptoms and avoidance of additional encounters with allergic contactants.

Pharmacologic Intervention

In the face of acute or symptomatic chronic contact dermatitis, pharmacologic intervention is necessary to alleviate the symptoms and physical limitations imposed by the eruption. The impact of the dermatitis on the activities of daily living and the ability to perform work functions must not be underestimated.

Acute vesicular, weeping eruptions may benefit from the use of drying agents such as topical aluminum sulfate/calcium acetate. Chronic, lichenified eruptions are best treated with emollients. Pruritus can be controlled with topical antipruritics or oral antihistamines, but topical antihistamines and anesthetics are best avoided because of the risk of inducing a secondary allergy in already dermatitic skin.

Despite the drawbacks associated with their long-term use, corticosteroids remain the gold standard and the mainstay for alleviating symptoms and hastening the recovery from ACD (see Chap. 216). Topical corticosteroids (divided into five stereochemical structural classes, each with similarly broad mechanisms of action and effectiveness[38]) have been shown in a number of models to reduce the signs and symptoms of ACD.[80] Furthermore, they are generally well tolerated when used short term. Long-term and widespread use of topical steroids, however, can result in cutaneous atrophy, hirsutism, hypopigmentation, folliculitis, acne, and systemic absorption. The use of systemic corticosteroids, on the other hand, is warranted only in moderate to severe acute cases and in cases of refractory ACD.

In the past decade, calcineurin inhibitors have been used as treatment options for many inflammatory skin disorders. Their mechanism of action is elaborated in Chap. 221. Oral cyclosporine and topical tacrolimus and pimecrolimus have demonstrated efficacy in the treatment of eczematous dermatitides, including atopic dermatitis predominantly, as well as contact dermatitis. Cyclosporine has been used orally to treat ACD, but limited penetration has hindered its topical use. In addition, tacrolimus and pimecrolimus (which share a macrolactam structure) have proved efficacious as topical anti-inflammatory drugs.

Phototherapy

Phototherapy has been reserved for patients with refractory ACD who are unresponsive to corticosteroids and for patients who are unable to avoid all provoking factors in their daily environment. Several studies have demonstrated the effectiveness of ultraviolet light (oral psoralen plus ultraviolet A photochemotherapy, and therapy with shortwave ultraviolet B light), due to its intrinsic immunosuppressive properties, in the treatment of both chronic ACD and ICD of the hands. Furthermore, ultraviolet B light therapy was said to produce an excellent effect in 7 of 10 patients with hand ACD.[81] Notably, the treatment duration was lengthy (5 months), maintenance therapy was required, and controls were not performed.

TABLE 13-3
Foods and Topical Items Reported to Provoke Reactions in Persons Allergic to Fragrance and Balsam of Peru

- Tomatoes
- Citrus fruits
- Spices such as cinnamon, cloves, vanilla, nutmeg, curry, allspice, paprika, anise, and ginger
- Chocolate
- Chili
- Beer and wine
- Vinegar
- Dairy products
- Coffee
- Baked goods
- Hemorrhoidal suppositories
- Fragranced personal hygiene products and cosmetics
- Flavored teas, coffee, and tobacco
- Deodorants
- After-shave lotions
- Confectionary
- Tincture of benzoin
- Colas and other soft drinks
- Wound spray
- Medicinal creams
- Calamine lotion
- Baby powder
- Dental cement
- Sunscreens
- Cough medicine
- Lozenges
- Suntan lotions
- Lip preparations

Data from Srivastava D, Chang YT, Kumar S, Cohen DE. Identification of the constituents of balsam of Peru in tomatoes. *Dermatitis* **16**:091, 2005. Oral presentation, abstract; and Salam TN, Fowler JF: Balsam-related systemic contact dermatitis *J Am Acad Dermatol* **45**:377, 2001.

PREVENTION

Prevention rests on the avoidance of allergens.

At times, the sensitization to allergens such as nickel and fragrance chemicals like balsam of Peru can induce non-localized reactions through their systemic absorption (Table 13-3). In some circumstances, the avoidance of these allergens in the diet can result in clinical improvement. In any event, the treatment of ACD is simply allergen avoidance. It is the process of elucidating and implementing this treatment plan that can be so arduous. This concept is reinforced by the results of one study of 230 workers,[82] in which only one-third of study participants accurately recalled their diagnoses and treatment regimens, and persistent dermatitis was three times more likely in those workers who could not remember this information than in those who did. The benefit of allergen avoidance and the consequences of not doing so are discussed in the Prognosis section.

For certain allergens found in topical preparations (e.g., vehicles, preservatives, stabilizers, and emulsifiers), it is important to impress upon patients the

need to read labels. In addition, a periodically updated electronic database of ingredients in cosmetics and over-the-counter and prescription topical preparations (Contact Allergen Replacement Database) is available on the Internet (http://www.contactderm.org) and allows practitioners to generate a unique list of topical preparations appropriate for the individual with specific allergies.

Patients with allergies to preservatives (e.g., methylchloroisothiazolone) must be aware that these materials can be found in any water-based formulation, such as latex paint. Furthermore, the name given a chemical used in a cosmetic or pharmaceutical product is frequently changed when it is used in an industrial product. For instance, the cosmetic preservative quaternium-15, when used in industry, is referred to as Dowicil 100 or Dowicil 200. Practitioners guiding patients through the synonymic jungle of these chemicals are advised to consult standard texts on the subject.

Unfortunately for patients and physicians alike, the allergenic components of many materials will fail to be labeled (e.g., rubber-, textile-, and metal-related allergens, to name a few). In counseling patients with reactions to these materials, the physician must provide information about what kinds of products are likely to contain the allergens, as well as appropriate replacements. Such information can be found in standard texts.[50]

Furthermore, some allergens may be incompletely labeled; for example, given the proprietary nature of a fragrance formulation, individual fragrances combined in a product may go unlisted. Patients with an allergic reaction to a fragrance should be advised to use fragrance-free materials, which include not only topical preparations but also a variety of other products such as toilet paper, sanitary napkins, and diapers.

Because many allergens share common antigenic moieties, the patient needs to be instructed not only about the known allergen but also about possible cross-reacting allergens. For example, the individual allergic to benzocaine must be aware of the many potentially cross-reacting substances, which include agents as diverse as other ester anesthetics (e.g., procaine), certain medications (e.g., sulfonamides), hair dyes (e.g., PPD), textile dyes (e.g., aniline dyes), some sunscreens (e.g., para-aminobenzoic acid), and other products.

To date, hyposensitization or tolerance induction has remained an elusive method for coping with ACD.

CHAPTER 14

Atopic Dermatitis (Atopic Eczema)

Donald Y. M. Leung
Lawrence F. Eichenfield
Mark Boguniewicz

Atopic dermatitis (AD) is a chronically relapsing skin disease that occurs most commonly during early infancy and childhood. It is frequently associated with abnormalities in skin barrier function and allergen sensitization. There is no single distinguishing feature of AD or a diagnostic laboratory test. Thus, the diagnosis is based on the constellation of clinical findings described by Hanifin and Rajka[1] and listed in Table 14-1.

EPIDEMIOLOGY

Since the 1960s, there has been a greater than threefold increase in the prevalence of AD.[2] Indeed, the most recent estimates indicate that AD is a major public health problem worldwide, with a prevalence in children of 10 percent to 20 percent in the United States, northern and western Europe, urban Africa, Japan, Australia, and other industrialized countries.[3] The prevalence of AD in adults is approximately 1 percent to 3 percent. Interestingly, the prevalence of AD is much lower in agricultural countries such as China and in Eastern Europe, rural Africa, and Central Asia. There is also a female preponderance for AD, with an overall female/male ratio of 1.3:1.0.

The basis for this increased prevalence of AD is not well understood. However, wide variations in prevalence have been observed within countries inhabited by similar ethnic groups, suggesting that environmental factors are critical in determining disease expression.[4] Some of the potential risk factors that have received attention as being associated with the rise in atopic disease include small family size, increased income and education both in whites and blacks, migration from rural to urban environments, and increased use of antibiotics, that is, the so-called *Western lifestyle*.[5,6] This has resulted in the "hygiene hypothesis" that allergic diseases might be prevented by "infection in early childhood transmitted by unhygienic contact with older siblings."[7]

ETIOLOGY AND PATHOGENESIS

AD is a highly pruritic inflammatory skin disease that results from complex interactions between genetic susceptibility genes resulting in a defective skin barrier, defects in the innate immune system,

ATOPIC DERMATITIS AT A GLANCE

- Prevalence peak of 15 percent to 20 percent in early childhood in industrialized countries.
- A chronic or chronically relapsing disorder with major features of:
  - Pruritus
  - Eczematous dermatitis (acute, subacute, or chronic) with typical morphology and age-specific patterns
  - Facial and extensor involvement in infancy
  - Flexural eczema/lichenification in children and adults.
- Commonly associated with:
  - Personal or family history of atopy (allergic rhinitis, asthma, atopic dermatitis)
  - Xerosis/skin barrier dysfunction
  - Immunoglobulin E reactivity.
- Genetic basis influenced by environmental factors with alterations in immunologic responses in T cells, antigen processing, inflammatory cytokines, host defense proteins, allergen sensitivity, and infection.

and heightened immunologic responses to allergens and microbial antigens.[8]

Decreased Skin Barrier Function

AD is associated with a marked decrease in skin barrier function due to the downregulation of cornified envelope genes (filaggrin and loricrin), reduced ceramide levels, increased levels of endogenous proteolytic enzymes, and enhanced trans-epidermal water loss.[9,10] Addition of soap and detergents to the skin raises its pH, thereby increasing activity of endogenous proteases, leading to further breakdown of epidermal barrier function. The epidermal barrier may also be damaged by exposure to exogenous proteases from house dust mites and *Staphylococcus aureus*. This is worsened by the lack of certain endogenous protease inhibitors in atopic skin. These epidermal changes likely contribute to increased allergen absorption into the skin and microbial colonization. Because epicutaneous, as compared to systemic or airway, sensitization to allergen results in higher level allergic immune responses, decreased skin barrier function could act as a site for allergen sensitization and predispose such children to the development of respiratory allergy later in life.[11]

TABLE 14-1
Features of Atopic Dermatitis

- Major features
  - Pruritus
  - Rash on face and/or extensors in infants and young children
  - Lichenification in flexural areas in older children
  - Tendency toward chronic or chronically relapsing dermatitis
  - Personal or family history of atopic disease: asthma, allergic rhinitis, atopic dermatitis
- Other common findings
  - Dryness
  - Dennie-Morgan folds (accentuated lines or grooves below the margin of the lower eyelid)
  - Allergic shiners (darkening beneath the eyes)
  - Facial pallor
  - Pityriasis alba
  - Keratosis pilaris
  - Ichthyosis vulgaris
  - Hyperlinearity of palms and soles
  - White dermatographism (white line appears on skin within 1 minute of being stroked with blunt instrument)
  - Conjunctivitis
  - Keratoconus
  - Anterior subcapsular cataracts
  - Elevated serum immunoglobulin E
  - Immediate skin test reactivity

Immunopathology of Atopic Dermatitis

Clinically unaffected skin of AD patients manifests mild epidermal hyperplasia and a sparse perivascular T-cell infiltrate.[8] Acute eczematous skin lesions are characterized by marked intercellular edema (spongiosis) of the epidermis. Dendritic antigen-presenting cells [e.g., Langerhans cells (LCs), macrophages] in lesional and, to a lesser extent, in nonlesional skin of AD exhibit surface-bound immunoglobulin E (IgE) molecules. A sparse epidermal infiltrate consisting primarily of T lymphocytes is also frequently observed. In the dermis of the acute lesion, there is an influx of T cells with occasional monocyte-macrophages. The lymphocytic infiltrate consists predominantly of activated memory T cells bearing CD3, CD4, and CD45 RO (suggesting previous encounter with antigen). Eosinophils are rarely present in acute AD. Mast cells are found in normal numbers in different stages of degranulation.

Chronic lichenified lesions are characterized by a hyperplastic epidermis with elongation of the rete ridges, prominent hyperkeratosis, and minimal spongiosis. There is an increased number of IgE-bearing LCs in the epidermis, and macrophages dominate the dermal mononuclear cell infiltrate. Mast cells are increased in number but are generally fully granulated. Neutrophils are absent in AD skin lesions even in the setting of increased *S. aureus* colonization and infection. Increased numbers of eosinophils are observed in chronic AD skin lesions. These eosinophils undergo cytolysis with release of granule protein contents into the upper dermis of lesional skin. Eosinophil-derived extracellular major basic protein can be detected in a fibrillar pattern associated with the distribution of elastic fibers throughout the upper dermis. Eosinophils are thought to contribute to allergic inflammation by the secretion of cytokines and mediators that augment allergic inflammation and induce tissue injury in AD through the production of reactive oxygen intermediates and release of toxic granule proteins.

Cytokines and Chemokines

Atopic skin inflammation is orchestrated by the local expression of pro-inflammatory cytokines and chemokines.[12] Cytokines such as tumor necrosis factor-α (TNF-α) and interleukin 1 (IL-1) from resident cells [keratinocytes, mast cells, dendritic cells (DCs)] bind to receptors on the vascular endothelium, activating cellular signaling pathways, which leads to the induction of vascular endothelial cell adhesion molecules. These events initiate the process of tethering, activation, and adhesion to vascular endothelium followed by extravasation of inflammatory cells into the skin. Once inflammatory cells have infiltrated into the skin, they respond to chemotactic gradients established by chemokines which emanate from sites of injury or infection.

Acute AD is associated with the production of T helper 2 type (Th2) cytokines, notably IL-4 and IL-13,[13] which mediate immunoglobulin isotype switch-

ing to IgE synthesis, and upregulate expression of adhesion molecules on endothelial cells. In contrast, IL-5, is involved in eosinophil development and survival, and predominates in chronic AD.[13] The important role that Th2 cytokines play in the skin's inflammatory response is supported by the observation that transgenic mice genetically engineered to overexpress IL-4 in their skin develop inflammatory pruritic skin lesions similar to AD, suggesting that local skin expression of Th2 cytokines plays a critical role in AD.[14] Allergen-sensitized skin from IL-5–deficient mice has been found to have no detectable eosinophils and exhibits decreased thickening, whereas skin from IL-4–deficient mice displays normal thickening of the skin layers, but has a reduction in eosinophils.[15] Increased production of granulocyte macrophage colony-stimulating factor in AD is reported to inhibit apoptosis of monocytes, thereby contributing to the persistence of AD.[16] The maintenance of chronic AD also involves production of the Th1-like cytokines IL-12 and IL-18, as well as several remodeling-associated cytokines, including IL-11 and transforming growth factor-β1.[17]

The skin-specific chemokine, cutaneous T cell–attracting chemokine [CTACK; CC chemokine ligand 27 (CCL27)], is highly upregulated in AD and preferentially attracts skin homing cutaneous lymphoid antigen $(CLA)^+$ CC chemokine receptor 10^+ ($CCR10^+$) T cells into the skin.[12] CCR4 expressed on skin homing CLA^+ T cells can also bind to CCL17 on the vascular endothelium of cutaneous venules. Selective recruitment of CCR4-expressing Th2 cells is mediated by macrophage-derived chemokine and thymus and activation-regulated cytokine, both of which are increased in AD. Severity of AD has been linked to the magnitude of thymus and activation-regulated cytokine levels. In addition, chemokines such as fractalkine, interferon (IFN)-γ–inducible protein 10, and monokine induced by IFN-γ are strongly upregulated in keratinocytes and result in Th1-cell migration toward epidermis, particularly in chronic AD. Increased expression of the CC chemokines, macrophage chemoattractant protein-4, eotaxin, and RANTES (regulated on activation normal T-cell expressed and secreted) contribute to infiltration of macrophages, eosinophils, and T cells into both acute and chronic AD skin lesions. See Chaps. 11 and 12 for a more detailed review of cytokines and chemokines in skin inflammation.

Key Cell Types in Atopic Dermatitis Skin

ANTIGEN-PRESENTING CELLS AD skin contains two types of high-affinity, IgE-receptor–bearing myeloid DCs: (1) LCs and (2) inflammatory dendritic epidermal cells (IDECs), IgE-bearing LCs that appear to play an important role in cutaneous allergen presentation to IL-4–producing Th2 cells.[18] In this regard, IgE-bearing LCs from AD skin lesions, but not LCs that lack surface IgE, are capable of presenting inhalant allergens to T cells. These results suggest that cell-bound IgE on LCs facilitates capture and internalization of allergens into LCs before their processing and antigen presentation to T cells. IgE-bearing LCs that have captured allergen likely activate memory Th2 cells in atopic skin, but they may also migrate to the lymph nodes to stimulate naive T cells there to further expand the pool of systemic Th2 cells. Stimulation of FcεRI on the surface of LCs by allergens induces the release of chemotactic signals and recruitment of precursor cells of IDECs and T cells in vitro. Stimulation of FcεRI on IDECs leads to the release of high amounts of pro-inflammatory signals, which contribute to the amplification of allergic immune response.

In contrast to other inflammatory skin diseases, such as allergic contact dermatitis or psoriasis vulgaris, very low numbers of plasmacytoid DCs (pDCs), which play an important role in host defense against viral infections, can be detected within the AD skin lesion.[19] pDCs in the peripheral blood of patients with AD have been shown to bear the trimeric variant of FcεRI on their cell surface, which is occupied by IgE molecules. The modified immune function of pDCs of patients with AD after FcεRI-mediated allergen stimulation might contribute to a local deficiency of type I IFNs, thereby contributing to increased susceptibility of AD patients toward viral skin infections such as eczema herpeticum.[20]

T CELLS Skin homing memory T cells play an important role in the pathogenesis of AD, particularly during the acute phase of illness. This concept is supported by the observation that primary T-cell immunodeficiency disorders are frequently associated with eczematous skin lesions that clear after successful bone marrow transplantation.[21] Furthermore, in animal models of AD, the eczematous rash does not occur in the absence of T cells.[15] In addition, treatment with topical calcineurin inhibitors, which specifically target activated T cells, significantly reduces the clinical skin rash of AD.[22]

Several studies have demonstrated, in acute AD, the presence of Th2-like T cells that produce cytokines that enhance allergic skin inflammation. During the chronic phase of AD, there is a switch to Th1-like cells which primarily produce IFN-γ. These Th2-like cells induce the activation and apoptosis of keratinocytes.[23] Recently, T regulatory (Treg) cells have been described as a further subtype of T cells that have immunosuppressive function and cytokine profiles distinct from either Th1 and Th2 cells.[24] Treg cells are able to inhibit the development of both Th1 and Th2 responses. Mutations in a nuclear factor expressed in Treg cells, FoxP3, result in IPEX (*i*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, *X*-linked) syndrome characterized by elevated serum IgE, food allergy, and eczema.[25] Interestingly, staphylococcal superantigens subvert Treg cell function and may thereby augment skin inflammation.[26]

KERATINOCYTES Keratinocytes play a critical role in the augmentation of atopic skin inflammation. AD keratinocytes secrete a unique profile of chemokines and cytokines after exposure to pro-inflammatory cytokines. This includes high levels of RANTES after stimulation with TNF-α and IFN-γ.[27] They are also an important source of thymic stromal lymphopoietin (TSLP), which activates DCs to prime naive T cells to produce IL-4 and IL-13 (i.e., Th2 cell differentiation).[28] The importance of TSLP in AD pathogenesis is supported by the observation that mice genetically manipulated to overexpression TSLP in the skin develop AD-like skin inflammation.

Keratinocytes also play a key role in the skin's innate immune responses via the expression of Toll-like receptors, production of pro-inflammatory cytokines and antimicrobial peptides (such as human β defensins and cathelicidins) in response to tissue injury or invading microbes.[29] Several studies have now demonstrated that AD keratinocytes produce reduced amounts of antimicrobial peptides and this may predispose such individuals to skin colonization and infection with *S. aureus*, viruses, and fungi. This defect, however, appears to be acquired as the result of Th2-cytokine (IL-4, IL-10, and IL-13)–mediated inhibi-

tion of TNF- and IFN-γ–induced antimicrobial peptide generation.

Genetics

AD is familially transmitted with a strong maternal influence. Genome screens of families with AD have implicated chromosomal regions that overlap with other inflammatory skin diseases such as psoriasis. Together with candidate gene studies, these have provided interesting insights into the pathogenesis of AD. Although many genes are likely to be involved in the development of AD, there has been particular interest in the potential role of skin barrier/epidermal differentiation genes and immune response/host defense genes.

Loss-of-function mutations of the epidermal barrier protein, filaggrin, have been demonstrated to be a major predisposing factor for AD[30] as well as ichthyosis vulgaris, a common keratinizing disorder associated with AD. Of note, the filaggrin gene is found on chromosome 1q21 which contains genes (including loricrin and S100 calcium binding proteins) in the epidermal differentiation complex, which are known to be expressed during terminal differentiation of the epidermis. DNA microarray analyses have demonstrated upregulation of S100 calcium binding proteins and downregulation of loricrin and filaggrin in AD. Candidate gene approaches have also implicated variants in the *SPINK5* gene, which is expressed in the uppermost epidermis where its product, LEKT1, inhibits two serine proteases involved in desquamation and inflammation (stratum corneum tryptic enzyme and stratum corneum chymotryptic enzyme). Stratum corneum tryptic enzyme and stratum corneum tryptic enzyme expression is increased in AD, suggesting that an imbalance of protease versus protease inhibitor activity may contribute to atopic skin inflammation. These observations establish a key role for impaired skin barrier function in the pathogenesis of AD, as impaired skin barrier formation allows increased transepidermal water loss and, importantly, increased entry of allergens, antigens, and chemicals from the environment resulting in skin inflammatory responses. It is important to note that these filaggrin mutations, and likely other mutations affecting the skin barrier, can occur in unaffected individuals, patients with ichthyosis vulgaris who do not have AD, and that the majority of patients with AD outgrow their inflammatory skin disease. Thus, other gene products must also be involved in AD pathology.

Chromosome 5q31-33 contains a clustered family of functionally related cytokine genes—IL-3, IL-4, IL-5, IL-13, and granulocyte macrophage colony-stimulating factor—which are expressed by Th2 cells. A case control comparison has suggested a genotypic association between the T allele of the 590C/T polymorphism of the IL-4 gene promoter region with AD. Because the T allele is associated with increased IL-4 gene promoter activity when compared to the C allele, this suggests that genetic differences in transcriptional activity of the IL-4 gene influence AD predisposition. In addition, an association of AD with a gain-of-function mutation in the α subunit of the IL-4 receptor has been reported, providing further support of the concept that IL-4 gene expression plays a role in AD. Functional mutations in the promoter region of the C-C chemokines, RANTES and eotaxin, as well as variants in IL-13, the β subunit of the high affinity cell surface receptor for IgE (FcεR1) found on basophils and mast cells suggest an overlapping genetic basis with other atopic diseases. The involvement of T-cell immunoglobulin- and mucin-domain–containing molecule-1 and IL-18 genes support the role of $CD4^+$ T cells and dysregulation of Th1 genes in the pathophysiology of AD. As well, reports of AD association with polymorphisms of the NOD1 gene, which encodes cytosolic pathogen recognition receptor and Toll-like receptors, suggest an important role for host defense genes in the pathogenesis of AD. The reader is referred to Chap. 8 and reference 31 for a detailed discussion of the genetics of AD.

Role of Pruritus in Atopic Dermatitis

Pruritus is a prominent feature of AD, manifested as cutaneous hyperreactivity and scratching following exposure to allergens, changes in humidity, excessive sweating, and low concentrations of irritants.[32] Control of pruritus is important because mechanical injury from scratching can induce pro-inflammatory cytokine and chemokine release, leading to a vicious scratch-itch cycle perpetuating the AD skin rash. The mechanisms of pruritus in AD are poorly understood. Allergen-induced release of histamine from skin mast cells is not an exclusive cause of pruritus in AD, because antihistamines are not effective in controlling the itch of AD.[33] The observation that treatment with topical corticosteroids and calcineurin inhibitors is effective at reducing pruritus suggests that the inflammatory cells play an important role in pruritus.[34,35] Molecules that have been implicated in pruritus include T-cell–derived cytokines such as IL-31, stress-induced neuropeptides, proteases such as proteases which can act on protease-activated receptors, eicosanoids, and eosinophil-derived proteins.[36–38] The reader is referred to Chap. 102 for a detailed discussion of the pathophysiology of pruritus.

CLINICAL FINDINGS

The diagnosis of AD is based on the constellation of clinical features summarized in Table 14-1. AD typically begins during infancy. Approximately 50 percent of patients develop this illness by the first year of life and an additional 30 percent between the ages of 1 and 5 years. Between 50 percent and 80 percent of patients with AD develop allergic rhinitis or asthma later in childhood. Many of these patients outgrow their AD as they are developing respiratory allergy.

Cutaneous Lesions

Intense pruritus and cutaneous reactivity are cardinal features of AD. Pruritus may be intermittent throughout the day but is usually worse in the early evening and night. Its consequences are scratching, prurigo papules (Fig. 14-1), lichenification (Fig. 14-2), and eczematous skin lesions. Acute skin lesions are characterized by intensely pruritic, erythematous papules associated with excoriation, vesicles over erythematous skin, and serous exudate (Fig. 14-3). Subacute dermatitis is characterized by erythematous, excoriated, scaling papules (Fig.

▲ **FIGURE 14-1** Prurigo papules in a patient with atopic dermatitis.

▲ **FIGURE 14-2** Lichenification of the neck and shoulders in an adult with atopic dermatitis.

14-4). Chronic AD is characterized by thickened plaques of skin, accentuated skin markings (lichenification), and fibrotic papules (prurigo nodularis; Fig. 14-5). In chronic AD, all three stages of skin reactions frequently co-exist in the same individual. At all stages of AD, patients usually have dry, lackluster skin (Fig. 14-6).

The distribution and skin reaction pattern vary according to the patient's age and disease activity. During infancy, the AD is generally more acute and primarily involves the face, scalp, and the extensor surfaces of the extremities (Fig. 14-7). The diaper area is usually spared. In older children, and in those who have long-standing skin disease, the patient develops the chronic form of AD with lichenification and localization of the rash to the flexural folds of the extremities (Fig. 14-8). AD often subsides as the patient grows older, leaving an adult with skin that is prone to itching and inflammation when exposed to exogenous irritants. Chronic hand eczema may be the primary manifestation of many adults with AD (Fig. 14-9). Other associated features of AD are listed in Table 14-1.

▲ **FIGURE 14-5** Severe lichenification and hyperpigmented prurigo papules seen in a patient with chronic atopic dermatitis.

Laboratory Tests

Laboratory testing is not needed in the routine evaluation and treatment of uncomplicated AD. Serum IgE levels are elevated in approximately 70 percent to 80 percent of AD patients. This is associated with sensitization against inhalant and food allergens and/or concomitant allergic rhinitis and asthma.[39,40] In contrast, 20 percent to 30 percent of AD patients have normal serum IgE levels. This subtype of AD has a lack of IgE sensitization against inhalant or food allergens. However, some of these patients may possess IgE sensitization against microbial antigens such as *S. aureus* toxins, and *Candida albicans* or *Malassezia sympodialis* can be detected. As well, some of these patients show positive reactions using the atopy patch test despite negative immediate skin tests.

The majority of patients with AD also have peripheral blood eosinophilia. Patients with AD have increased spontaneous histamine release from baso-

◀ **FIGURE 14-3** **A.** Pronounced weeping and crusting of eczematous lesions in childhood atopic dermatitis. **B.** Excoriated papules and crusting in an acute flare of atopic dermatitis.

phils. These findings likely reflect a systemic Th2 immune response in AD especially those patients who have elevated serum IgE levels. Importantly, the peripheral blood skin homing CLA^+ T cells in AD expressing either CD4 or CD8 spontaneously secrete IL-5 and IL-13, which functionally prolong eosinophil survival and induce IgE synthesis.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Table 14-1 lists the clinical features of AD. Of the major features, pruritus and chronic or remitting eczematous dermatitis with typical morphology and distribution are essential for diagnosis. Other features, including exogenous allergy or elevated IgE, are variable, and some of the "associated features" in the table may not be useful discriminators of individuals with AD from the unaffected general population. Various diagnostic criteria have been proposed to assist with clinical diagnosis, definition of patients for clinical studies, and epidemiologic population studies.[41] A refined list of diagnostic criteria suitable for epidemiologic studies has been derived and validated by workers in the United Kingdom.[42]

▲ **FIGURE 14-7** Itching infant with atopic dermatitis. (Used with permission from Oholm Larsen, MD.)

▲ **FIGURE 14-8** Childhood atopic dermatitis with lichenification of antecubital fossae and generalized severely pruritic eczematous plaques.

Box 14-1 lists a number of inflammatory skin diseases, immunodeficiencies, skin malignancies, genetic disorders, infectious diseases, and infestations that share symptoms and signs with AD. These should be considered and ruled out before a diagnosis of AD is made. Infants presenting in the first year of life with failure to thrive, diarrhea, a generalized scaling erythematous rash, and recurrent cutaneous and/or systemic infections should be evaluated for severe combined immunodeficiency syndrome. Wiskott-Aldrich syndrome is an X-linked recessive disorder characterized by cutaneous findings almost indistinguishable from AD. It is associated with thrombocytopenia, variable abnormalities in humoral and cellular immunity, and recurrent severe bacterial infections. The hyper-IgE syndrome is characterized by elevated serum IgE levels, defective T-cell function, recurrent deep-seated bacterial infections, including cutaneous abscesses due to *S. aureus* and/or pruritic skin disease due to *S. aureus* pustulosis, or by recalcitrant dermatophytosis. A papulopustular eruption of the face and scalp may be seen in early life.[43] Although *S. aureus* is an important pathogen in this disorder, infection with other bacteria, viruses, and fungi may occur, particularly when patients are on chronic antistaphylococcal antibiotic prophylaxis. Other features of hyper-IgE syndrome include pneumonia with pneumatocele formation, dental anomalies with retained primary teeth, bone fractures, and osteopenia.

It is important to recognize that an adult who presents with an eczematous dermatitis with no history of childhood eczema, respiratory allergy, or atopic family history may have allergic contact dermatitis. A contact allergen should be considered in any patient whose AD does not respond to appropriate therapy. Of note, contact allergy to topical glucocorticoids and topical calcineurin inhibitors has been reported in patients with chronic dermatitis. In addition, cutaneous T-cell lymphoma must be ruled out in any adult presenting with chronic dermatitis poorly responsive to topical glucocorticoid therapy. Ideally, biopsies should be obtained from three separate sites, because the histology may show spongiosis and cellular infiltrate similar to AD. Eczematous dermatitis has been also reported with human immunodeficiency virus as well as with a variety of infestations such as scabies. Other conditions that can be confused with AD include psoriasis, ichthyoses, and seborrheic dermatitis.

Box 14-1

Differential Diagnosis of Atopic Dermatitis

Most Likely

- Contact dermatitis (allergic and irritant)
- Seborrheic dermatitis
- Scabies
- Psoriasis
- Ichthyosis vulgaris
- Keratosis pilaris
- Dermatophytosis

Consider

- Asteatotic eczema
- Lichen simplex chronicus
- Nummular dermatitis
- Juvenile palmar-plantar dermatosis
- Impetigo
- Drug eruptions
- Perioral dermatitis
- Pityriasis alba
- Photosensitivity disorders (hydroa vacciniforme; polymorphous light eruption, porphyrias)
- Molluscum dermatitis

LESS COMMON/RARE DISORDERS PREDOMINANTLY IN ADOLESCENTS AND ADULTS

- Cutaneous T-cell lymphoma (mycosis fungoides or Sézary syndrome)
- Human immunodeficiency virus–associated dermatoses
- Lupus erythematosus
- Dermatomyositis
- Graft-versus-host disease
- Pemphigus foliaceus
- Dermatitis herpetiformis
- Photosensitivity disorders (hydroa vacciniforme, polymorphous light eruption, porphyrias)

LESS COMMON/RARE DISORDERS PREDOMINANTLY IN INFANTS/CHILDREN

- Metabolic/nutritional
  - Phenylketonuria
  - Prolidase deficiency
  - Multiple carboxylase deficiency
  - Zinc deficiency (acrodermatitis enteropathica; prematurity; deficient breast milk zinc; cystic fibrosis)
  - Others: biotin, essential fatty acids, organic acidurias
- Primary immunodeficiency disorders
  - Severe combined immunodeficiency disorder
  - DiGeorge syndrome
  - Hypogammaglobulinemia
  - Agammaglobulinemia
  - Wiskott-Aldrich syndrome
  - Ataxia-telangiectasia
  - Hyperimmunoglobulin E syndrome
  - Chronic mucocutaneous candidiasis
  - Omenn syndrome
- Genetic syndromes
  - Netherton syndrome
  - Hurler syndrome
- Inflammatory, autoimmune disorders
  - Eosinophilic gastroenteritis
  - Gluten-sensitive enteropathy
  - Neonatal lupus erythematosus
- Proliferative disorders
  - Langerhans cell histiocytosis

COMPLICATIONS

Ocular Problems

Eye complications associated with severe AD can lead to significant morbidity. Eyelid dermatitis and chronic blepharitis are commonly associated with AD and may result in visual impairment from corneal scarring. Atopic keratoconjunctivitis is usually bilateral and can have disabling symptoms that include itching, burning, tearing, and copious mucoid discharge. Vernal conjunctivitis is a severe bilateral recurrent chronic inflammatory process associated with papillary hypertrophy, or cobblestoning of the upper eyelid conjunctiva. It usually occurs in younger patients and has a marked seasonal incidence, often in the spring. The associated intense pruritus is exacerbated by exposure to irritants, light, or sweating. Keratoconus is a conical deformity of the cornea believed to result from chronic rubbing of the eyes in patients with AD and allergic rhinitis. Cataracts were reported in the early literature to occur in up to 21 percent of patients with severe AD. However, it is unclear whether this was a primary manifestation of AD or the result of the extensive use of systemic and topical glucocorticoids, particularly around the eyes. Indeed, more recent studies suggest that routine screening for cataracts in patients with AD may not be productive unless there is concern about potential side effects from steroid therapy.

Infections

AD can be complicated by recurrent viral skin infections that may reflect local defects in T-cell function. The most serious viral infection is herpes simplex (see Chap. 193), which can affect patients of all ages, resulting in Kaposi varicelliform eruption or eczema herpeticum. After an incubation period of 5 to 12 days, multiple, itchy, vesiculopustular lesions erupt in a disseminated pattern; vesicular lesions are umbilicated, tend to crop, and often become hemorrhagic and crusted (Fig. 14-10). Punched out and extremely painful erosions result. These lesions may coalesce to large, denuded, and bleeding areas that can extend over the entire body.

Although smallpox infections have been eradicated worldwide since the late 1970s, threats of bioterrorism (with smallpox and other infectious agents) have made nations reconsider their policies toward initiating vaccination programs. In AD patients, smallpox vaccination (or even exposure to vaccinated individuals) (see Chap. 195) may cause a severe widespread eruption (called *eczema vaccinatum*) that appears very similar to eczema herpeticum. Thus, in patients with AD, vaccination is contraindicated unless there is a clear risk of smallpox. In addition, decisions regarding vaccination of family members should take into consideration the potential of eczema vaccinatum in household contacts.

Superficial fungal infections are also more common in atopic individuals and may contribute to the exacerbation of AD. Patients with AD have an increased prevalence of *Trichophyton rubrum* infections compared to nonatopic controls. There has been particular interest in the role of *M. furfur* (*Pityrosporum ovale* or *P. orbiculare*) in AD. *M. furfur* is a lipophilic yeast (see Chap. 189) commonly present in the seborrheic areas of the skin. IgE antibodies against *M. furfur* are commonly found in AD patients and most frequently in patients with head and neck dermatitis. In contrast, IgE sensitization to *M. furfur* is rarely observed in normal controls or asthmatics. Positive allergen patch test reactions to this yeast have also been demonstrated. The potential importance of *M. furfur* as well as other dermatophyte infections is further supported by the reduction of AD skin severity in such patients after treatment with antifungal agents.

S. aureus is found in more than 90 percent of AD skin lesions. Honey-colored crusting, folliculitis, and pyoderma are indicators of secondary bacterial skin infection, usually due to *S. aureus,* that requires antibiotic therapy. Regional lymphadenopathy is common in such patients. The importance of *S. aureus* in AD is supported by the observation that patients with severe AD, even those without overt infection, can show clini-

▲ **FIGURE 14-10** Eczema herpeticum. Typical vesicles and crusting in a patient with disseminated disease.

cal response to combined treatment with antistaphylococcal antibiotics and topical glucocorticoids. Although recurrent staphylococcal pustulosis can be a significant problem in AD, deep-seated *S. aureus* infections occur rarely and should raise the possibility of an immunodeficiency syndrome such as hyper-IgE syndrome. Methicillin-resistant staphylococcus may be an important pathogen in some patients.

Hand Dermatitis

Patients with AD often develop nonspecific, irritant hand dermatitis. It is frequently aggravated by repeated wetting and by washing of the hands with harsh soaps, detergents, and disinfectants. Atopic individuals with occupations involving wet work are prone to develop an intractable hand dermatitis in the occupational setting. This is a common cause of occupational disability.

Exfoliative Dermatitis

Patients with extensive skin involvement may develop exfoliative dermatitis (see Chap. 23). This is associated with generalized redness, scaling, weeping, crusting, systemic toxicity, lymphadenopathy, and fever. Although this complication is rare, it is potentially life threatening. It is usually due to superinfection, for example, with toxin-producing *S. aureus* or herpes simplex infection, continued irritation of the skin, or inappropriate therapy. In some cases, the withdrawal of systemic glucocorticoids used to control severe AD may be a precipitating factor for exfoliative erythroderma.

PROGNOSIS AND CLINICAL COURSE

The natural history of AD is not completely known because studies have been flawed in terms of inadequate sample size, an unclear definition of remission, inadequate length of follow up, selection bias in the initial cohort, and excessive loss of patients to follow up. Nevertheless, although the outcome of AD may be difficult to predict in any given individual, the disease generally tends to be more severe and persistent in young children. Periods of remission appear more frequently as the patient grows older. Spontaneous resolution of AD has been reported to occur after age 5 years in 40 percent to 60 percent of patients affected during infancy, particularly if their disease is mild. Although earlier studies suggested that approximately 84 percent of children outgrow their AD by adolescence, more recent studies have reported that AD disappears in approximately 20 percent of children followed from infancy until adolescence, but becomes less severe in 65 percent. In addition, more than one-half of adolescents treated for mild dermatitis may experience a relapse of disease as adults.

Importantly for occupational counseling, adults whose childhood AD has been in remission for a number of years may present with hand dermatitis, especially if daily activities require repeated hand wetting. The following predictive factors correlate with a poor prognosis for AD: widespread AD in childhood, associated allergic rhinitis and asthma, family history of AD in parents or siblings, early age at onset of AD, being an only child, and very high serum IgE levels.

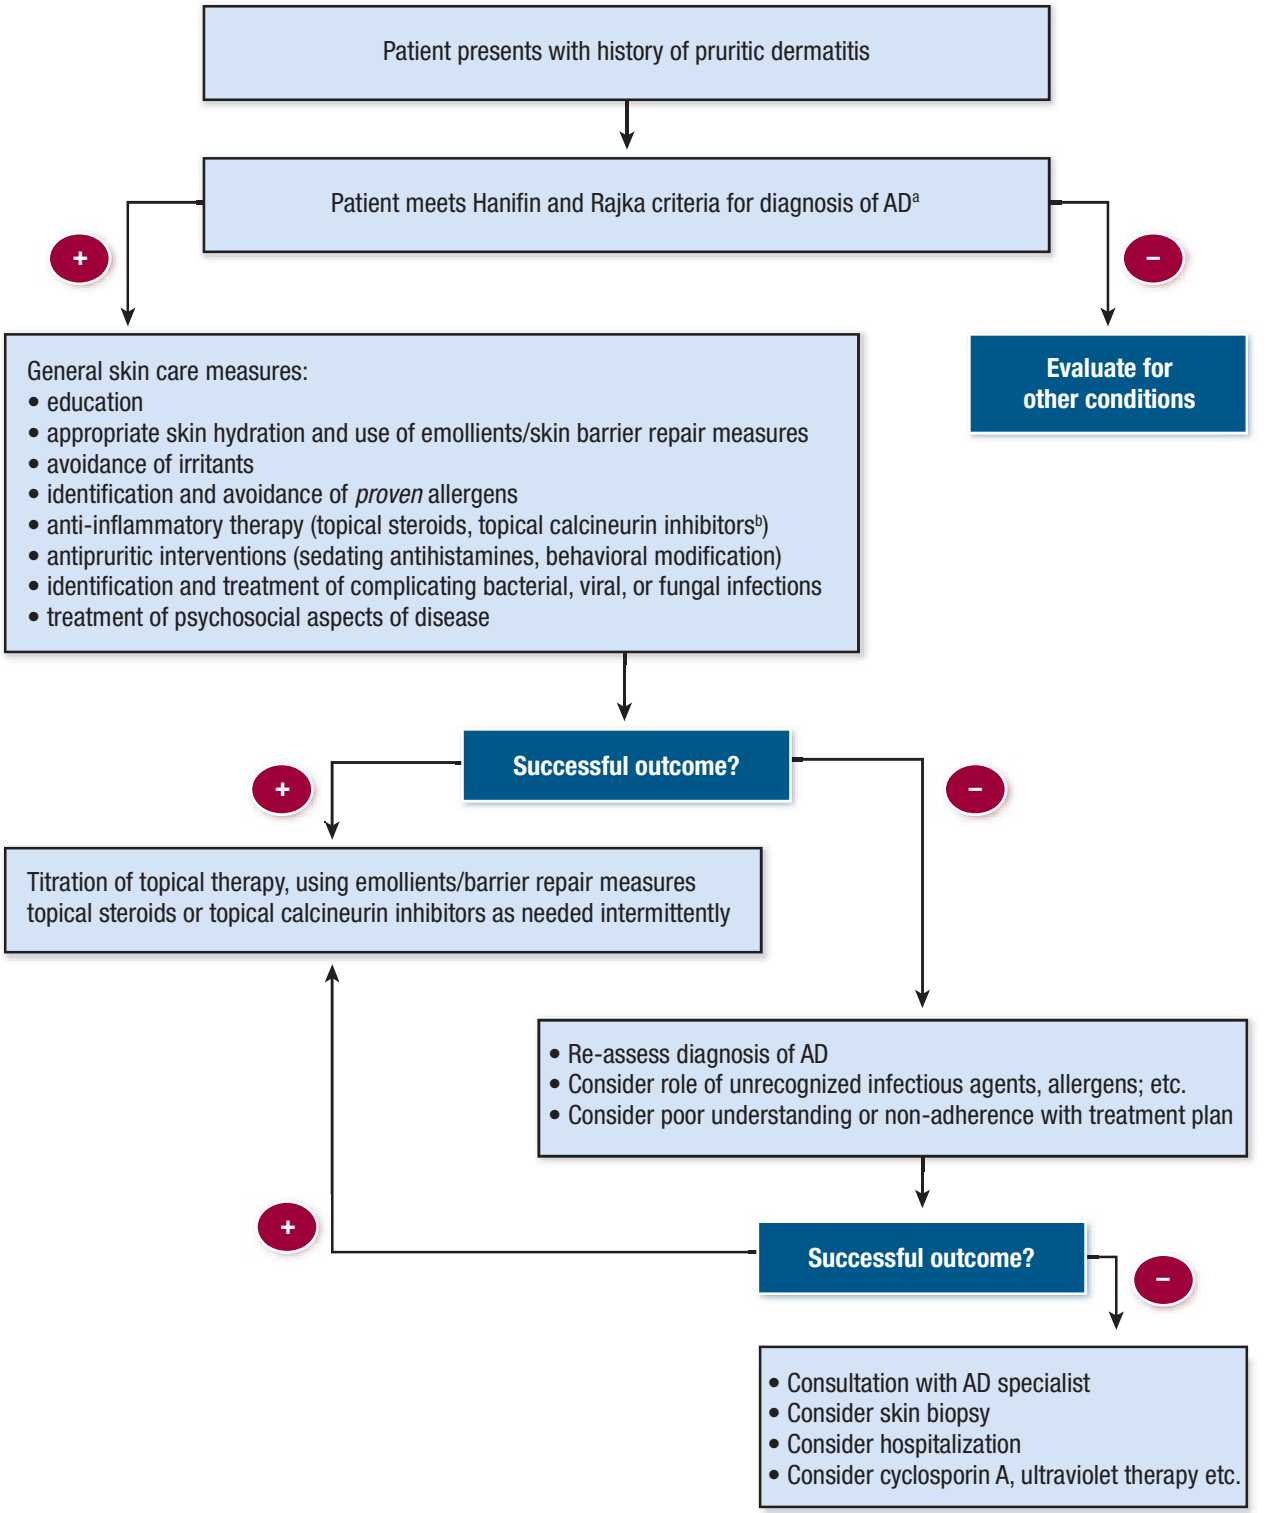
TREATMENT

Successful treatment of AD requires a systematic, multipronged approach that incorporates skin hydration, pharmacologic therapy, and the identification and elimination of flare factors such as irritants, allergens, infectious agents, and emotional stressors (Fig. 14-11).[44] Many factors lead to the symptom complex characterizing AD. Thus, treatment plans should be individualized to address each patient's skin disease reaction pattern, including the acuity of the rash, and the trigger factors that are unique to the particular patient. In patients refractory to conventional forms of therapy, alternative anti-inflammatory and immunomodulatory agents may be necessary.

Topical Therapy

CUTANEOUS HYDRATION Patients with AD have reduced skin barrier function and dry skin (xerosis) contributing to disease morbidity by the development of microfissures and cracks in the skin, which serve as portals of entry for skin pathogens, irritants, and allergens. This problem can become aggravated during the dry winter months and in certain work environments. Lukewarm soaking baths for at least 20 minutes followed by the application of an occlusive emollient to retain moisture can give such patients excellent symptomatic relief. Use of an effective emollient combined with hydration therapy helps to restore and preserve the stratum corneum barrier, and may decrease the need for topical glucocorticoids. Moisturizers are available in the form of lotions, creams, or ointments. Some lotions and creams may be irritating due to added preservatives, solubilizers, and fragrances. Lotions containing water may be drying due to an evaporative effect. Hydrophilic ointments can be obtained in varying degrees of viscosity according to the patient's preference. Occlusive ointments are sometimes not well tolerated because of interference with the function of the eccrine sweat ducts and the induction of folliculitis. In these patients, less occlusive agents should be used.

Topical therapy to replace abnormal epidermal lipids, improve skin hydration, and decrease skin barrier dysfunction may be useful therapeutically. Studies have shown benefits of topical preparations with distinct compositions of lipids and ceramides, as well as a nonsteroidal cream containing palmitamide MEA, an essential fatty acid, and



▲ **FIGURE 14-11** Approach to patient with atopic dermatitis (AD). [a]See Table 14-1. [b]Second-line therapy per black box warning.

a hydrolipidic cream with glycyrrhetinic acid (MAS063ADP).[45,46] Further clinical studies to define the benefits relative to traditional moisturizers and topical anti-inflammatory agents will be helpful.

Hydration, by baths or wet dressings, promotes transepidermal penetration of topical glucocorticoids. Dressings may also serve as an effective barrier against persistent scratching, allowing more rapid healing of excoriated lesions. Wet dressings are recommended for use on severely affected or chronically involved areas of dermatitis refractory to therapy. However, overuse of wet dressings may result in maceration of the skin complicated by secondary infection. Wet dressings or baths also have the potential to promote drying and fissuring of the skin if not followed by topical emollient use. Thus, wet dressing therapy is reserved for poorly controlled AD and should be closely monitored by a physician.

TOPICAL GLUCOCORTICOID THERAPY Topical glucocorticoids are the cornerstone of treatment for anti-inflammatory eczematous skin lesions. Because of potential side effects, most physicians use topical glucocorticoids only to control acute ex-

acerbations of AD. However, recent studies suggest that once control of AD is achieved with a daily regimen of topical glucocorticoid, long-term control can be maintained in a subset of patients with twice weekly applications of topical fluticasone to areas that have healed but are prone to developing eczema.[47]

Patients should be carefully instructed in the use of topical glucocorticoids to avoid potential side effects. The potent fluorinated glucocorticoids should be avoided on the face, the genitalia, and the intertriginous areas. A low-potency glucocorticoid preparation is generally recommended for these areas. Patients should be instructed to apply topical glucocorticoids to their skin lesions and to use emollients over uninvolved skin. Failure of a patient to respond to topical glucocorticoids is sometimes due in part to an inadequate supply. It is important to remember that it takes approximately 30 g of cream or ointment to cover the entire skin surface of an adult once. To treat the entire body twice daily for 2 weeks requires approximately 840 g (2 lb) of topical glucocorticoids.

There are seven classes of topical glucocorticoids, ranked according to their potency based on vasoconstrictor assays. Because of their potential side effects, the ultrahigh-potency glucocorticoids should be used only for very short periods of time and in areas that are lichenified but not on the face or intertriginous areas. The goal is to use emollients to enhance skin hydration and low-potency glucocorticoids for maintenance therapy. Midpotency glucocorticoids can be used for longer periods of time to treat chronic AD involving the trunk and extremities. Glucocorticoids in gels are often in a propylene glycol base and may be irritating to the skin in addition to promoting dryness, thus limiting their use to the scalp and beard areas.

Factors which influence topical glucocorticoid potency and side effects include the molecular structure of the compound, the vehicle, the amount of medication applied, the duration of application, occlusion, as well as host factors, including age, body surface area and weight, skin inflammation, anatomic location of treated skin, and individual differences in cutaneous or systemic metabolism. Side effects from topical glucocorticoids are directly related to the potency ranking of the compound and the length of use, so it is incumbent on the clinician to balance the need for a more potent steroid with the potential for side effects. In addition, ointments have a greater potential to occlude the epidermis, resulting in enhanced systemic absorption when compared to creams. Side effects from topical glucocorticoids can be divided into local side effects and systemic side effects resulting from suppression of the hypothalamic-pituitary-adrenal axis. Local side effects include the development of striae, skin atrophy, perioral dermatitis, and acne rosacea. The potential for potent topical glucocorticoid to cause adrenal suppression is greatest in infants and young children. Of note, a study of children as young as 3 months of age found that fluticasone propionate 0.05 percent cream, a midpotency formulation, was safe and effective even when applied on the face and over significant areas of the body for up to 1 month[48] and fluticasone 0.05 percent cream has been approved for use in children as young as 3 months for up to 4 weeks with fluticasone lotion approved for use in children 12 months and older. Mometasone cream and ointment are approved for children ages 2 years and older.

Because normal-appearing skin in AD shows evidence of immunologic dysregulation, the use of topical corticosteroids as maintenance therapy has been reported in several controlled studies.[49] Once control of AD with a once daily regimen was achieved, long-term control could be maintained with twice weekly application of fluticasone to previously involved areas.

TOPICAL CALCINEURIN INHIBITORS Topical tacrolimus and pimecrolimus have been developed as nonsteroidal immunomodulators.[50] Tacrolimus ointment 0.03 percent has been approved for intermittent treatment of moderate to severe AD in children aged 2 years and older, with tacrolimus ointment 0.1 percent approved for use in adults; whereas pimecrolimus cream 1 percent is approved for treatment of patients aged 2 years and older with mild-moderate AD. Both drugs have proven to be effective with a good safety profile for treatment up to 4 years with tacrolimus ointment[51] and up to 2 years with pimecrolimus cream.[52] A frequently observed side effect with topical calcineurin inhibitors is a transient burning sensation of the skin. Importantly, treatment with topical calcineurin inhibitors is not associated with skin atrophy,[53] thus they are particularly useful for the treatment of areas such as the face and intertriginous regions. Ongoing surveillance and recent reports have not shown a trend for increased frequency of viral superinfections especially eczema herpeticum.[54] The long-term safety of topical calcineurin inhibitors has not been established. Rare cases of skin malignancy and lymphoma have been reported with topical tacrolimus, though the level of data quality and applicability of these reports was judged low in the report of a scientific consensus conference.[55]

Identification and Elimination of Triggering Factors

GENERAL CONSIDERATIONS Patients with AD are more susceptible to irritants than are unaffected individuals. Thus, it is important to identify and eliminate aggravating factors that trigger the itch-scratch cycle. These include soaps or detergents, contact with chemicals, smoke, abrasive clothing, and exposure to extremes of temperature and humidity. Alcohol and astringents found in toiletries are drying. When soaps are used, they should have minimal defatting activity and a neutral pH. New clothing may be laundered before wearing to decrease levels of formaldehyde and other added chemicals. Residual laundry detergent in clothing may be irritating. Using a liquid rather than powder detergent and adding a second rinse cycle facilitates removal of the detergent.

Recommendations regarding environmental living conditions should include temperature and humidity control to avoid problems related to heat, humidity, and perspiration. Every attempt should be made to allow children to be as normally active as possible. Certain sports, such as swimming, may be better tolerated than other sports involving intense perspiration, physical contact, or heavy clothing and equipment, but chlorine should be rinsed off immediately after swimming and the skin lubricated. Although ultraviolet (UV) light may be beneficial to some patients with AD, sunscreens should be used to avoid sunburn. However, because sunscreens can be irritants, care should be used to identify a nonirritating product.

SPECIFIC ALLERGENS Foods and aeroallergens such as dust mites, animal danders, molds, and pollens have been demonstrated to exacerbate AD. Potential allergens can be identified by taking a careful history and carrying out selective skin-prick tests or specific serum IgE levels. Negative skin tests or serum tests for allergen-specific IgE have a high predictive value for ruling out suspected allergens. A normal total serum IgE

level, however, does not rule out the possibility of allergen-specific IgE being present. Positive skin or in vitro tests, particularly to foods, often do not correlate with clinical symptoms and should be confirmed with controlled food challenges and elimination diets. Avoidance of foods implicated in controlled challenges results in clinical improvement. Extensive elimination diets, which in some cases can be nutritionally deficient, are rarely, if ever, required, because even with multiple positive skin tests, the majority of patients react to three or fewer foods on controlled challenge. In dust mite–allergic patients with AD, prolonged avoidance of dust mites has been found to result in improvement of their skin disease. Avoidance measures include use of dust mite–proof encasings on pillows, mattresses, and box springs; washing bedding in hot water weekly; removal of bedroom carpeting; and decreasing indoor humidity levels with air conditioning. Because there are many triggers contributing to the flares of AD, attention should be focused on identifying and controlling the flare factors that are important to the individual patient. Infants and young children are more likely to have food allergies, whereas older children and adults are more likely to be sensitive to environmental aeroallergens.

EMOTIONAL STRESSORS Although emotional stress does not cause AD, it often exacerbates the illness. AD patients often respond to frustration, embarrassment, or other stressful events with increased pruritus and scratching. In some instances, scratching is simply habitual and less commonly associated with significant secondary gain. Psychological evaluation or counseling should be considered in patients who have difficulty with emotional triggers or psychological problems, contributing to difficulty in managing their disease. It may be especially useful in adolescents and young adults who consider their skin disease disfiguring. Relaxation, behavioral modification, or biofeedback may be helpful in patients with habitual scratching.

INFECTIOUS AGENTS Anti-staphylococcal antibiotics are very helpful in the treatment of patients who are heavily colonized or infected with *S. aureus*.[56] Cephalosporins or penicillinase-resistant penicillins (dicloxacillin, oxacillin, or cloxacillin) are usually beneficial for patients who are not colonized with resistant *S. aureus* strains. Because erythromycin-resistant staphylococci are common, erythromycin and newer macrolide antibiotics are usually of limited utility. Topical mupirocin offers some utility in the treatment of impetiginized lesions; however, in patients with extensive superinfection, a course of systemic antibiotics is most practical. Methicillin-resistant staphylococci may require culture and sensitivity testing to assist in appropriate antibiotic selection.

Herpes simplex can provoke recurrent dermatitis and may be misdiagnosed as *S. aureus* infection. The presence of punched-out erosions, vesicles, and/or infected skin lesions that do not respond to oral antibiotics should initiate a search for herpes simplex. This can be diagnosed by a Giemsa-stained Tzanck smear of cells scraped from the vesicle base, direct immunofluorescence assay, polymerase chain reaction identification of herpes genetic material, or by viral culture. For infection suspected to be caused by herpes simplex, topical anti-inflammatory agents might be discontinued, at least temporarily. Antiviral treatment for cutaneous herpes simplex infections is of critical importance in the patient with widespread AD because life-threatening dissemination has been reported. Acyclovir, 400 mg three times daily for 10 days or 200 mg four times daily for 10 days by oral administration (or an equivalent dosage of one of the newer antiherpetic medications), is useful in adults with herpes simplex confined to the skin. Intravenous treatment may be necessary for severe disseminated eczema herpeticum. The dosage should be adjusted according to weight in children.

Dermatophyte infections can complicate AD and may contribute to exacerbation of disease activity. Patients with dermatophyte infection or IgE antibodies to *Malassezia* may benefit from a trial of topical or systemic antifungal therapy.

PRURITUS The treatment of pruritus in AD should be directed primarily at the underlying causes. Reduction of skin inflammation and dryness with topical glucocorticoids and skin hydration, respectively, often symptomatically reduce pruritus. Inhaled and ingested allergens should be eliminated if documented to cause skin rash in controlled challenges. Systemic antihistamines act primarily by blocking the H_1 receptors in the dermis, thereby ameliorating histamine-induced pruritus. However, histamine is only one of many mediators that can induce pruritus of the skin. Therefore, certain patients may derive minimal benefit from antihistaminic therapy. Some antihistamines are also mild anxiolytics and may offer symptomatic relief through tranquilizing and sedative effects. Studies of newer, non-sedating antihistamines show variable results in the effectiveness of controlling pruritus in AD, although they may be useful in the subset of AD patients with concomitant urticaria or concurrent allergic rhinitis.

Because pruritus is usually worse at night, the sedating antihistamines, for example, hydroxyzine or diphenhydramine, may offer an advantage with their soporific side effects when used at bedtime. Doxepin hydrochloride has both tricyclic antidepressant and H_1- and H_2-histamine receptor–blocking effects. It can be used in doses of 10 to 75 mg orally at night or up to 75 mg bid in adult patients. If nocturnal pruritus remains severe, short-term use of a sedative to allow adequate rest may be appropriate. Treatment of AD with topical antihistamines is generally not recommended because of potential cutaneous sensitization. However, short-term (1 week) application of topical 5 percent doxepin cream has been reported to reduce pruritus without sensitization. Of note, sedation is a side effect of widespread application of doxepin cream, and allergic contact dermatitis has been reported.

Tar Preparations

Coal tar preparations may have antipruritic and anti-inflammatory effects on the skin although usually not as pronounced as those of topical glucocorticoids.[57] Tar preparations may be useful in reducing the potency of topical glucocorticoids required in chronic maintenance therapy of AD. Newer coal tar products have been developed that are more acceptable with respect to odor and staining of clothes than some older products. Tar shampoos can be beneficial for scalp dermatitis and are often helpful in reducing the concentration and frequency of topical glucocorticoid applications. Tar preparations should not be used on acutely inflamed skin, because this often results in skin irritation. Side effects associated with tars include folliculitis and photosensitivity. There is a theoretic risk of tar being a carcinogen based on observational studies of workers using tar components in their occupations.

Phototherapy

Natural sunlight is frequently beneficial to patients with AD. However, if the

sunlight occurs in the setting of high heat or humidity, thereby triggering sweating and pruritus, it may be deleterious to patients. Broadband UVB, broadband UVA, narrowband UVB (311 nm), UVA-1 (340 to 400 nm), and combined UVA-B phototherapy can be useful adjuncts in the treatment of AD. Investigation of the photoimmunologic mechanisms responsible for therapeutic effectiveness indicates that epidermal LCs and eosinophils may be targets of UVA phototherapy with and without psoralen, whereas UVB exerts immunosuppressive effects via blocking of function of antigen-presenting LCs and altered keratinocyte cytokine production. Photochemotherapy with psoralen and UVA light may be indicated in patients with severe, widespread AD, although studies comparing it with other modes of phototherapy are limited. Short-term adverse effects with phototherapy may include erythema, skin pain, pruritus, and pigmentation. Long-term adverse effects include premature skin aging and cutaneous malignancies (see Chaps. 238 and 239 for detailed discussion of phototherapy and photochemotherapy).

Hospitalization

AD patients who appear erythrodermic or who have widespread severe skin disease resistant to outpatient therapy should be hospitalized before considering systemic alternative therapies (see Systemic Therapy). In many cases, removing the patient from environmental allergens or emotional stresses, intense patient education, and assurance of compliance with therapy results in a sustained improvement in their AD. Clearing of the patient's skin during hospitalization also allows the patient to undergo allergen skin testing and appropriately controlled provocative challenges to correctly identify or rule out potential allergens.

Systemic Therapy

SYSTEMIC GLUCOCORTICOIDS The use of systemic glucocorticoids, such as oral prednisone, is rarely indicated in the treatment of chronic AD. Some patients and physicians prefer the use of systemic glucocorticoids to avoid the time-consuming skin care involving hydration and topical therapy. However, the dramatic clinical improvement that may occur with systemic glucocorticoids is frequently associated with a severe rebound flare of AD after the discontinuation of systemic glucocorticoids. Short courses of oral glucocorticoids may be appropriate for an acute exacerbation of AD whereas other treatment measures are being instituted. If a short course of oral glucocorticoids is given, it is important to taper the dosage and to begin intensified skin care, particularly with topical glucocorticoids and frequent bathing followed by application of emollients, to prevent rebound flaring of AD.

CYCLOSPORINE Cyclosporine is a potent immunosuppressive drug that acts primarily on T cells by suppressing cytokine transcription. The drug binds to cyclophilin, an intracellular protein, and this complex, in turn, inhibits calcineurin, a molecule required for initiation of cytokine gene transcription. Multiple studies demonstrate that both children and adults with severe AD, refractory to conventional treatment, can benefit from short-term cyclosporine treatment. Various oral-dosing regimens have been recommended: 5 mg/kg has generally been used with success in short-term and long-term (1 year) use, whereas some authorities advocate body-weight–independent daily dosing of adults with 150 mg (low dose) or 300 mg (high dose) daily of cyclosporine microemulsion. Treatment with cyclosporine is associated with reduced skin disease and an improved quality of life (see Chap. 234 for further discussion). Discontinuation of treatment may result in rapid relapse of skin disease, although some patients may have sustained remission. Elevated serum creatinine or more significant renal impairment and hypertension are specific side effects of concern with cyclosporine use.

ANTIMETABOLITES Mycophenolate mofetil is a purine biosynthesis inhibitor used as an immunosuppressant in organ transplantation, that has been used for treatment of refractory inflammatory skin disorders (see Chap. 228). Open-label studies report that short-term oral mycophenolate mofetil, 2 g daily, as monotherapy results in clearing of skin lesions in adults with AD resistant to other treatment, including topical and oral steroids and psoralen and UVA light. The drug has generally been well tolerated with the exception of one patient developing herpes retinitis that may have been secondary to this immunosuppressive agent. Dose-related bone marrow suppression has also been observed. Similar results were previously reported in another open study of ten patients with a mean reduction in the SCORAD (SCORing Atopic Dermatitis) index of 68 percent in all ten patients. Of note, not all patients benefit from treatment. Therefore the medication should be discontinued if patients do not respond within four to eight weeks. Dose finding and well-controlled studies are needed for this drug.

Methotrexate is an antimetabolite with potent inhibitory effects on inflammatory cytokine synthesis and cell chemotaxis. Methotrexate has been used for AD patients with recalcitrant disease, although controlled trials are lacking. Dosing is more frequent than the weekly dosing used for psoriasis. Azathioprine is a purine analog with anti-inflammatory and antiproliferative effects; azathioprine has been used for severe AD, although no controlled trials have been reported. Myelosuppression is a significant adverse effect, and thiopurinemethyl transferase levels may predict individuals at risk.

Unproven Therapies

INTERFERON-γ IFN-γ is known to suppress IgE responses and downregulate Th2 cell proliferation and function. Several studies of patients with AD, including a multicenter, double-blind, placebo-controlled trial[58] and two long-term open trials,[59,60] have demonstrated that treatment with recombinant human IFN-γ results in clinical improvement. Reduction in clinical severity of AD correlated with the ability of IFN-γ to decrease total circulating eosinophil counts. Influenza-like symptoms are commonly observed side effects early in the treatment course.

OMALIZUMAB Treatment of patients with severe AD and elevated serum IgE levels with monoclonal anti-IgE has shown lack of efficacy in three adult patients[61] and significant improvement in three adolescent patients.[62]

ALLERGEN IMMUNOTHERAPY Unlike allergic rhinitis and extrinsic asthma, immunotherapy with aeroallergens has not proven to be efficacious in the treatment of AD. There are anecdotal reports of both disease exacerbation and improvement. A recent study of specific immunotherapy over 12 months in adults with AD sensitized to dust mite allergen showed improvement in SCORAD as well as reduction in topical steroid use.[63] However, well-controlled studies are still required to determine the role for immunotherapy with this disease.

EXTRACORPOREAL PHOTOPHERESIS Extracorporeal photopheresis consists of the passage of psoralen-treated leukocytes through an extracorporeal UVA light system. Clinical improvement in skin lesions associated with reduced IgE levels has been reported in a few patients with severe, resistant AD who were treated with extracorporeal photopheresis and topical glucocorticoids.

PROBIOTICS Perinatal administration of the probiotic *Lactobacillus rhamnosus* strain GG was shown to reduce the incidence of AD in at-risk children during the first 2 years of life.[64] Mothers were given either placebo or lactobacillus GG daily for 4 weeks before delivery and then either the mother (if breast feeding) or the infant continued with daily therapy for 6 months. In a follow-up study, the same group assessed the persistence of potential to prevent AD at 4 years.[65] The results suggest that the preventive effect of *Lactobacillus* GG on AD could extend beyond infancy. In a second study, children with AD treated with two *Lactobacillus* strains for 6 weeks experienced improvement of their eczema compared to placebo treated patients, although their SCORAD index did not change significantly.[66] The treatment response was found to be more pronounced in patients with positive skin-prick tests and elevated IgE levels. Another study of children with moderate to severe AD treated for 8 weeks with *L. fermentum* in a placebo-controlled study showed persistent improvement in SCORAD at 16 weeks.[67] These studies suggest that probiotics, or at least some lactobacillus strains, may have preventative, lasting effects on the incidence of AD in a subset of patients. More research into subgroups of responders, optimal therapy [route (i.e., directly to infant or via mother's milk); length of treatment; strain of lactobacillus], as well as mechanisms involved is clearly needed.[68]

CHINESE HERBAL MEDICATIONS Several placebo-controlled clinical trials have suggested that patients with severe AD may benefit from treatment with traditional Chinese herbal therapy (see Chap. 242). They had significantly reduced skin disease and decreased pruritus. The beneficial response of Chinese herbal therapy, however, is often temporary, and effectiveness may wear off despite continued treatment. The possibility of hepatic toxicity, cardiac side effects, or idiosyncratic reactions remains a concern. The specific ingredients of the herbs also remain to be elucidated and some preparations have been found to be contaminated with corticosteroids. At present, Chinese herbal therapy for AD is considered investigational.

CHAPTER 15

Nummular Eczema and Lichen Simplex Chronicus/Prurigo Nodularis

Susan Burgin

NUMMULAR ECZEMA

Epidemiology

Nummular eczema (also nummular dermatitis) is predominantly a disease of adulthood. Men are more frequently affected than women. The peak incidence in both males and females is around 50 to 65 years of age. There is a second peak in women around 15 to 25 years of age. Nummular eczema is rare in infancy and childhood. The peak age of onset in childhood is 5 years.[1]

Etiology and Pathogenesis

The pathogenesis of nummular eczema is unknown. The vast majority of patients with nummular eczema do not have a personal or family history of atopy,[2,3] although nummular plaques may be seen in atopic eczema. Numerous factors have been implicated as causal. The state of hydration of the skin in elderly patients has been shown to be decreased.[4] The role of infection previously received much attention in the literature. An internal focus of infection, including teeth, upper respiratory tract, and lower respiratory tract, was found in 68 percent of patients in one study.[5] A role for environmental allergens, such as the house dust mite and *Candida albicans* has also been touted.[4] Nummular eczema has been reported during therapy with isotretinoin and gold.[6,7] Generalized nummular eczema is seen in patients with hepatitis C undergoing combination therapy with interferon-α 2b and ribavirin.[8,9] Mercury amalgam was implicated as a cause in two patients.[10]

NUMMULAR ECZEMA

AT A GLANCE

- Also known as *discoid eczema.*
- A chronic disorder of unknown etiology.
- Papules and papulovesicles coalesce to form nummular plaques with oozing, crust, and scale.
- Most common sites of involvement are upper extremities, including the dorsal hands in women, and the lower extremities in men.
- Pathology may show acute, subacute, or chronic eczema.

Clinical Findings

Well-demarcated, coin-shaped plaques form from coalescing papules and papulovesicles. Pinpoint oozing and crusting eventuate and are distinctive (Fig. 15-1). Crust may however cover the entire surface (Fig. 15-2). Plaques range from 1 to 3 cm in size. The surrounding skin is generally normal, but may be xerotic. Pruritus varies from minimal to severe. Central resolution may occur, leading to annular forms. Chronic plaques are dry, scaly, and lichenified. The classic distribution of lesions is the extensor aspects of the extremities. In women, the upper extremities, including the dorsal aspects of the hands, are more frequently affected than the lower extremities.[2] Exudative discoid and lichenoid dermatitis of Sulzberger-Garbe may represent a variant of nummular eczema.[11]

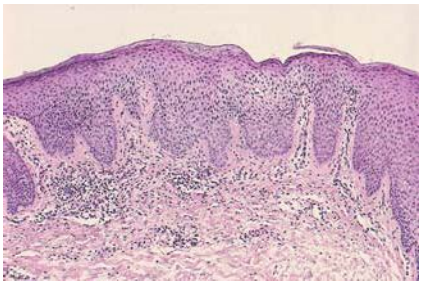
▲ **FIGURE 15-2** Nummular eczema in a child. Crusted plaques. (Used with permission from P. Lio, M.D., Beth Israel Deaconess Medical Center, Boston, Massachusetts.)

Laboratory Tests

Patch testing may be useful in chronic recalcitrant cases to rule out a superimposed contact dermatitis. In a series from India, just under one-half of 50 patients had positive patch tests to colophony, nitrofurazone, neomycin sulfate, and nickel sulfate.[12] Serum immunoglobulin E levels are normal.

Special Tests

Histopathologic changes are reflective of the stage at which the biopsy is performed. Acutely, there is spongiosis, with or without spongiotic microvesicles. In subacute plaques, there is parakeratosis, scale-crust, epidermal hyperplasia, and spongiosis of the epidermis (Fig. 15-3). There is a mixed cell infiltrate in the dermis. Chronic lesions may resemble lichen simplex chronicus microscopically.



▲ **FIGURE 15-3** Histopathology of nummular eczema. Parakeratosis containing plasma and neutrophils (scale-crust) and psoriasiform epidermal hyperplasia with spongiosis are present, with a superficial dermal perivascular infiltrate of lymphocytes, macrophages, and eosinophils.

Differential Diagnosis

See Box 15-1.

Complications

Nummular eczema may be complicated by secondary bacterial infection.

Prognosis and Clinical Course

The course is usually chronic. Recurrence at prior sites of involvement is a feature of the disease.[5]

Treatment

Topical steroids in the mid- to high-potency range are the mainstay of treatment. The calcineurin inhibitors, tac-

Differential Diagnosis of Nummular Eczema

Most Likely

- Allergic contact dermatitis
- Stasis dermatitis
- Atopic dermatitis
- Tinea corporis

Consider

- Impetigo
- Psoriasis (long-standing plaques)
- Mycosis fungoides (long-standing plaques)
- Paget disease, when there is unilateral involvement of nipple/areola
- Other nummular dermatoses
  - Fixed drug eruption
  - Pityriasis rotunda

Always Rule Out

- Tinea corporis

rolimus and pimecrolimus, and tar preparations are also effective. Emollients can be added adjunctively if there is accompanying xerosis. Oral antihistamines are useful if pruritus is severe. Oral antibiotics are indicated when secondary infection is present. For widespread involvement, phototherapy with broad or narrow band ultraviolet B may be beneficial.

LICHEN SIMPLEX CHRONICUS AND PRURIGO NODULARIS

Epidemiology

Lichen simplex chronicus affects adults, predominantly from ages 30 to 50 years. Females are affected more commonly than males. Prurigo nodularis may occur at any age, but most patients are between 20 and 60 years old.[13] Men and women are equally affected. Patients with co-existent atopic dermatitis have been found to have an earlier age of onset (mean: 19 years) as compared to the non-atopic group (mean: 48 years).[14]

Etiology and Pathogenesis

Lichen simplex chronicus is induced by rubbing and scratching secondary to itch. The prurigo nodule is induced by picking and scratching most commonly, but not always, in response to itch. Various factors incite itch in both disorders, and not all are well understood. A variable association between lichen simplex chronicus and atopic disorders has been reported, ranging from approximately 26 percent to 75 percent.[15,16] Similarly, a subset of patients with prurigo nodularis has coexistent atopic eczema. Here, prurigo nodules occur in concert with subacute prurigo, lichenification, and xerosis. "Besnier prurigo" refers to the pruriginous nodules seen in atopic dermatitis. In the non-atopic nodular prurigo group, systemic causes of pruritus, including renal insufficiency, hyper- or hypothyroidism, liver failure, human immunodeficiency virus disease, parasitic infection, or an underlying malignancy, must be excluded. Hepatitis B and C have been reported as associations without liver failure.[17] Prurigo nodularis has also been reported to occur in the setting of celiac disease in the presence or absence of dermatitis herpetiformis.[18,19]

Environmental factors have been implicated in inducing itch, such as heat, sweat, and irritation associated with anogenital lichen simplex chronicus.[16] The presence of emotional or psychological factors in patients with prurigo nodularis and lichen simplex chronicus has been alluded to in the literature. One study of prurigo nodularis patients found that approximately one-half of 46 patients had a history of depression, anxiety, or other treatable psychological disorders.[20] Lichen simplex chronicus patients also had higher depression scores in one study.[21] Whether these emotional factors are secondary to the primary dermatologic disease, or whether they are primary and causative (altering perception of itch) is unclear. It has been postulated that neurotransmitters that affect mood, such as dopamine, serotonin, or opioid peptides, modulate perception of itch via descending spinal pathways.[13] Obsessive-compulsive disorder has also been associated with picking in these disorders.[22]

At a microscopic level, increased numbers of Merkel cells are also seen adjacent to the dermal nerve fibers and mast cells in prurigo nodularis. It is thought that this complex may mediate the abnormally heightened perception of touch and itch in these patients. Nerve growth factor is overexpressed in prurigo nodularis lesions and it has been implicated in the pathogenesis of the characteristic cutaneous neural hyperplasia seen.[23] Nerve growth factor is produced and released by mast cells, which are increased in number and size on histologic sections. It upregulates the expression of neuropeptides, such as calcitonin gene–related peptide and substance P. These are thought to mediate inflammation and itch.[17]

Clinical Findings

HISTORY Severe itching is the hallmark of lichen simplex chronicus. Itching may be paroxysmal, continuous, or sporadic. Rubbing and scratching may be conscious and to the point of replacing the sensation of itch with pain, or may be unconscious, occurring during sleep. Itch severity is worse with sweating, heat, or irritation from clothing. Itching is also worse in times of psychological distress.[16]

CUTANEOUS LESIONS In lichen simplex chronicus, repeated rubbing and scratching gives rise to a lichenified (thickened skin with accentuated skin markings), scaly plaque with excoriations. Hyper- and hypopigmentation are seen with chronicity. Usually, only one plaque is present; however, more than one site may be involved. The most common sites of involvement are the scalp, the nape of the neck (especially in women), the ankles, the extensor aspects of the extremities, and the anogenital region.[24] The labia majora in women and the scrotum in men (Fig. 15-4) are the most common sites of genital involvement.[16] The upper inner thighs may also be affected.

Prurigo nodules vary in size from 0.5 to 3.0 cm and are firm to hard on palpation. The surface may be hyperkeratotic or crateriform. There is often overlying

LICHEN SIMPLEX CHRONICUS AND PRURIGO NODULARIS AT A GLANCE

Lichen Simplex Chronicus

- Also known as *neurodermatitis circumscripta* or *circumscribed neurodermatitis*.
- A chronic, severely pruritic disorder characterized by one or more lichenified plaques in which the skin is thickened and there are accentuated skin markings.
- Most common sites of involvement are scalp, nape of neck, extensor aspects of extremities, ankles, and anogenital area.
- Pathology consists of hyperkeratosis, hypergranulosis, psoriasiform epidermal hyperplasia, and thickened papillary dermal collagen.

Prurigo Nodularis

- Described by Hyde in 1909; also known as *nodular prurigo*.
- A pruritic disorder that runs a chronic course.
- Hyperkeratotic, firm nodules vary in size from 0.5 to 3.0 cm and may be excoriated.
- Associations include atopic dermatitis or systemic causes of pruritus.
- Pathology consists of hyperkeratosis, hypergranulosis, and psoriasiform epidermal hyperplasia. Dermal changes include thickened papillary dermal collagen and characteristic neural hyperplasia.

▲ **FIGURE 15-4** Lichen simplex chronicus of the scrotum: lichenification, hyper- and hypopigmentation with excoriation. (Image from Division of Dermatology, University of the Witwatersrand, Johannesburg, South Africa, with permission from Professor D. Modi.)

excoriation. Pruritus is usually severe. Limbs are affected in most cases, especially the extensor aspects (Fig. 15-5). The abdomen and sacrum were the next most common sites of involvement in one study.[20] Face and palms are rarely involved; however, nodules may occur on any site that can be reached by the patient. Lesions may vary in number from few to more than 100. Nodules resolve with post-inflammatory hyper- or hypopigmentation with or without scarring.

▲ **FIGURE 15-5** Prurigo nodularis. (Used with permission from Professor D. Modi, Division of Dermatology, University of the Witwatersrand, Johannesburg, South Africa.)

RELATED PHYSICAL FINDINGS In patients with atopic eczema, the intervening skin is often lichenified and xerotic. In non-atopic patients, cutaneous signs of underlying systemic disease or lymphadenopathy, signifying lymphoma, may be present.

Laboratory Tests

In patients with prurigo nodularis in whom an underlying systemic cause of pruritus is suspected, a complete blood count with differential count, renal, liver, and thyroid function tests may be ordered. A chest x-ray may be obtained to screen for lymphoma. Human immunodeficiency virus testing may also be indicated. The need for a more extensive evaluation may be individualized based on patient history and results of the aforementioned tests.

Special Tests

On histopathologic sections, lichen simplex chronicus shows varying degrees of hyperkeratosis with para- and orthokeratosis, hypergranulosis, and psoriasiform epidermal hyperplasia. The papillary dermis shows thickening of collagen with coarse collagen bundles and vertical streaks. There is a variable inflammatory infiltrate around the superficial vascular plexus with lymphocytes, histiocytes, and eosinophils. A biopsy may also reveal a primary pruritic disorder that has led to secondary lichenification, such as psoriasis.

The epidermal findings in prurigo nodularis are similar to lichen simplex chronicus. The lesion is more papular with bulbous epidermal hyperplasia. Papillary dermal changes also resemble lichen simplex chronicus. There is cutaneous neural hyperplasia with thickened nerve bundles and an increase in nerve fibers by S-100 staining. This is not seen in other pruritic disorders, including lichen simplex chronicus.

Differential Diagnosis

See Boxes 15-2 and 15-3.

Complications

Sleep studies have shown that disturbances in the sleep cycle in patients with lichen simplex chronicus are present. Non–rapid eye movement sleep is disturbed, and patients have an increased arousal index (brief awakenings from sleep) caused by scratching.[25]

Box 15-2

Differential Diagnosis of Lichen Simplex Chronicus

Most Likely
- Lichenified atopic eczema
- Lichenified psoriasis
- Hypertrophic lichen planus

Consider
- Genital: Extramammary Paget disease

Always Rule Out
- Vulva, perianally: Underlying lichen sclerosus, HPV, or tinea cruris
- Scrotum: Underlying HPV or tinea cruris

HPV = human papillomavirus.

Prognosis and Clinical Course

Both diseases run a chronic course with persistence or recurrence of lesions. Exacerbations may occur in response to emotional stress.

Treatment

Treatment is aimed at interrupting the itch-scratch cycle. Both components should be addressed. Systemic causes of itch should be identified and addressed. In both conditions, first-line measures to control itch include potent topical steroids, best under occlusion, as well as nonsteroidal antipruritic preparations such as menthol, phenol, or pramoxine. Emollients are an important adjunct. Intralesional steroids, such as triamcinolone acetonide, given in varying concentrations according to the thickness of the plaque or nodule, are beneficial. Sedating antihistamines, such as hydroxyzine, or tricyclic antidepressants, such as doxepin, may be used to abolish nighttime itch in both conditions. Selective serotonin reuptake inhibitors have

Box 15-3

- Perforating disease
- Hypertrophic lichen planus
- Pemphigoid nodularis
- Actinic prurigo
- Multiple keratoacanthomas

Consider
- Nodular scabies
- Dermatitis herpetiformis

been recommended for relief of daytime pruritus or in patients with obsessive-compulsive disorder.[16]

Capsaicin, calcipotriene, topical tacrolimus, and cryotherapy, with or without intralesional steroid injections, have all been successfully used in prurigo nodularis. Both broad- and narrowband ultraviolet B, as well as topical or oral psoralen and ultraviolet A light, show efficacy and are indicated in widespread cases. Thalidomide and cyclosporine have also been shown to be beneficial. Naltrexone has shown efficacy in a small series.[26]

The importance of avoiding scratching should be addressed with the patient. Nails should be kept short and occlusive measures, such as plastic films, topical steroid tape, or Unna boots in widespread cases, may be needed.

CHAPTER 16

Vesicular Palmoplantar Eczema

Daven N. Doshi
Alexa B. Kimball

Vesicular palmoplantar eczema is a dermatitis of the hands and feet characterized by small to large blisters clinically and spongiotic vesicles histologically. It can manifest as either an acute or a chronic dermatitis, or both. Because clinical and histologic presentations of the variants of hand dermatitis, including vesicular palmoplantar eczema, often overlap, rendering the formulation of precise diagnostic categories can be difficult. For example, patients with pompholyx, the most acute form of vesicular palmoplantar eczema, have been noted to have higher incidence rates of both atopy and contact dermatitis than controls.

With the preceding caveat in mind, vesicular palmoplantar eczema can be divided into four categories: pompholyx, chronic vesiculobullous hand dermatitis, hyperkeratotic hand dermatitis, and id reactions. These conditions can be grouped under the category of endogenous hand dermatitis, in contrast to dermatitis clearly caused by exogenous factors such as contact allergy or irritation.

Pompholyx is a term best reserved for acute explosive outbreaks of small to large vesicles and bullae on the palms and soles. It tends to occur more often in the spring and fall, and may be associated with stress. Other etiologic factors are less well established. *Cheiropompholyx* and *podopompholyx* are terms occasionally used to describe cases affecting the palms or soles, respectively.

Chronic vesiculobullous hand dermatitis, also known as *dyshidrotic hand eczema* or *dyshidrotic hand dermatitis*, is usually characterized by small vesicles on the lateral aspects of the fingers. "Dyshidrosis," a dysfunction of the sweat gland, was long postulated to be a cause, but its role has been subsequently disproved. However, the terminology persists and is commonly used.

A third category is chronic hyperkeratotic hand dermatitis, an entity that generally occurs on the central palms. Unlike the other classifications of vesicular palmoplantar eczema, vesicles do not dominate the clinical presentation. However, the spongiosis observed histologically is indistinguishable from the other categories.

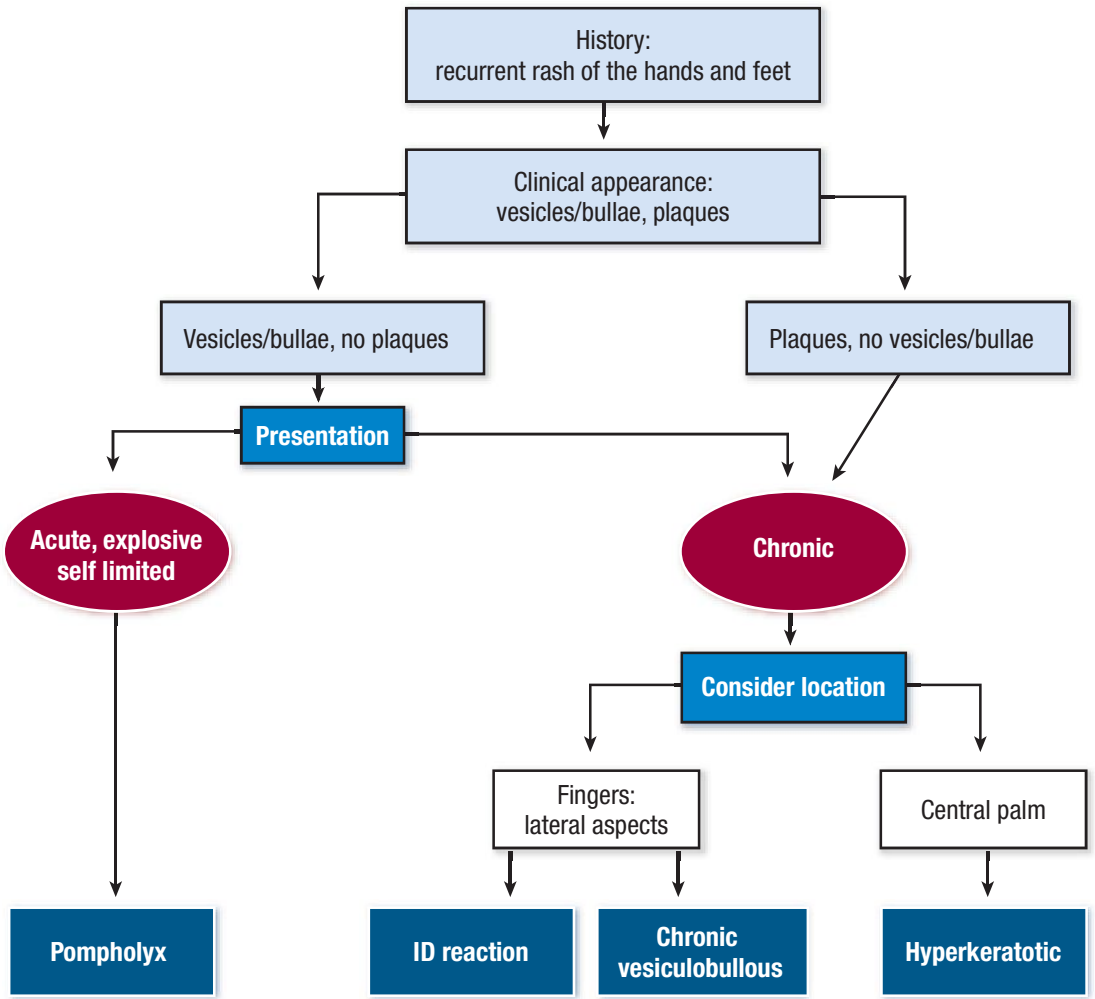
An id reaction is a vesiculobullous dermatitis, generally appearing on the lateral aspects of the fingers, elicited by an infection elsewhere in the body. The most common cause is a fungal infection. Treatment of the underlying causative factor usually leads to resolution. Endogenous hand dermatitis can, of course, be exacerbated by exogenous factors, most notably irritant dermatitis and allergic contact dermatitis. In addition, atopy may in some cases predispose to the development of vesicular palmoplantar eczema.

VESICULAR PALMOPLANTAR ECZEMA AT A GLANCE

- An acute and/or chronic dermatitis clinically characterized by small to large blisters on the palms and soles.
- Histopathology characterized by spongiotic vesicles.
- Considered an endogenous dermatitis, distinct from dermatitis caused by exogenous factors such as contact, allergy, or irritation.
- Can be divided into four categories: pompholyx, chronic vesiculobullous hand dermatitis, hyperkeratotic hand dermatitis, and id reactions.
- Does not respond well to treatment.

EPIDEMIOLOGY

Differences in classification and definition have made it difficult to assess the true incidence of the endogenous hand disorders. Most studies have focused on the prevalence of exogenous hand disorders as seen in occupational settings.



▲ **FIGURE 16-1** Approach to the patient with vesicular palmoplantar eczema.

Pompholyx is the least common presentation of hand dermatitis; in one population study, the 1-year prevalence of pompholyx was estimated to be 0.5 percent.[1] In the same study, hyperkeratotic hand dermatitis represented 2 percent of all hand dermatoses.[1]

ETIOLOGY AND PATHOGENESIS

With the exception of the id reaction, a direct cause of vesicular palmoplantar eczema is rarely identified. A number of etiologic factors have been associated with pompholyx, including atopy (see Chap. 14), contact allergy (see Chap. 13), psychological stress, and hot weather.[1] Pompholyx has also been reported after intravenous immunoglobulin therapy,[3] ingestion of piroxicam,[2] and after ingestion of certain metals in predisposed or sensitized patients.[2] More recently, there has been a report of five cases of photo-induced pompholyx[2]; patients with a reported history of photo-induced disease were challenged by ultraviolet A (UVA). Histologic evaluation confirmed the diagnosis of pompholyx and a true photosensitivity rather than photoaggravation.

EXACERBATING FACTORS

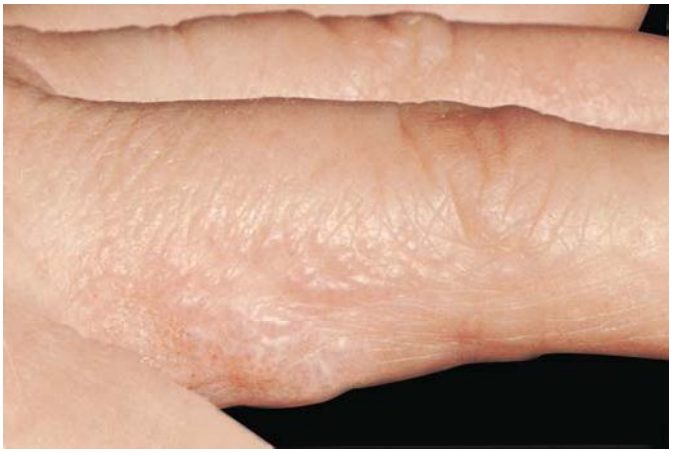
Contact allergy is common in patients affected with vesicular palmoplantar eczema, especially the chronic type, but the causal relationship is not always clear. There are cases in which contact allergy has exacerbated pre-existing hand dermatitis and also reports that ingestion of certain metals, including nickel, cobalt, and chromium, have caused flares. However, in other cases, the causal relationship may be the reverse. The skin's impaired barrier function in vesiculobullous hand dermatitis (see Chap. 46) may in some cases lead to sensitization and a higher prevalence of contact dermatitis in the affected population.

Investigations into the role of atopy (see Chap. 14) have yielded mixed results. Some studies have shown levels of personal or familial atopy as high as 50 percent in affected subjects, compared to 11.5 percent of controls, but other studies have demonstrated no difference in the prevalence in people with vesiculobullous hand dermatitis versus controls.[4]

CLINICAL FINDINGS

Pompholyx

Fig. 16-1 is an algorithm showing the approach to the patient with vesicular palmoplantar eczema. The severity of pompholyx can range from the inconvenient to the severe and can even be serious enough to necessitate hospitalization. In true acute pompholyx, there is an explosive outbreak of deep-seated vesicles on the palms, the lateral aspects of the fingers (Fig. 16-2), and sometimes the soles, usually in a symmetric pattern. Discomfort and itching usually precede the development of the blisters, which have been described as having a "tapioca" appearance (see Fig. 16-2). Blisters may coalesce then desiccate and resolve without rupture (Fig. 16-3). Intact, large blisters can be drained, but should not be un-



▲ **FIGURE 16-2** Chronic vesiculobullous hand dermatitis. There is a vesicular dermatitis on the lateral sides of the fingers. Note the tapioca-like, deep seated vesicles.

▲ **FIGURE 16-4** Podopompholyx. Large blisters have ruptured leaving erosions that are drying up. Note large bulla on the arch of the right foot: The roof of the blister still contains tapioca-like vesicles. This is characteristic.

roofed. However, large blisters may rupture spontaneously, leaving oozing or dried up erosions (Fig. 16-4).

This acute phase is generally followed by desquamation of the affected areas. Individual outbreaks are usually self-limited over 2 to 3 weeks, although they may recur. Secondary bacterial infection is common, often resulting in a local cellulitis, and can sometimes potentiate the development of lymphatic damage, resulting in lymphedema. Attacks are most common among adolescents and young adults and seem to be more common in the spring and summer months.

Chronic Vesiculobullous Dermatitis

Chronic vesiculobullous hand dermatitis is more common than true pompholyx and more difficult to manage because of its relapsing course. The clinical presentation includes small 1- to 2-mm vesicles filled with clear fluid localizing to the lateral aspects of the fingers, palms, and soles as in pompholyx (see Fig. 16-2). As the condition becomes more chronic, the clinical appearance may evolve and subsequently appear more fissured and hyperkeratotic (as in Fig. 16-5). A clear history of vesicles or exacerbations characterized by blistering may help to narrow the classification of a given presentation of hand dermatitis.

Hyperkeratotic Hand Dermatitis

Patients with hyperkeratotic hand dermatitis are usually male and generally present with chronic keratotic pruritic plaques, sometimes with fissures on the central palm (see Fig. 16-5). This condition may be the end result of contact allergy, excoriation, and irritation, but generally the cause is not identifiable, and contact allergy does not seem to play an important role. This hand dermatitis commonly occurs in middle-aged to elderly men and is normally very refractory to treatment. Frictional factors of lichen simplex chronicus may be an important factor in some cases. Plantar involvement is present in a minority of cases.

Id Reaction

In an id reaction, erythematous vesicles usually are seen on the lateral aspects of the fingers and the palms and are typically pruritic (Fig. 16-6). This eruption of vesicles is usually sudden and classically occurs in response to an intense inflammatory process, especially fungal infections, taking place somewhere else on the body. The id reaction is thought to be an allergic reaction to fungi or to some antigen created during the inflammatory process. Treatment of the underlying infection results in resolution of the vesicular eruption.

LABORATORY FINDINGS

There are no distinctive laboratory findings characteristic of vesicular palmoplantar eczema, although immuno-

▲ **FIGURE 16-3** Cheiropompholyx. Apart from small vesicles, there are large bullae, some purulent; others have collapsed and are drying up.

▲ **FIGURE 16-5** Hyperkeratotic hand dermatitis. There are pruritic keratotic plaques on the central palm: Occasional vesiculation and fissuring may occur.

▲ **FIGURE 16-6** Id reaction to tinea pedis. Erythematous, partially dried up vesicles on the foot. Lesions are very pruritic.

globulin E levels may be elevated in atopic patients.

PATHOLOGY

The histology of these entities depends on the chronicity of the disease. The primary vesicle appears as an intraepidermal spongiotic vesicle that does not involve the acrosyringia on either conventional and electron microscopy. Lymphocytic infiltration is common in the epidermis, with a mixed infiltrate observed in the dermis. In more chronic cases, the epidermis may show hyperproliferation, hyperkeratosis, or even psoriasiform epidermal hyperplasia. Periodic acid-Schiff staining can be helpful in excluding fungal elements.

DIAGNOSIS

The diagnosis of vesiculobullous hand dermatitis is usually made on the basis of clinical presentation, history, and sometimes histology. Patch testing may be useful in helping to distinguish this entity from other palmoplantar disorders or in eliminating other exacerbating factors such as irritant exposure and contact allergy.

There are many other skin conditions of the hands and feet that can be difficult to distinguish from vesiculobullous hand dermatitis. Several of the diagnoses may also co-exist.

DIFFERENTIAL DIAGNOSIS (Box 16-1)

Allergic contact dermatitis (see Chap. 13) may be clinically indistinguishable from constitutional forms of hand eczema, and patch testing should always be considered for those with recurrent, atypical, or persistent forms of the disease. Common allergens include nickel, thimerosal, neomycin sulfate, formaldehyde, *p*-phenylenediamine, quaternium-15, colophony, potassium dichromate, benzoyl peroxide, fragrances, rubber, and lanolin. Although frequently considered, laundry detergents are a rare cause of allergic contact dermatitis.

Irritant contact dermatitis (see Chap. 46) is by far the most common hand dermatitis and is often exacerbated by occupational exposures. It is usually symmetric, chronic, and affects the dorsal fingertips and web spaces.

Atopic hand dermatitis (see Chap. 14) is associated with a number of factors: hand dermatitis before age 15 years, persistent eczema on the body, dry or itchy skin in adult life, and widespread atopic dermatitis in childhood. The backs of the hands, particularly the fingers, are affected with erythema, vesiculation, crusting, excoriation, and scale.

Infections, most commonly from tinea, can mimic endogenous hand dermatitis. In cases of asymmetric or atypical cases, or in cases of small vesicles confined to the feet, a potassium hydroxide examination may be useful in ruling out primary tinea infection. In chronic cases of hand dermatitis, fungal and bacterial infections may be superimposed, and treatment may result in improvement of clinical symptoms.

Herpes simplex may, in unusual cases, present as blisters on the hands.

Psoriasis and psoriasiform hand dermatitis (see Chap. 18) are most prominent over pressure points. Psoriasis can normally be distinguished by its sharply marginated, nummular, or circinate scaly plaques; relative lack of itching; silvery scales; and the presence of psoriasis elsewhere. Psoriasiform hand dermatitis can occur without a family or personal history of psoriasis. It is a diagnosis made primarily on clinical and histologic presentation. At times, however, it appears as though eczematous, hyperkeratotic, and psoriatic diatheses co-exist. Repeated pressure or friction may cause hyperkeratosis in some individuals.

Pustular eruptions of palms and soles (see Chap. 21) is generally easy to distinguish because, unlike the presentation of clear fluid-filled blisters and bullae of hand dermatitis, pustules are the primary lesion. For example, in pustular psoriasis, the vesicles are cloudy and painful.

Keratolysis exfoliativa (recurrent focal palmar peeling) is a chronic, asymptomatic, noninflammatory peeling of the palms and soles, most commonly seen during the summer months. It is thought to occur more frequently in people with hyperhidrosis in these areas. Scaling usually starts from one to two fine points and expands outward to larger circular areas. The condition is usually self-limited and asymptomatic, requiring only emollients.

Bazex acrokeratosis paraneoplastica is a rare, acute, erythematous, scaling, vesiculobullous hand dermatitis with nail dystrophy associated with neoplasia, usually squamous carcinomas of the upper digestive and respiratory tracts, although there have been some reports of similar findings in patients with colon cancer and genitourinary tumors.

Other blistering diseases, such as pemphigoid, pemphigus, or epidermolysis bullosa, may affect the hands and feet, but usually do so in the setting of blisters elsewhere on the body.

Box 16-1

Differential Diagnosis of Vesicular Palmoplantar Eczema

Most Likely

- Allergic contact dermatitis
- Irritant contact dermatitis
- Atopic hand dermatitis
- Infections, commonly from tinea

Consider

- Bazex acrokeratosis paraneoplastica
- Psoriasis
- Psoriasiform hand dermatitis
- Pustular eruption of palms and soles
- Keratolysis exfoliativa
- Bullous disorders
- Herpes simplex (never bilateral)

COMPLICATIONS

Secondary bacterial infection of the vesicles can result in cellulitis, lymphangitis, and, in rare instances, septicemia.

PROGNOSIS AND CLINICAL COURSE

Pompholyx tends to occur as intermittent explosive outbreaks and becomes less frequent with middle age. The more chronic forms of vesicular palmoplantar eczema, however, are much more persistent and frustrating to manage and often require multiple therapeutic approaches over time.

TREATMENT (Box 16-2)

Treatment of vesiculobullous hand dermatitis should be based on the acuity of the condition, the severity of the disease, the prominence of blisters versus chronic changes, and any relevant history that reveals possible co-factors.

Topical Therapy

Topical steroids, typically high potency, are usually first-line agents. They are often more effective if used under occlusion, although this approach may increase the chance of infection. Topical drying agents, such as Domeboro soaks, Burow's solutions (aluminum subacetate), or dilute potassium permanganate solution (1 to 8000) may be useful in acute forms with a predominance of vesicles.

Nonsteroidal topical immunomodulating agents, such as tacrolimus and pimecrolimus, have been studied for treatment of individuals with mild to moderate chronic hand dermatitis. The majority of these studies, however, did not limit study subjects to those with vesicular palmoplantar eczema; patients with atopic, allergic, and irritant dermatitis were included. With this in mind, statistically significant improvements from baseline were observed for erythema, scaling, induration, fissuring, and pruritus, but not for vesiculation.[2]

Hyperkeratotic palmar eczema is notoriously difficult to manage. Topical retinoids and calcipotriene, both of which act to regulate epidermal cell maturation, have anecdotally been shown to improve this category of hand dermatitis.[1]

Systemic Therapy

For recurrent pompholyx and chronic vesicular dermatitis, oral prednisone may be required and is often effective if treatment is initiated early, at the onset of the itching prodrome. However, because of significant side effects, systemic glucocorticoids are typically inappropriate for long-term management.

Cyclosporine has been studied at dosing levels of 3 mg/kg/day and 5 mg/kg/day in the treatment of chronic vesicular dermatitis. Although patients showed improvement with treatment, relapses occurred shortly after discontinuation of cyclosporine.[5]

Mycophenolate mofetil has been used in the treatment of chronic vesicular dermatitis at dosing levels of 2 to 3 g/day (in divided doses). It has been anecdotally shown to improve chronic vesicular dermatitis that has been otherwise recalcitrant to corticosteroids, iontophoresis, and phototherapy. However, it has also been anecdotally shown to induce biopsy-proven dyshidrotic eczema.

Methotrexate has proven a useful therapy of a wide range of skin diseases. In chronic vesicular eczema, it has been reported to partially or completely clear lesions at low doses ranging from 12.5 to 22.5 mg/week.[5] However, its wide spectrum of potential side effects remains a limiting factor to its use in this particular skin disease.

Alitretinoin, 9-*cis*-retinoic acid, in preliminary studies has been reported to be successful in the treatment of chronic hyperkeratotic hand eczema. Patients refractory to treatments with corticosteroids, radiation therapy, tretinoin, isotretinoin, and acitretin reported "good" to "very good" responses to alitretinoin.[2]

Box 16-2

Treatments for Vesicular Palmoplantar Eczema

	TOPICAL	PHYSICAL	SYSTEMIC
First line	Corticosteroids	Ultraviolet A-1 Psoralen and ultraviolet A light Narrowband ultraviolet B	Prednisone Cyclosporine Mycophenolate mofetil Methotrexate Alitretinoin
Second line	Drying agents Tacrolimus Pimecrolimus Retinoids Calcipotriene	Grenz ray Iontophoresis Intradermal botulinum toxin Sympathectomy	

Radiation Therapy

Superficial radiotherapy (Grenz ray) is still sometimes used at a few centers. This condition may be one of the last indications for this treatment modality, although it is one of the few therapies tested successfully in a double-blind study.[5]

UVB, systemic, topical and bath water psoralen and UVA light (PUVA) have been used in severe cases of chronic vesicular hand eczema. Recent studies have evaluated the use of UVA-1; one study compared localized high-dose UVA-1 irradiation against topical cream psoralen UVA for the treatment of dyshidrotic eczema.[6] This study demonstrated that UVA-1 irradiation and topical PUVA showed similar beneficial responses. In addition, the potential side effects noted with PUVA, such as phototoxic reactions and long-term carcinogenic risk, are at least theoretically reduced with UVA-1 therapy.

Other Therapies

Iontophoresis, sympathectomy, and intradermal botulinum toxin are effective therapies for hyperhidrosis and have been studied as treatments for chronic vesicular dermatitis.[5] Tap water iontophoresis with pulsed direct current showed no benefit for subjects with hand dermatitis over controls in time to improvement, but those who were treated had much longer remissions, by a factor of months.[3] In one study, intradermal botulinum toxin A was shown to have good effect in treating patients with treatment-refractory vesicular dermatitis, especially those patients whose condition was aggravated by hyperhidrosis and during summer months.[7]

Two severity indices, the dyshidrosis area and severity index and the total sign and symptoms score, have been validated and may prove useful in clinical trials to better assess the effectiveness of some of these approaches.

PREVENTION

Prevention is a critical part of therapy in most cases, especially when known exacerbating factors are present. Avoidance of commonly encountered allergens, such as foods and plants, and irritants, such as soaps, solvents, acids, and alkalis, can be helpful. Vinyl gloves, rather than latex, are recommended because of the risk of either having an underlying allergy or of developing one in the setting of impaired barrier function. Modification of environmental exposure to exacerbating factors, such as friction and cold

air, may also help with persistent or refractory disease. For maintenance, frequent use of emollients, such as ointments, helps to preserve normal skin-barrier function.

CHAPTER 17

Autosensitization Dermatitis

Donald V. Belsito

EPIDEMIOLOGY

Autosensitization dermatitis refers to a phenomenon in which an acute dermatitis develops at cutaneous sites distant from an inflammatory focus, and where the secondary acute dermatitis is not explained by the inciting cause of the primary inflammation. The classic presentation of autosensitization is that seen in patients with venous stasis disease,[1] where as many as 37 percent of patients have been reported to develop at least one episode of autosensitization.[2]

ETIOLOGY AND PATHOGENESIS

The term *autosensitization dermatitis* was coined in 1921 by Whitfield to describe reaction patterns ranging from a generalized, erythematous, morbilliform, and urticarial eruption after blunt trauma to a generalized, petechial, papulovesicular dermatitis after the acute irritation of chronic stasis dermatitis.[3] Subsequently, the vesicular id reactions associated with infections caused by tuberculosis,[4] histoplasmosis,[5] dermatophytes,[6] and bacteria[7] were included under this rubric.[8–10] Other precipitating factors for this phenomenon have included the application of irritant or sensitizing chemicals,[11] ionizing radiation,[12,13] and retained suture material.[14]

Although the disease was originally thought to be due to autosensitization to epidermal antigens,[10] this concept has not been experimentally verified. In murine studies designed to determine whether keratinocyte-derived proteins can serve as antigenic carriers for hapten, Fehr et al.[15] derived major histocompatibility complex–restricted, T-cell receptor α/β, $CD4^+$ T-cell clones that proliferated in response to keratinocyte extracts unconjugated to hapten. In these studies, such autoreactive T-cell clones could not be derived after treatment with irritants. Nonetheless, the authors speculated that T cells autoreactive to keratinocyte antigens may be generated during the course of contact hypersensitivity and lead to the development of an id reaction.

In the most extensive study to date,[1] only 4 of 81 patients with autosensitization dermatitis had serum antibodies cytotoxic to autologous or homologous skin. However, the role of such autoantibodies in mediating the disorder, even in these four patients, must be interpreted cautiously, given the high frequency of epidermal autoantibodies in the normal adult population.[16]

In an experiment in which guinea pigs were injected with autologous skin, Wilhelmj et al.[17] reported dermatitis in 2 of 11 guinea pigs, but it was not clear whether these reactions were immunologic and, if so, what the causal allergen(s) was. Other investigators using similar techniques have been unable to induce cutaneous disease in animals by means of epidermal extracts.[18] In contrast, 19 of 24 patients with active autosensitization who were intradermally challenged with water-soluble extracts of autologous epidermal scale developed a reaction.[19]

The term *autosensitization* is probably a misnomer. The disease is more likely due to a hyperirritability of the skin induced by either immunologic or nonimmunologic stimuli. Factors such as irritation, sensitization, infection, and wounding, which are known to precipitate autosensitization, have been reported to release a variety of epidermal cytokines.[20,21] Once hematogenously disseminated in sufficient amounts, these cytokines could heighten the sensitivity of skin to a variety of non-specific, but otherwise innocuous, stimuli, producing a pattern of "spillover" reactions[22] that have been classically termed *autosensitization*. Such a hypothesis would account for (1) the results in humans of delayed-type hypersensitivity testing with autologous epidermal scale,[19] (2) the histopathologic findings noted in the disease (see the section Clinical Findings), and (3) the activated T lymphocytes occasionally observed in the blood of patients with autosensitization.[23] The characteristic distribution of the disease

AUTOSENSITIZATION DERMATITIS AT A GLANCE

- An acute disorder triggered by infection, stasis and contact dermatitides, ionizing radiation, blunt trauma, and retained suture material.
- Widespread, pruritic, papulovesicular eruption, most frequently affecting the extremities.
- Related features are those of the precipitating disorder.
- Pathology is non-diagnostic and consistent with an acute spongiotic process of the epidermis with a superficial, perivascular, lymphohistiocytic infiltrate of the dermis containing occasional eosinophils.

▲ **FIGURE 17-1** Stasis dermatitis with autosensitization. An elderly woman with a long-standing history of stasis dermatitis presented with gradual worsening of the edema; pruritus; and multiple, punctate, superficial, excoriated ulcers overlying the medial malleoli (**A**). Nine days after the ulcers appeared, she developed an acute, extremely pruritic, erythematous, papulovesicular eruption over the forearms (**B**), which progressively involved the upper arms, upper torso, and hands. The acute papulovesicular dermatitis also involved the lower extremities and can be noted overlying the chronic stasis dermatitis (**A**).

might perhaps be explained if the skin overlying the arms and legs was found to contain increased numbers of, or more avid receptors for, various cytokines than the skin of the face or hands. Such a geographic variation in the distribution of bullous pemphigoid antigen has been observed and hypothesized to account for the clinical patterns of this autoimmune disease.[24] Application of modern biotechnological tools should provide insight into the mysteries of autosensitization.

CLINICAL FINDINGS

Typically, 1 to 2 weeks after an acute inflammation, an extremely pruritic, symmetric, scattered, erythematous eruption with macules, papules, and vesicles develops (Fig. 17-1). The eruption involves the forearms, thighs, legs, trunk, face, hands, neck, and feet in descending order of frequency.[2,10] During the evolution of the dermatitis, its morphology may change in a manner consistent with the chronicity (i.e., vesicles to scale). Histopathologically, the findings are not pathognomonic: spongiotic epidermal vesicles associated with a superficial, perivascular lymphohistiocytic infiltrate of the dermis, which may contain scattered eosinophils.[25] Immunophenotypic studies of skin have revealed that most of the lymphocytes in the epidermis are $CD3^+$ and $CD8^+$ T cells, whereas those in the dermis are primarily $CD4^+$.[22] In the majority of individuals with autosensitization,[1] deposition of antibody or complement in affected skin is not detected.

DIFFERENTIAL DIAGNOSIS

See Box 17-1.

PROGNOSIS AND CLINICAL COURSE

The rash often persists and spreads until the underlying causative primary site of inflammation is treated.

Box 17-1

Differential Diagnosis of Autosensitization Dermatitis

Most Likely

- Allergic contact dermatitis
- Irritant contact dermatitis
- Atopic dermatitis
- Nummular dermatitis

Consider

- Polymorphous light eruption

Always Rule Out

- Infectious processes
  - Dermatophyte infections
  - Scabies and other mite infestations
  - Viral exanthems
- Drug eruptions

TREATMENT

Treatment is best directed toward the inciting disease. The frequently weeping, vesicular eruption of autosensitization benefits from drying agents such as aluminum sulfate and calcium acetate. Given the likely involvement of cytokines and inflammatory mediators sensitive to glucocorticoids[26] or macrolactams,[27] systemic and/or topical treatment with these drugs may be helpful. To prevent the secondary effects of excoriation, pruritus must be controlled with topical antipruritic agents or oral antihistamines. However, one must remain alert to the possibility of inducing an allergy in existing dermatitic skin with topical medicaments.

CHAPTER 18

Psoriasis

Johann E. Gudjonsson
James T. Elder

EPIDEMIOLOGY

Prevalence

Psoriasis is universal in occurrence. However, its prevalence in different populations varies from 0.1 percent to 11.8 percent, according to published reports.[1] The highest reported incidences in Europe have been in Denmark (2.9 percent) and the Faeroe Islands (2.8 percent), with the average for northern Europe being around 2 percent. Prevalences ranging from 2.2 percent to 2.6 percent have been measured in the United States, with approximately 150,000 newly diagnosed cases per year. A higher prevalence in East Africans as opposed to West Africans may explain the relatively low prevalence of psoriasis in African Americans (1.3 percent vs. 2.5 percent in white Americans[2]). The incidence of psoriasis is also low in Asians (0.4 percent), and in an examination of 26,000 South American Indians, not a single case was seen. Psoriasis is equally common in males and females.[3,4]

Age of Onset

Psoriasis may begin at any age, but it is uncommon under the age of 10 years. It is most likely to appear between the ages of 15 and 30 years. Possession of certain HLA class I antigens, particularly HLA-Cw6, is associated with an earlier age of onset and with a positive family history. This finding led Henseler and Christophers[5] to propose that two different forms of psoriasis exist: type I psoriasis, with age of onset before 40 years and HLA-associated, and type II, with age of onset after 40 years and lacking HLA associations, although many patients do not fit into this classification. There is no evidence that type I and type II psoriasis respond differently to different therapies.

ETIOLOGY AND PATHOGENESIS

Psoriasis is a chronic inflammatory skin disease, with a strong genetic basis, characterized by complex alterations in epidermal growth and differentiation and multiple biochemical, immunologic, and vascular abnormalities, and a poorly understood relationship to nervous system function. Its root cause remains unknown. Historically, psoriasis was widely considered to be a primary disorder of keratinocytes. With the discovery that the T-cell specific immunosuppressant cyclosporin A (CsA) was highly active against psoriasis, most researchers have focused on the immune system.

Genetics of Psoriasis

The genetic basis of psoriasis has been appreciated for nearly 100 years.[6] However, as Gunnar Lomholt lamented in 1963 in his classic study of psoriasis in the Faeroe Islands[7]: "That psoriasis is genetically conditioned is beyond doubt. But when the mode of inheritance appears to have been almost demonstrated, it again slips out of the fetters of fixed rules!" Over the years, based on some very large pedigrees and population surveys, single-gene recessive, two-gene recessive, dominant with reduced penetrance, and polygenic models have been suggested. Analysis of the population-based studies of Lomholt[7] and Hellgren[8] utilizing recurrence risk analysis[9] demonstrated that λ_r-1, the excess recurrence risk for relatives of degree r, dropped by a factor of 6 to 7 as r increased from 1 to 2, as opposed to the factor of 2 predicted for monogenic disorders. This analysis favors a polygenic model.[10] Based on population studies, the risk of psoriasis in an offspring has been estimated to be 41 percent if both parents are affected, 14 percent if one parent is affected, and 6 percent if one sibling is affected, compared to 2 percent when no parent or sibling is affected.[11]

Concordance for psoriasis in monozygotic twins ranged from 35 percent to 73 percent in various studies.[12–14] This variability, and the fact that these rates do not approach 100 percent, supports a role for environmental factors. Interestingly, concordance in both monozygotic and dizygotic twins decreases as one moves closer to the equator.[14] Given the strong therapeutic effects of ultraviolet (UV) light on psoriasis (see Treatment, below), these data suggest that UV exposure may be a major environmental factor interacting with genetic factors in psoriasis.

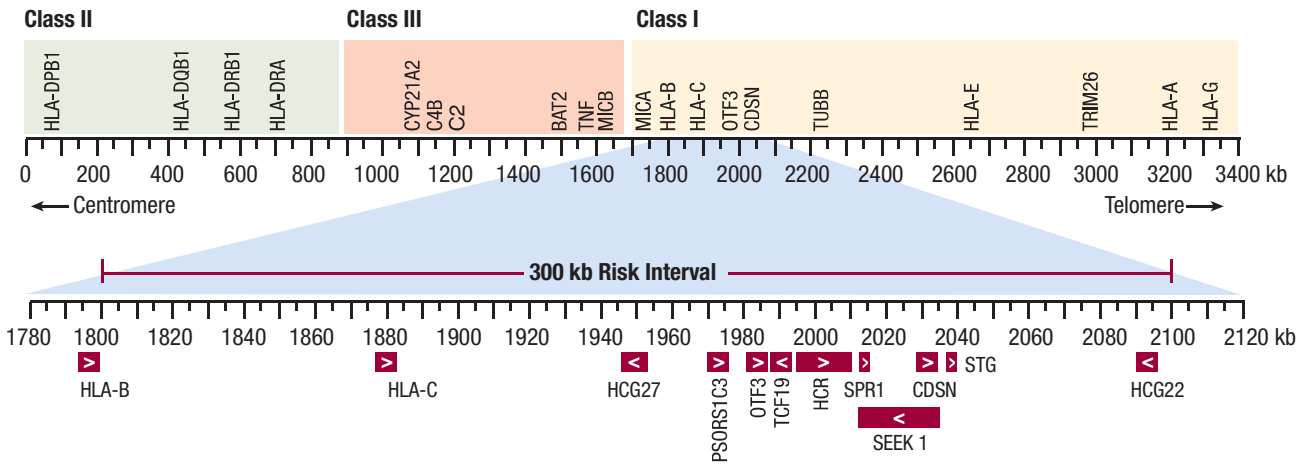
The search for the involvement of specific genes in psoriasis began over a decade ago with studies of genetic linkage (i.e., the co-transmission of marker and disease alleles within families).

PSORIASIS AT A GLANCE

- World-wide occurrence: Affects approximately 2 percent of Americans; prevalence ranges from 0.1 percent to 3 percent in various populations.
- A chronic disorder with polygenic predisposition combined with triggering environmental factors such as trauma, infection, or medication.
- Erythematous scaly papules and plaques; pustular and erythrodermic eruptions occur.
- Most common sites of involvement are scalp, elbows and knees, hands, feet, trunk, and nails.
- Psoriatic arthritis occurs in 10 percent to 25 percent of patients; pustular and erythrodermic forms may be associated with fever.
- Pathology is characterized by uniform elongation of the rete ridges, with dilated blood vessels, thinning of the suprapapillary plate, and intermittent parakeratosis. Epidermal and perivascular dermal infiltrates of lymphocytes, with neutrophils occasionally in aggregates in the epidermis.

However, despite multiple genome-wide linkage studies, only one locus, termed *psoriasis susceptibility 1* (PSORS1), has been consistently confirmed.[16] PSORS1 is located in the major histocompatibility complex (MHC, chromosome 6p21.3), home of the HLA) genes.[17] Multiple HLA alleles have been associated with psoriasis, particularly HLA-B13, HLA-B37, HLA-B46, HLA-B57, HLA-Cw1, HLA-Cw6, HLA-DR7, and HLA-DQ9.[10] Many of these alleles are in linkage disequilibrium with HLA-Cw6 (i.e., found together on the same chromosome more often than would be predicted by chance). HLA-Cw6 has consistently demonstrated the highest relative risk for psoriasis in Caucasian populations.[10]

HLA-Cw6 is also associated with psoriatic arthritis, with a tendency for early onset of skin lesions.[24] HLA-B27, HLA-B38, and HLA-B39 are also associated with psoriatic arthritis,[25] with HLA-B27 being most strongly associ-



▲ **FIGURE 18-1** Map of the major histocompatibility complex (MHC) and psoriasis susceptibility 1 (PSORS1). The upper panel depicts the entire MHC; only a few of the over 200 genes contained in this interval are shown. The lower panel depicts the gene content of the PSORS1 risk interval determined by several independent studies. The 10 genes extending from HLA-C to STG reside in a region of strong linkage disequilibrium in the genome, and each of these genes has been associated with psoriasis. Of these, only HLA-C and CDSN have protein-altering (missense) variants unique to psoriasis-risk haplotypes (HLA-Cw6 and CDSN*TTC), and in a sample of 76 haplotypes in which these putative risk alleles were separated from each other, only those haplotypes carrying HLA-Cw6 carried risk for psoriasis. See on-line text for details.

ated with the axial variant (see Chap. 19).

HLA-Cw6 remains strongly associated with psoriasis when found together with several different HLA-B alleles,[27] suggesting that the PSORS1 gene must reside telomeric to HLA-B (Fig. 18-1).

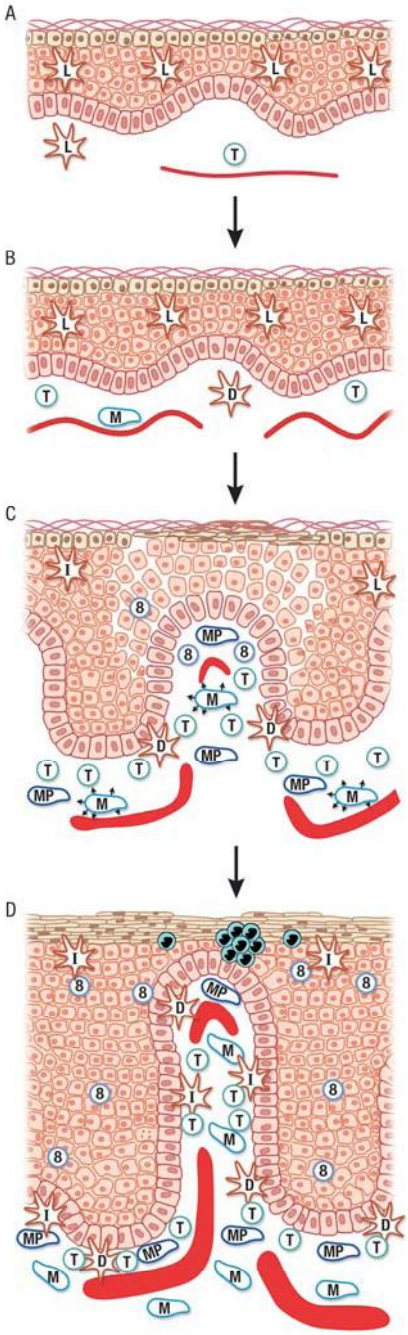
Only about 10 percent of HLA-Cw6 carriers develop psoriasis, and it has been estimated that PSORS1 accounts for only one-third to one-half of the variation in genetic liability to psoriasis.[32] Therefore, it is highly likely that additional non-MHC genes are also involved. In addition to PSORS1, linkage studies have identified 18 potential susceptibility loci.[16,33] However, many of these have proven difficult to replicate. After PSORS1, the second-most replicated psoriasis susceptibility locus is PSORS2 (17q24-q25),[34] with four independent studies providing confirmatory evidence ($p < 0.01$) in support of the original report.[35–38] It has been reported recently that this locus contributes to psoriasis by influencing the expression of the SLC9A3R1, NAT1, and/or RAPTOR genes involved in immunologic regulation,[39] but others have been unable to confirm these findings.[40,41] Other loci showing evidence of reproducibility include PSORS4 (1q21.3),[42–44] PSORS5 (3q21),[45–47] PSORS8 (16q12-q13),[48] and PSORS9 (4q28-q31).[49,50] PSORS4 resides in the epidermal differentiation complex, the location of at least 58 genes involved in epidermal differentiation, including the loricrin, involucrin, filaggrin, small proline rich region, S100, and late cornified envelope genes.[51] The PSORS5 locus (3q21) was originally linked to psoriasis in Swedish families[46]; the evidence for replication is based on two association studies.[46,47] The PSORS8 locus overlaps with a known susceptibility gene for Crohn disease (NOD2/CARD15) and has been implicated in psoriatic arthritis.[48] The PSORS9 locus was originally identified in a Chinese population, but also provided some evidence for linkage in four other genome-wide linkage scans involving largely Caucasian populations.[50]

Pathogenesis of Psoriasis

DEVELOPMENT OF LESIONS Detailed light, electron microscopic, immunohistochemical, and molecular studies of involved and uninvolved skin of both newly appearing and established psoriatic lesions provide a useful framework for cause-and-effect relationships between the many cellular events that take place in a psoriatic lesion. They are illustrated schematically in Fig. 18-2 and with actual photomicrographs in Fig. 18-3.

Initial Lesion. In the initial pinhead-sized macular lesions there is marked edema, and mononuclear cell infiltrates are found in the upper dermis.[52] These findings are usually confined to the area of one or two papillae. The overlying epidermis soon becomes spongiotic, with focal loss of the granular layer. The venules in the upper dermis dilate and become surrounded by a mononuclear cell infiltrate.[53] Similar findings have been described in early macules and papules of psoriasis[54] and in clinically normal-appearing skin 2 to 4 cm away from any active lesion in patients undergoing an acute flare of guttate psoriasis.[55] These findings are suggestive of a "pre-psoriatic state," which could be related to underlying genetic factors.

Developing Lesion. Studies of the clinical margins of somewhat larger lesions (0.5 to 1.0 cm) reveal an approximately 50 percent increase in epidermal thickening in the "normal-appearing" skin immediately adjacent to lesions.[53] There is a large increase in the metabolic activity of epidermal cells, including the stratum corneum, increased DNA synthesis, an increased number of mast cells and dermal macrophages, and increased mast cell degranulation.[53,56,57] Subsequent studies revealed increased numbers of dermal T cells[58] and dendritic cells (DCs)[59] in both uninvolved and involved psoriatic skin relative to normal skin. Toward the center of the lesion, a "marginal zone" can be identified, with increasing band-like epidermal thickness, increasing parakeratosis and capillary elongation, and perivascular infiltration of lymphocytes and macrophages, without exudation into the epidermis. More centrally, rete ridges begin to develop in the marginal zone, before finally transitioning into the fully developed psoriatic plaque. Squamous cells manifest enlarged extracellular spaces with only a few desmosomal connections. Parakeratosis is typically mounded or spotty.



▶ **FIGURE 18-2** Development of psoriatic lesions. This figure depicts the transition from normal skin to fully developed lesion described in the text. Normal skin from a healthy individual (*panel A*) contains epidermal Langerhans cells, scattered immature dendritic cells (D), and skin-homing memory T cells (T) in the dermis. Normal-appearing skin from a psoriatic individual (*panel B*) manifests slight capillary dilatation and curvature, and a slight increase in the numbers of dermal mononuclear cells and mast cells (M). A slight increase in epidermal thickness is usually present. In chronic plaque psoriasis, the intensity of these changes may depend on distance from an established lesion. The transition zone of a developing lesion (*panel C*) is characterized by progressive increases in capillary dilatation and tortuosity, numbers of mast cells, macrophages (MP), and T cells, and mast cell degranulation (*arrowheads*). In the epidermis, there is increasing thickness with increasingly prominent rete pegs, widening of the extracellular spaces, transient dyskeratosis, spotty loss of the granular layer, and parakeratosis. Langerhans cells (L) begin to exit the epidermis, and inflammatory dendritic epidermal cells (I) and $CD8^+$ T cells (8) begin to enter the epidermis. The fully developed lesion (*panel D*) is characterized by fully developed capillary dilatation and tortuosity with a 10-fold increase in blood flow, numerous macrophages underlying the basement membrane, and increased numbers of dermal T cells (mainly $CD4^+$) making contact with maturing dermal dendritic cells (D). The epidermis of the mature lesion manifests markedly increased (approximately 10-fold) keratinocyte hyperproliferation extending to the lower suprabasal layers, marked but not necessarily uniform loss of the granular layer with overlying compaction of the stratum corneum and parakeratosis, increased numbers of $CD8^+$ T cells, and accumulation of neutrophils in the stratum corneum (Munro's microabscesses).

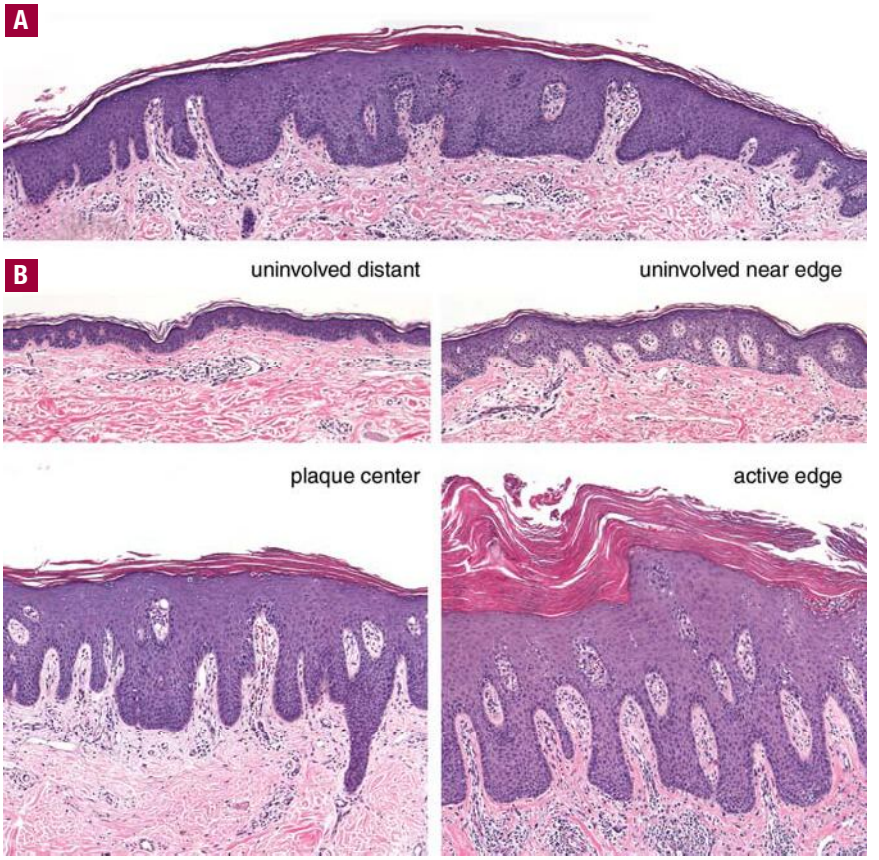
Mature Lesion. Mature lesions of psoriasis are characterized by uniform elongation of rete ridges, with thinning of the epidermis overlying the dermal papillae.[53,54] Epidermal mass is increased three to five times, and there are many more mitoses observed frequently above the basal layer. About 10 percent of basal keratinocytes are cycling in normal skin, whereas this value rises to 100 percent in lesional psoriatic skin.[60] Widening of the extracellular spaces between keratinocytes persists but is less prominent than in developing lesions and is more uniform than the typical spongiosis of eczematous skin lesions. The tips of the rete ridges are often clubbed or fused with adjacent ones, with thin, elongated, edematous papillae containing dilated, tortuous capillaries. Parakeratosis, with accompanying loss of the granular layer, is often horizontally confluent but may alternate with orthokeratosis,[61] and hyperkeratosis is more extensive than in the transitional zone. The inflammatory infiltrate around the blood vessels in the papillary dermis becomes more intense but still consists of lymphocytes, macrophages, DCs, and mast cells. Unlike the initial lesion and the transitional zone, lymphocytes are observed in the epidermis of the mature lesion. Neutrophils exit from the tips of a subset of dermal capillaries (the "squirting papillae"), leading to their accumulation in the overlying parakeratotic stratum corneum (Munro's microabscesses) and, less frequently, in the spinous layer (spongiform pustules of Kogoj). Collections of serum can also be seen in the epidermis and the stratum corneum.[53,54]

CELLULAR PARTICIPANTS IN PSORIASIS

T Cells[39,62,63]***.*** In 1984, it was demonstrated that the eruption of psoriatic skin lesions coincided with epidermal influx and activation of T cells,[58] and shortly thereafter it was further shown that resolution of psoriasis during phototherapy was preceded by depletion of T cells, predominantly from the epidermis.[64] CsA was highly effective in psoriasis,[65,66] and this effect was demonstrated to be primarily through blockade of T cells rather than keratinocytes.[67] Furthermore, psoriasis has been triggered or cured by bone marrow transplantation, depending on whether the donor or the host was psoriatic.[68,69] The role of T cells in psoriasis was functionally demonstrated in 1996 when it was shown that the psoriasis process could be induced by injecting activated autologous T cells into uninvolved psoriatic skin transplanted onto severe combined immunodeficient mice.[70]

The best-characterized T cells are the $CD4^+$ and $CD8^+$ subsets. Predominantly of the memory phenotype ($CD45RO^+$), these cells express the cutaneous lymphocyte antigen (CLA), a ligand for E-selectin, which is selectively expressed on skin capillaries and therefore provides them with access to the skin.[75] $CD8^+$ T cells are predominantly located in the epidermis, whereas $CD4^+$ T cells are predominantly located in the upper dermis.[76,77] The cytokine profile of psoriatic lesions is rich in interferon (IFN)-γ,[78] indicative of T helper 1 (Th1) polarization of $CD4^+$ cells, and T cytotoxic 1 (Tc1) polarization of $CD8^+$ cells.[79] However, a novel subset of $CD4^+$ T cells, stimulated by interleukin (IL)-23 and characterized by IL-17 production, was recently described and may play an important role in maintaining chronic inflammation in psoriasis and other autoinflammatory conditions.[80–82]

Regulatory T Cells. Several different populations of regulatory T cells (Tregs) exist but the best characterized one is the $CD4^+CD25^+$ subset.[83] A recent study of this subset in psoriasis demonstrated impaired inhibitory function and failure to suppress effector T-cell proliferation.[84]



▲ **FIGURE 18-3** Histopathology of psoriasis. **A.** Pinpoint papule of psoriasis. In the transition from the edges to the center of the lesion, note progressive thickening of epidermis with elongation of rete pegs, increasing dilatation and tortuosity of vessels, and increasing mononuclear cell infiltrate. Also note the transition from basket-weave to compact stratum corneum with loss of granular layer in the center of the lesion. (4-mm punch biopsy, hematoxylin and eosin, scale bar = 100 μM.) **B.** Comparison of uninvolved versus involved skin. Four 4-mm biopsies were taken from the same individual sampled in **A** on the same day. "Uninvolved distant" skin was taken from the upper back 30 cm from the nearest visible lesion of psoriasis. "Uninvolved near edge" skin was taken 0.5 cm from the edge of a 20-cm plaque, which had been present for several years, according to the patient. "Center plaque" skin was taken from a relatively inactive (less red and scaly) area in the center of this plaque. "Involved edge" skin was taken from an active (more red and scaly) area about 1 cm inside the edge of the same plaque. In comparing "uninvolved distant" to "uninvolved near edge" skin, note that the latter manifests increased thickness and early elongation of the rete pegs, dilatation and early tortuosity of blood vessels, and increased numbers of mononuclear cells in the upper dermis, many of which are in a perivascular location. In this patient, "uninvolved near edge" skin also manifests an increased frequency of dyskeratotic keratinocytes, a finding that has been noted previously at the periphery of psoriatic lesions.[53] In comparing less active to more active areas of the plaque, note that the more active area manifests increased dermal mononuclear infiltrate, increased hyperkeratosis and parakeratosis, and Munro's microabscesses. (4-mm punch biopsies, hematoxylin and eosin, scale bar = 100 μM.)

Natural Killer and Natural Killer T Cells. Natural killer (NK) cells are major producers of IFN-γ and serve as a bridge between innate and acquired immunity. NK cells are present in psoriasis,[85,86] and can trigger the formation of psoriasis lesions in a xenograft model system.[87] NK cells are regulated in part by killer immunoglobulin-like receptors (KIRs), which recognize HLA-C and other MHC class I molecules. KIRs are a family of ~15 closely linked genes located on chromosome 19q13.4,[88] some of which stimulate and others of which inhibit NK cell activation. Recently, KIR genes have been associated with psoriasis[89–91] and psoriatic arthritis.[92,93]

Dendritic Cells. Treatments directed primarily against key co-stimulatory molecules expressed by "professional" antigen-presenting DCs markedly improve psoriasis.[39] This suggests that T cells in psoriatic lesions are in constant communication with DCs, which have a role in both the priming of adaptive immune responses and the induction of self-tolerance[95] (see Chap. 10). Several subsets of DCs have been defined, and many of these are found in a mature state within psoriatic lesions[96,97] (see Fig. 18-2). Although these cells are believed to be central to the pathogenesis of psoriasis, the specific role of each subset is still unclear.

LANGERHANS CELLS. (See Chap. 10) Langerhans cells (LCs) are considered to be immature DCs (iDCs). LCs have a well-defined role as antigen-presenting cells (APCs) in contact dermatitis,[98] but their role in psoriasis, in which their numbers are characteristically decreased,[96,99] is unclear. DCs lacking the characteristic Birbeck granule but positive for the maturation molecule DC-LAMP are found in the dermis of psoriatic lesions, suggesting that these cells mature and exit the epidermis during the course of lesion formation[100] (see Fig. 18-2). Interestingly, migration of LCs in response to inflammatory cytokines is markedly impaired in uninvolved psoriatic epidermis.[101]

INFLAMMATORY DENDRITIC EPIDERMAL CELLS. (See Chap. 10) Thought to be monocyte-derived iDCs,[102] inflammatory dendritic epidermal cells (IDECs) are distinguished from LCs by the lack of Birbeck granules and lower expression of CD1a. Unlike LCs, IDECs are nearly absent in normal skin, and their numbers are markedly increased in the epidermis of active psoriasis lesions, as well as a large number of other inflammatory dermatoses[96,99] (see Fig. 18-2).

DERMAL DENDRITIC CELLS. Identified initially by strong expression of MHC class II or factor XIIIa, dermal DCs do not express activation markers in resting normal skin and can be considered another type of iDC that is similar to myeloid iDCs found in other tissues.[103] Psoriasis lesions demonstrate a marked increase in the number and maturation state of these cells[96,104,105] (see Fig. 18-2).

PLASMACYTOID DENDRITIC CELLS. Plasmacytoid DCs (pDCs) are inefficient presenters of antigens to T cells. However, they regulate inflammation and link innate with adaptive immunity, producing large amounts of IFN-α when activated[106] (see Chap. 10). Absent from normal skin, pDCs are significantly increased in both uninvolved and involved psoriatic skin,

but activated only in involved skin.[96,107] Interestingly, inhibition of pDCs was shown to prevent development of psoriasis in a mouse xenograft model.[107] Conversely, imiquimod, which has been reported to exacerbate psoriasis,[108] likely acts through this type I IFN system by binding to Toll-like receptor 7 on pDCs.[109]

Mast Cells and Macrophages. Mast cells and macrophages are prominent in initial and developing psoriasis lesions (see Fig. 18-2). Many of the macrophages lie scattered just under the basement membrane, subadjacent to proliferating keratinocytes expressing the macrophage chemokine MCP-1.[110–112] These phagocytically active cells could be involved in generating fenestrations (holes) in the epidermal basement membrane.[113] Recent studies in two different mouse models of psoriasis, one dependent on and the other independent of T cells, showed that selective elimination of macrophages led to prompt improvement of lesions. These new findings suggest that macrophages may play a key role in the pathogenesis of psoriasis, at least in part via production of tumor necrosis factor (TNF)-α.[114–116]

Neutrophils. Although neutrophils are commonly seen in the upper epidermis of psoriatic lesions, they appear late during the development of lesions, their number is quite variable, and their role in the pathogenesis of psoriasis is unclear. Recent studies in one of the same mouse models used to implicate macrophages indicate that neutrophils are probably unnecessary for lesional development.[116]

Keratinocytes. Keratinocytes are a major producer of pro-inflammatory cytokines, chemokines, and growth factors,[117] as well as other inflammatory mediators such as eicosanoids[118] and mediators of innate immunity such as cathelicidins, defensins, and S100 proteins.[119] Psoriatic keratinocytes are engaged in an alternative pathway of keratinocyte differentiation called *regenerative maturation*.[120] Regenerative maturation is activated in response to immunologic stimulation in psoriasis,[121] but the mechanism by which this occurs is presently unknown.

Other Cell Types. Other cell types, such as endothelial cells and fibroblasts, are also likely to be participants in the pathogenic process. Endothelial cells are strongly activated in developing and mature lesions of psoriasis[53,54] and in addition to delivering a 10-fold increase in blood flow to the lesion, they play a major role in controlling the flux of leukocytes and serum proteins into psoriatic tissue.[122–124] Fibroblasts support keratinocyte proliferation in a paracrine manner,[125] and this process is exaggerated in psoriasis.[126] Fibroblasts produce many chemotactic factors and support the migration of T cells out of psoriatic lesions.[127] Thus, fibroblasts may also be intimately involved in psoriasis by directing the localization of T cells.

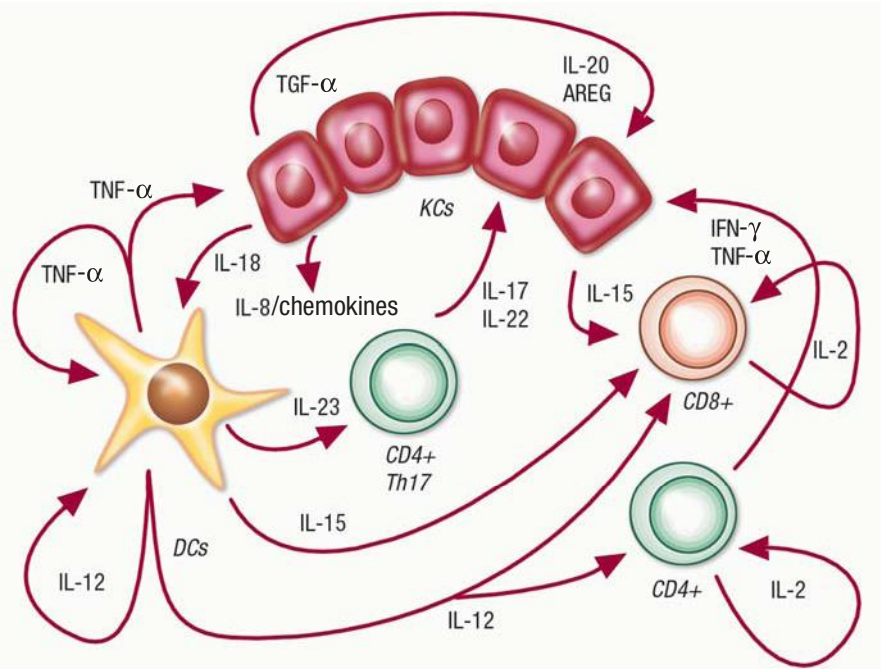
SIGNALING MOLECULES IN PSORIASIS

Cytokines and Chemokines. The cytokine network in psoriasis is extremely complex, involving the actions and interactions of multiple cytokines, chemokines, and growth factors and their receptors in addition to other mediators produced by multiple cell types.[63] Combinations of cytokines and growth factors can result in effects that are not seen when these factors are studied individually. For example, T-cell clones isolated from psoriatic skin lesions are able to promote keratinocyte proliferation in an IFN-γ–dependent manner,[128,129] but by itself, IFN-γ has an antiproliferative effect on cultured keratinocytes.[130]

Besides IFN-γ, a plethora of cytokines and chemokines are upregulated in psoriasis, including the cytokines TNF-α,[131] IL-2,[78] IL-6,[132] IL-8,[133] IL-15,[134] IL-17,[135] IL-18,[136] IL-19, IL-20, and IL-22[137] and the chemokines MIG/CXCL9, IP-10/CXCL10, I-TAC/CXCL11, and MIP3α/CCL20.[39,63] More complex abnormalities have been observed for other immunomodulatory cytokines and their receptors, including IL-1 and transforming growth factor-β.[138–140] The psoriatic plaque is characterized by the predominance of cytokines produced by Th1 cells (IFN-γ, IL2, and TNF-α) over those produced by Th2 cells (IL-4, IL-5, and IL-10). DCs also contribute cytokines to the environment, including IL-18, IL-20, IL-23, and TNF-α. IL-18 and IL-23 stimulate production of IFN-γ, and it is now clear that IL-23 and not IL-12 (which shares the p40 subunit with IL-23) is the predominant source of upregulated p40 expression in psoriatic lesions.[141] As mentioned earlier, IL-23 supports chronic inflammation by maintaining a separate $CD4^+$ T-cell subset characterized by IL-17 production.[80] Recently, this Th17 subset has been shown to elaborate IL-22, which mediates IL-23–induced dermal inflammation and epidermal hyperplasia in mice.[141a] The most prominent cytokines currently thought to be involved in the pathogenesis of psoriasis are summarized in Fig. 18-4.

Innate Immune Mediators. In addition to cytokines and chemokines, several mediators of innate immunity are abnormally expressed in psoriasis.[119] Prominent among the innate immune mediators are the antimicrobial peptides human β-defensin-2 (HBD-2) and cathelicidin (LL-37), both of which are increased in psoriasis but not in atopic dermatitis.[142] Notably, expression of HBD-2 and LL-37 is increased in response to pro-inflammatory and type I cytokines (TNF-α, IL-1, and IFN-γ) and suppressed by type II cytokines (IL-4, IL-10, and IL-13).[142] These differences in antimicrobial peptide expression help to explain why approximately 30 percent of patients with atopic dermatitis have bacterial or viral infections, as opposed to only 7 percent of psoriasis patients, even though both conditions have a defective skin barrier.[143] They may also explain why psoriasis patients, though frequently colonized with *Staphylococcus aureus*, are not markedly improved by antibiotic treatment, whereas atopic dermatitis patients often obtain dramatic benefit from antibiotic therapy. The S100 proteins are a large family of dimeric low-molecular-weight proteins that bind calcium and other divalent cations. S100A2, S100A7 (psoriasin), and the S100A8/A9 heterodimer (calprotectin) are markedly overexpressed in psoriasis lesions.[144] These proteins exert chemotactic and antimicrobial activity, the latter through sequestration of zinc ions.[145,146] Nitric oxide is produced in large amounts by DCs in psoriasis via the enzyme inducible nitric oxide synthase, where it appears to trigger multiple signal transduction events.[104] Finally, the complement component C5a is a potent chemoattractant for neutrophils and may contribute to the accumulation of neutrophils in the stratum corneum of psoriasis.[147] Interestingly, it is also the most potent chemoattractant for DCs in psoriatic scale extracts.[148] Many of these mediators are regulated in response to Toll-like receptors, providing a mechanism whereby the innate immune system can rapidly recognize a wide variety of pathogens according to their pathogen-associated molecular patterns[149] (see Chap. 10).

Eicosanoids. The role of eicosanoids in psoriasis remains unclear.[150] Levels of free arachidonic acid, leukotriene B4, 12-hydroxyeicosatetraenoic acid, and 15-hydroxyeicosatetraenoic acid are



▲ **FIGURE 18-4** Key cytokine interactions in psoriatic lesions. The cytokine network in psoriasis is extremely complex with interactions of multiple cytokines, chemokines, and growth factors involving multiple positive and negative feedback cycles. Only key cytokines are depicted in this figure. T helper 1 (Th1) cytokines such as interferon (IFN)-γ and tumor necrosis factor (TNF)-α are characteristic, and interleukin (IL)-23 was recently implicated in the pathogenesis.[82,141] IL-23 is thought to maintain and expand a specific subset of $CD4^+$ T cells, named Th17, which is characterized by production of IL-17 and IL-22. Other major cytokine producers in the lesional skin are dendritic cells (DCs), $CD4^+$, and $CD8^+$ T cells and keratinocytes (KCs). IFN-γ and TNF-α induce KCs to produce IL-7, IL-8, IL-12, IL-15, IL-18, and TNF-α besides a multitude of other cytokines, chemokines, and growth factors. IL-18 acts on DCs synergistically with IL-12 to further increase the production of IFN-γ. IL-7 and IL-15 are important for the proliferation and homeostatic maintenance of the $CD8^+$ T cells. IL-17 synergizes with IFN-γ to elicit further production of pro-inflammatory cytokines and chemokines by the KCs. TGF-α = transforming growth factor-α.

markedly increased in lesional skin, whereas levels of prostaglandins E and F2α are increased less than two-fold.

Growth Factors. Multiple growth factors are overexpressed in psoriasis.[151] Members of the epidermal growth factor (EGF) family induce their own production in keratinocytes, including transforming growth factor-α, amphiregulin (ARE6), and heparin-binding EGF-like growth factor.[152] Recent studies in xenografted mice found a reduction in epidermal hyperplasia after antibody-mediated neutralization of ARE6.[153] Activation of the EGF receptor stimulates keratinocyte production of vascular endothelial growth factor (VEGF),[122] perhaps accounting for the long-standing observation that the angiogenic properties of normal and psoriatic skin associate with the epidermis.[154] Polymorphisms in the VEGF gene have also been reported to be associated with psoriasis.[155] Nerve growth factor (NGF) is also overexpressed by keratinocytes in psoriatic skin, and NGF receptors are increased in the peripheral nerves of lesional skin. Paracrine growth factors produced outside the epidermal compartment may also play an important role in stimulating epidermal hyperplasia in psoriasis, including insulin-like growth factor-1[159] and keratinocyte growth factor.[160]

Proteases and Their Inhibitors. The psoriatic lesion is characterized by marked overexpression of multiple classes of proteinases by both keratinocytes and leukocytes. Metalloproteinases release TNF-α, several EGF-like growth factors, and many other cytokines and growth factors from their membrane-anchored precursors.[161] Leukocyte-derived elastase has also been implicated in the release of EGF-like growth factors.[162] Serine proteases directly activate protease-activated receptors.[163] Each of these mechanisms may contribute to stimulation of keratinocyte proliferation. The protease inhibitors elafin, serpinB3, and serpinB13 (hurpin) are among the most markedly overexpressed genes in psoriatic lesions,[164,165] suggesting that homeostatic mechanisms are strongly engaged in an effort to regulate the proteolytic environment of psoriatic lesions.

Integrins. Several observations suggest an early role for α5 integrins and their ligand fibronectin in psoriasis. Fibronectin is increased in psoriatic epidermis,[166] and it has been suggested that fibronectin gains access to the epidermis via fenestrations in the epidermal basement membrane.[167]

Signal Transduction. As would be expected given this plethora of intercellular signaling alterations, multiple signal transduction mechanisms are dysregulated in psoriatic epidermis, including receptor tyrosine kinase, mitogen-activated protein kinase, Akt, STAT, Src family kinase, and NF-κB pathways. These abnormalities affect immunocyte activation and trafficking as well as keratinocyte responses of proliferation, differentiation, and survival.

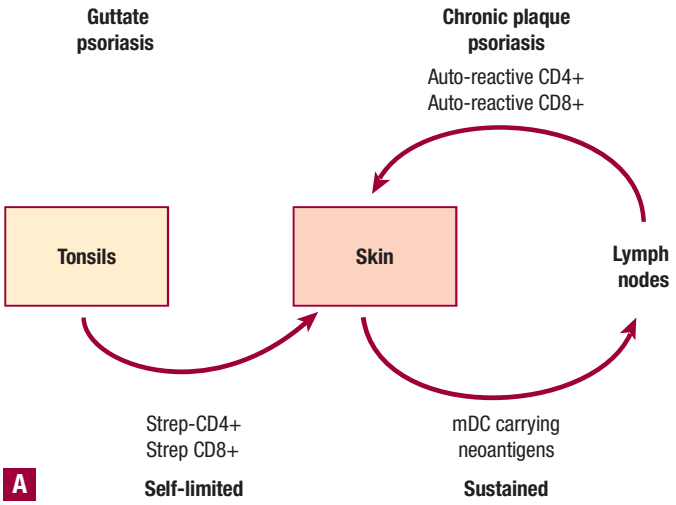
PSORIASIS AS AN AUTOIMMUNE DISEASE: INTEGRATING GENETICS AND IMMUNOLOGY $CD8^+$ T cells comprise at least 80 percent of the T cells in the epidermis of psoriatic lesions,[171] and their invasion into the epidermis correlates with lesional development.[77,172,173] Because it presents antigens to $CD8^+$ T cells, HLA-Cw6 is an excellent candidate for functional involvement in psoriasis. Fig. 18-5 is a model of the transition from guttate to chronic plaque psoriasis and of the role of HLA-Cw6 in the pathogenesis of psoriasis. Many aspects of this working model remain to be verified experimentally.

CLINICAL FINDINGS

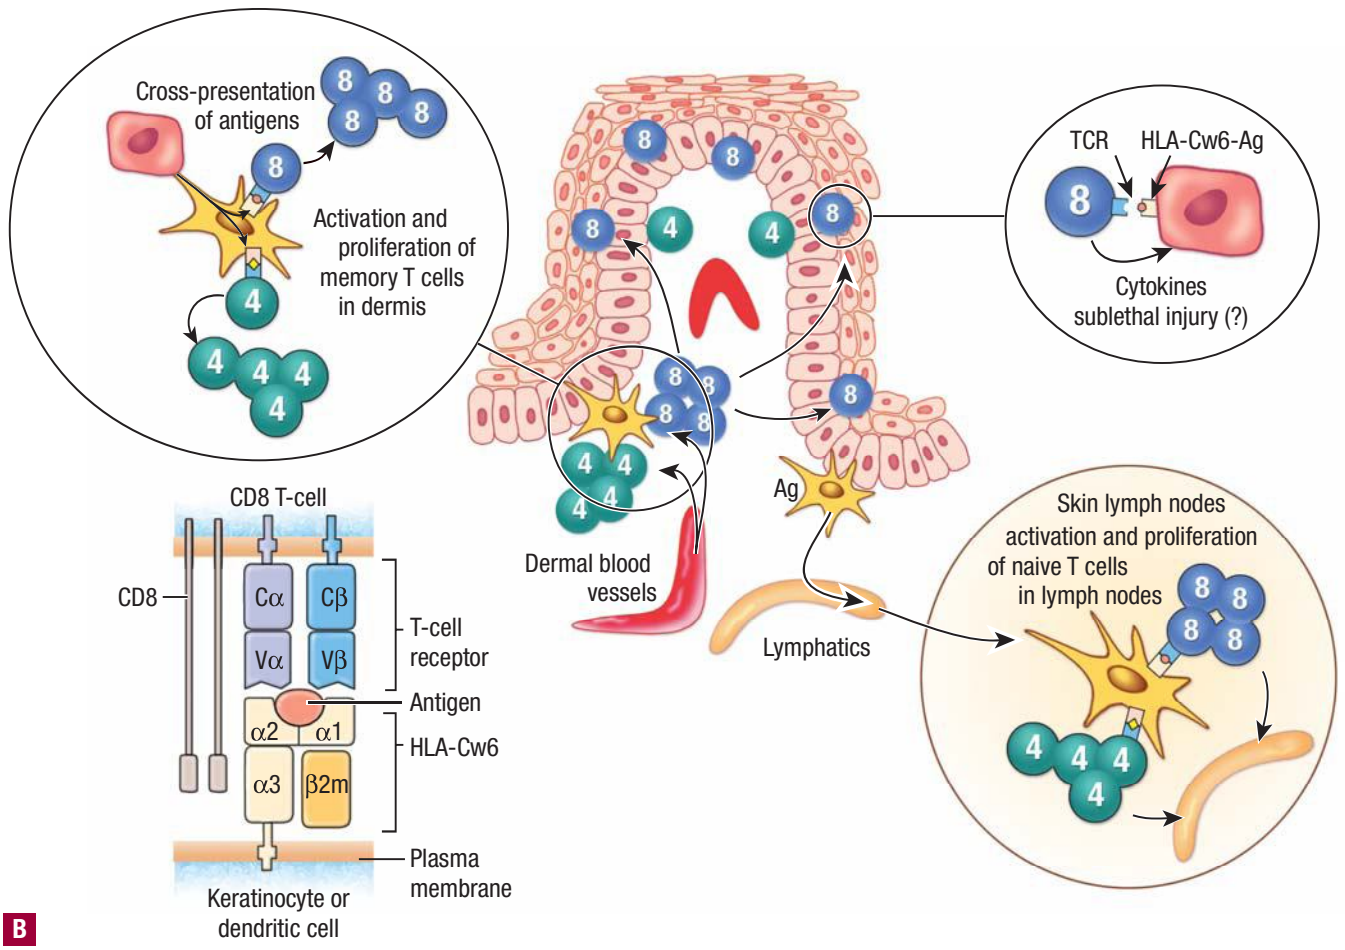
Fig. 18-6 is an algorithm showing clinical findings and treatment for psoriasis.

History

It is useful to determine the age at onset and the presence or absence of a family history of psoriasis, as younger age of onset and positive family history have been associated with more widespread and recurrent disease.[5,27] In addition, the physician should inquire about the prior course of the disease, as major differences exist between "acute" and "chronic" disease. In the latter form, lesions may persist unchanged for months or even years, whereas acute disease

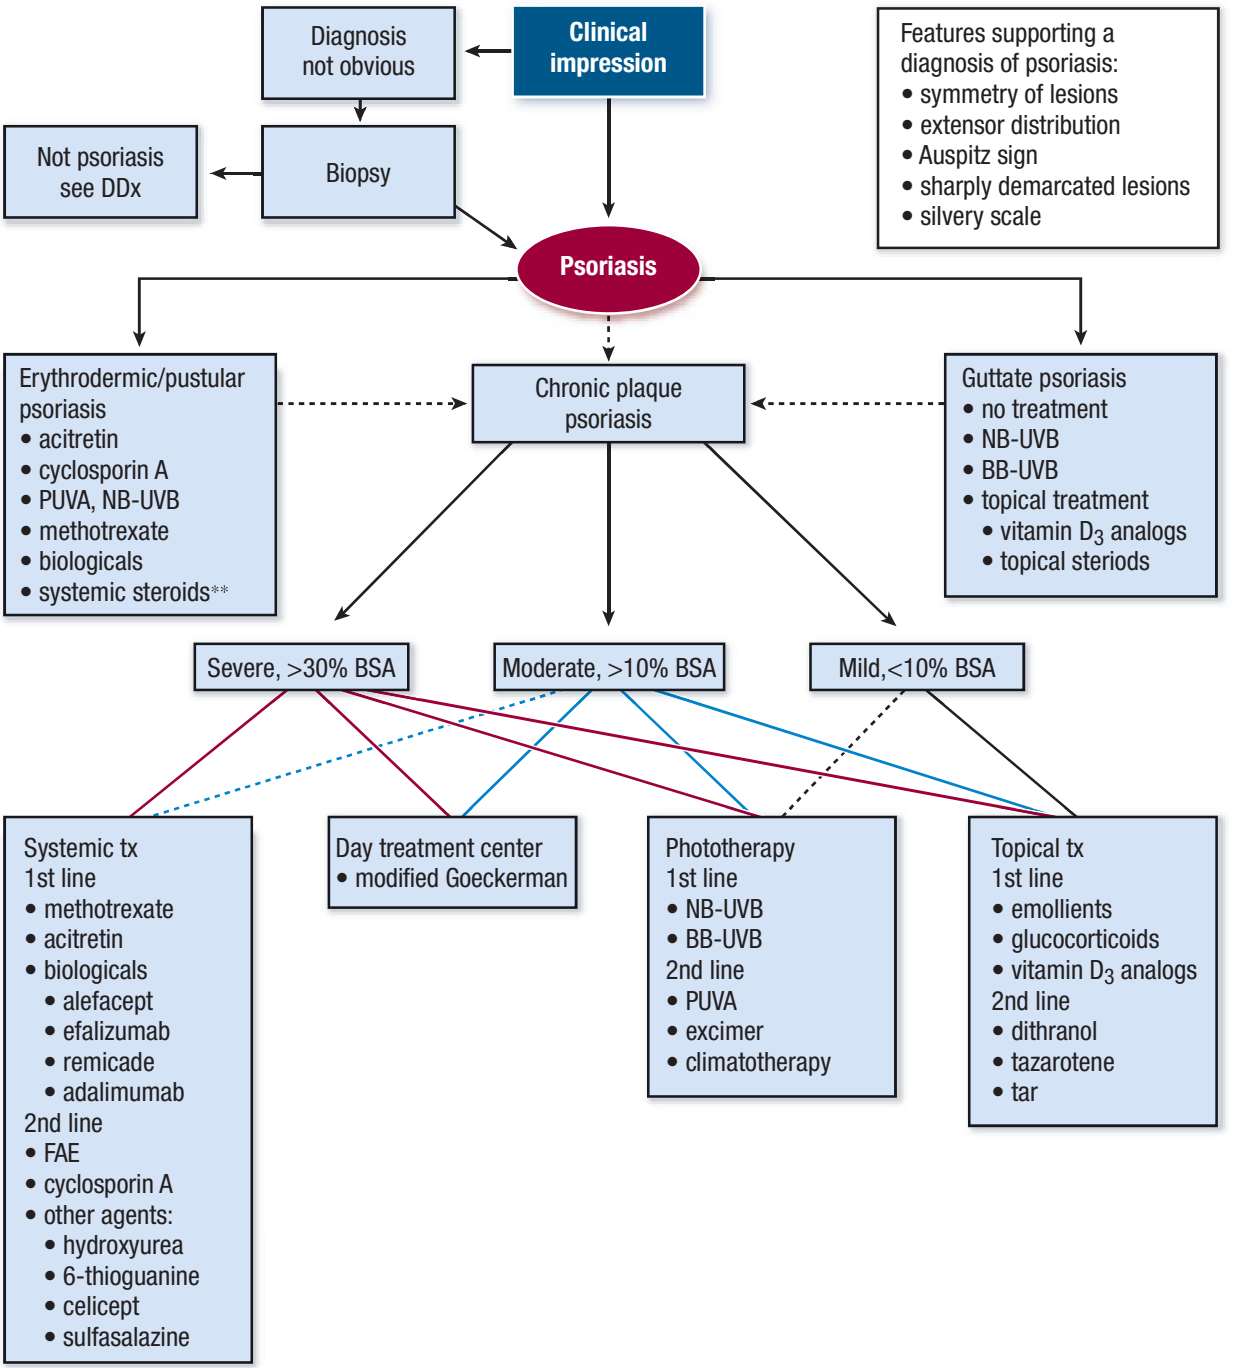


A



B

▲ **FIGURE 18-5** **A.** Proposed model for transition from guttate to chronic plaque psoriasis. It is envisaged that *Streptococcus*-specific T cells migrate from the tonsils into the skin where the T cells recognize cross-reactive antigens derived from keratinocytes with resulting inflammatory activity (guttate lesions). If effective cross-presentation does not occur, the disease process is self-limited. If effective cross-presentation is established in secondary skin lymphoid tissue, generation and recruitment of auto-reactive T cells occurs, with resulting chronicity of the process. **B.** Proposed role of HLA-Cw6 in the pathogenesis of psoriasis. The antigen in the binding pocket of HLA-C (in this case HLA-Cw6) interacts with a T-cell receptor (TCR). The region of the TCR that interacts directly with the antigen is the complement-determining region 3 (CDR3). Oligoclonality of the CDR3 region has been demonstrated for psoriatic $CD8^+$ T cells, strongly suggesting that psoriasis is an antigen-driven process. The role of HLA-Cw6 in psoriasis is likely to be two-fold. HLA-Cw6 is active in cross-presenting peptides on the surface of dendritic cells, allowing activation and clonal expansion of antigen-specific $CD8^+$ T cells. This process is dependent on $CD4^+$ T-cell help and is likely to happen both in the dermis (activation of memory resident T cells) and local lymph nodes (activation of naive T cells). Subsequently, the $CD8^+$ T cells are able to migrate into the epidermis where they encounter HLA-Cw6 on the surface of the keratinocytes presenting those same pathogenic peptides. This leads to release of inflammatory mediators by the $CD8^+$ T cells and activation of the keratinocytes, with the resulting development of psoriatic lesions. mDC = mature dendritic cells.



▲ **FIGURE 18-6** Diagnosis and treatment algorithm for psoriasis. The diagnosis of psoriasis is usually based on clinical features. In those few cases in which clinical history and examination is not diagnostic, biopsy is indicated to establish the correct diagnosis. The majority of psoriasis cases fall into three major categories; guttate, erythrodermic/pustular, and chronic plaque, of which the latter is by far the most common. Guttate psoriasis is often a self-limited disease with spontaneous resolution within 6 to 12 weeks. In mild cases of guttate psoriasis, treatment may not be needed, but, with widespread disease, ultraviolet B (UVB) phototherapy in association with topical therapy is very effective. Erythrodermic/pustular psoriasis is often associated with systemic symptoms and necessitates treatment with fast-acting systemic medications. The most commonly used drug for erythrodermic and pustular psoriasis is acitretin. In occasional cases of pustular psoriasis, systemic steroids may be indicated (**). *Dotted arrows* indicate that guttate, erythrodermic, and pustular forms often evolve into chronic plaque psoriasis. Therapeutic choices for chronic plaque psoriasis are typically based on the extent of the disease. Among the main treatment regimens (topical treatment, phototherapy, day treatment centers, and systemic treatments), first-line and second-line modalities are indicated by the *solid* and *dashed lines*, respectively. Individuals with conditions that limit their activities, including painful palmoplantar involvement and psoriatic arthritis, may require more potent treatments irrespective of the extent of affected body surface area. Likewise, psychological issues and the impact on quality of life should be taken into consideration. Within each treatment regimen, first-line and second-line choices are grouped. Cyclosporin A is not considered a first-line, long-term systemic treatment due to its side effects, but short-term treatment can be helpful for induction of remission. If patients have incomplete response to or are unable to tolerate individual first-line systemic medications, combination regimens (Table 18-5), rotational treatments, or use of biologic therapies should be considered. BB-UVB = broadband UVB; BSA = body surface area; DDx = differential diagnosis; FAE = fumaric acid ester; NB-UVB = narrowband UVB; PUVA = psoralen and UVA light; tx = therapy.

▲ **FIGURE 18-7** **A–F.** Chronic plaque psoriasis located at typical sites. Note marked symmetry of lesions. (Photos used with permission from Mr. Harrold Carter.)

shows sudden outbreak of lesions within a short time (days). Likewise, patients have great variability in regard to relapses. Some patients have frequent relapses occurring weekly or monthly, whereas others have more stable disease with only occasional recurrence. The frequently relapsing patients tend to develop more severe disease with rapidly enlarging lesions covering significant portions of the body surface[204] and may require more rigorous treatment compared to those with more stable disease. Certain medications may worsen psoriasis (see Treatment). The physician should also inquire about joint complaints. Although osteoarthritis is extremely common and can co-exist with psoriasis, a history of onset of joint symptoms before the fourth decade and/or a history of warm, swollen joints should raise the suspicion of psoriatic arthritis (see Chap. 19).

Cutaneous Lesions[205]

The classic lesion of psoriasis is a well-demarcated, raised, red plaque with a white scaly surface (Fig. 18-7). Lesions can vary in size from pinpoint papules to plaques that cover large areas of the body. Under the scale, the skin has a glossy homogeneous erythema, and bleeding points appear when the scale is removed, traumatizing the dilated capillaries below (the Auspitz sign) (Fig. 18-8).[205] Psoriasis tends to be a symmetric eruption, and symmetry is a helpful feature in establishing a diagnosis. Unilateral involvement can occur, however. The psoriatic phenotype may present a changing spectrum of disease expression even within the same patient.

Koebner phenomenon (also known as the *isomorphic response*) is the traumatic induction of psoriasis on nonlesional skin; it occurs more frequently during flares of disease and is an all-or-none phenomenon (i.e., if psoriasis occurs at one site of injury it will occur at all sites of injury) (Fig. 18-9). The Koebner reaction usually occurs 7 to 14 days after injury, and approximately 25 percent of patients may have a history of trauma-related Koebner phenomenon at some point in their lives.[206] Estimates of lifetime prevalence rise as high as 76 percent when factors such as infection, emotional stress, and drug reactions are included.[3] The Koebner phenomenon is not specific for psoriasis but can be helpful in making the diagnosis when present.

Clinical Patterns of Skin Presentation[205]

PSORIASIS VULGARIS, CHRONIC STATIONARY PSORIASIS, PLAQUE-TYPE PSORIASIS Psoriasis vulgaris is the most common form of psoriasis, seen in approximately 90 percent of patients. Red, scaly, symmetrically distributed plaques are characteristically localized to the extensor aspects of the extremities, particularly the elbows and knees, along with scalp, lower lumbosacral, buttocks, and genital involvement (see Fig. 18-7). Other sites of predilection include the umbilicus and the intergluteal cleft. The extent of involvement varies widely from patient to patient. There is constant production of large amounts of scale with little alteration in shape or distribution of individual plaques. Single small lesions may become confluent, forming plaques in which the borders resemble a land map (psoriasis geographica). Lesions may extend laterally and become circinate because of the confluence of several plaques (psoriasis gyrata). Occasionally, there is partial central clearing, resulting in ring-like lesions (annular psoriasis) (Fig. 18-10). This is usually associated with lesional clearing and portends a good prognosis. Other clinical variants of plaque psoriasis have been described, depending on the morphology of the lesions, particularly those associated with gross hyperkeratosis (see Fig. 18-10). *Rupioid psoriasis* refers to lesions in the shape of a cone or limpet. *Ostraceous psoriasis*, an infrequently used term, refers to a ring-like, hyperkeratotic concave lesion, resembling an oyster shell. Finally, elephantine psoriasis is an uncommon form characterized by thickly scaling, large plaques, usually on the lower extremities. A hypopigmented ring (Woronoff ring) surrounding individual psoriatic lesions may occasionally be seen and is usually associated with treatment, most commonly UV radiation or topical corticosteroids (see Fig. 18-10). The pathogenesis is not well understood but may result from inhibition of prostaglandin synthesis.[207]

GUTTATE (ERUPTIVE) PSORIASIS Guttate psoriasis (from the Latin *gutta*, meaning "a drop") is characterized by eruption of small (0.5 to 1.5 cm in diameter) papules over the upper trunk and proximal extremities (Fig. 18-11). It typically manifests at an early age and as such is found frequently in young adults. This form of psoriasis has the strongest association to HLA-Cw6,[22] and streptococcal throat infection frequently precedes or is concomitant with the onset or flare of guttate psoriasis.[208] However, antibiotic treatment has not been shown to be beneficial or to shorten the disease course.[209] Patients with a history of chronic plaque psoriasis may develop

▲ **FIGURE 18-11** Guttate psoriasis, involving thigh (**A**), hands (**B**), and back (**C** and **D**). The patient in **D** went on to develop chronic plaque psoriasis. (Photos used with permission from Drs. Johann Gudjonsson and Trilokraj Tejasvi, Mr. Harrold Carter, and Ms. Laura Vangoor.)

guttate lesions, with or without worsening of their chronic plaques.

SMALL PLAQUE PSORIASIS Small plaque psoriasis resembles guttate psoriasis clinically, but can be distinguished by its onset in older patients, by its chronicity, and by having somewhat larger lesions (typically 1 to 2 cm) that are thicker and scalier than in guttate disease. It is said to be a common adult-onset presentation of psoriasis in Korea and other Asian countries.[210]

INVERSE PSORIASIS Psoriasis lesions may be localized in the major skin folds, such as the axillae, the genito-crural region, and the neck. Scaling is usually minimal or absent, and the lesions show a glossy sharply demarcated erythema, which is often localized to areas of skin-to-skin contact (Fig. 18-12). Sweating is impaired in affected areas.[211]

ERYTHRODERMIC PSORIASIS Psoriatic erythroderma represents the generalized form of the disease that affects all body sites, including the face, hands, feet, nails, trunk, and extremities (Fig. 18-13). Although all the symptoms of psoriasis are present, erythema is the most prominent feature, and scaling is different compared with chronic stationary psoriasis. Instead of thick, adherent, white scale there is superficial scaling. Patients with erythrodermic psoriasis lose excessive heat because of generalized vasodilatation, and this may cause hypothermia. Patients may shiver in an attempt to raise their body temperature. Psoriatic skin is often hypohidrotic due to occlusion of the sweat ducts,[212] and there is an attendant risk of hyperthermia in warm climates. Lower extremity edema is common secondary to vasodilatation and loss of protein from the blood vessels into the tissues. High-output cardiac failure and impaired hepatic and renal function may also occur. Psoriatic erythroderma has a variable presentation, but two forms are thought to exist.[213] In the first form, chronic plaque psoriasis may worsen to involve most or all of the skin surface, and patients remain relative responsive to therapy. In

▲ **FIGURE 18-12** Inverse psoriasis. Note the well-demarcated, beefy-red, shiny plaques in **A**. The patient in **B** has atrophy and purpura of the upper inner arm, secondary to chronic topical corticosteroid treatment. (Photos used with permission from Mr. Harrold Carter.)

▲ **FIGURE 18-13** Erythrodermic psoriasis. The patient in **A** had chronic plaque psoriasis that progressed to near-complete involvement. The patient in **B** rapidly developed near-complete involvement and complained of fatigue and malaise. In both panels, note islands of sparing. (Photos used with permission from Mr. Harrold Carter.)

the second form, generalized erythroderma may present suddenly and unexpectedly or result from non-tolerated external treatment (e.g., UVB, anthralin), thus representing a generalized Koebner reaction. Generalized pustular psoriasis [see Generalized Pustular Psoriasis (von Zumbusch)] may revert to erythroderma with diminished or absent pustule formation. Occasional diagnostic problems may arise in differentiating psoriatic erythroderma from other causes (see Chap. 23).

PUSTULAR PSORIASIS Several clinical variants of pustular psoriasis exist: generalized pustular psoriasis (von Zumbusch type), annular pustular psoriasis, impetigo herpetiformis, and two variants of localized pustular psoriasis—pustulosis palmaris et plantaris and acrodermatitis continua. In children, pustular psoriasis can be complicated by sterile, lytic lesions of bones[214,215] and can be a manifestation of the SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, osteitis).[216]

Generalized Pustular Psoriasis (von Zumbusch). Generalized pustular psoriasis (von Zumbusch) is a distinctive acute variant of psoriasis. It is usually preceded by other forms of the disease. Attacks are characterized by fever that lasts several days and a sudden generalized eruption of sterile pustules 2 to 3 mm in diameter (Fig. 18-14). The pustules are disseminated over the trunk and extremities, including the nail beds, palms, and soles. The pustules usually arise on highly erythematous skin, first as patches (Fig. 18-15) and then becoming confluent as the disease becomes more severe. With prolonged disease, the fingertips may become atrophic. The erythema that surrounds the pustules often spreads and becomes confluent, leading to erythroderma. Characteristically, the disease occurs in waves of fevers and pustules. The etiology of generalized psoriasis von Zumbusch type is unknown. Various provoking agents include infections, irritating topical treatment (Koebner phenomenon), and withdrawal of oral corticosteroids.[217] This form of psoriasis is usually associated with prominent systemic signs and can potentially have life-threatening complications such as bacterial superinfection, sepsis, and dehydration.[218] Severe pustular psoriasis can be difficult to control and requires a potent treatment regimen with rapid onset of action to avoid life-threatening complications. Drugs commonly used include etretinate, methotrexate (MTX), cyclosporin, or oral corticosteroids.[219] Cases of acute respiratory distress syndrome associated with generalized pustular psoriasis have been reported.[220]

Exanthematic Pustular Psoriasis. Exanthematic pustular psoriasis tends to occur after a viral infection and consists of widespread pustules with generalized plaque psoriasis. However, unlike the von Zumbusch pattern, there are no constitutional symptoms, and the disorder tends not to recur.[205] There is an overlap between this form of pustular psoriasis and acute generalized exanthematous pustulosis, a type of drug eruption.

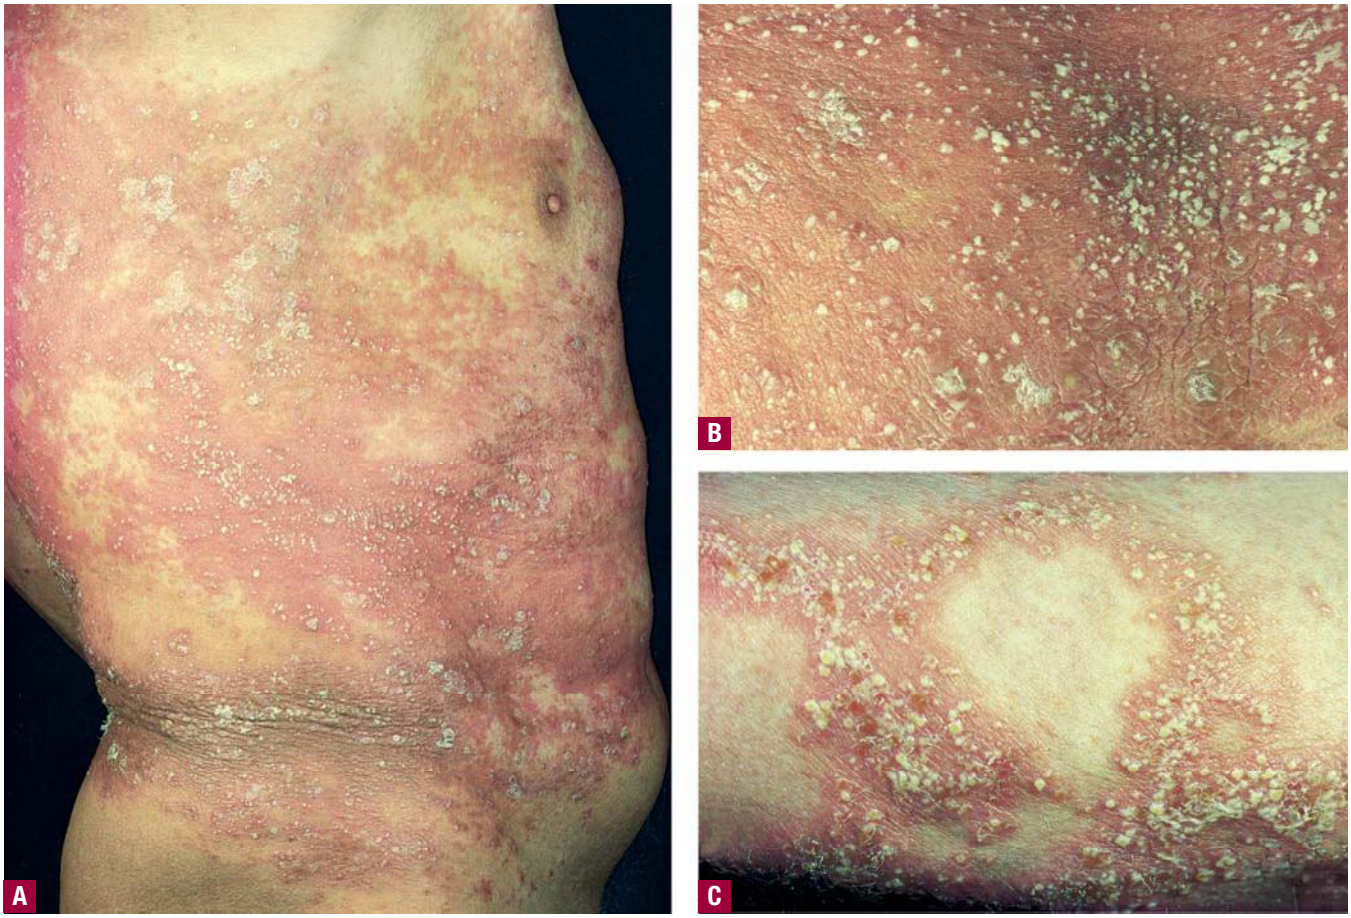
Annular Pustular Psoriasis. Annular pustular psoriasis is a rare variant of pustular psoriasis. It usually presents in an annular or circinate form. Lesions may appear at the onset of pustular psoriasis, with a tendency to spread and form enlarged rings, or they may develop during the course of generalized pustular psoriasis. The characteristic features are pustules on a ring-like erythema that sometimes resembles erythema annulare centrifugum. Identical lesions are found in patients with impetigo herpetiformis, an entity defined by some as a variant of pustular psoriasis occurring in pregnancy.[221] Onset in pregnancy is usually early in the third trimester and persists until delivery.[222] It tends to develop earlier in subsequent pregnancies. Impetigo herpetiformis is often associated with hypocalcemia.[217,223] There is usually no personal or family history of psoriasis.[224]

Localized Pustular Psoriasis Variants. Localized pustular psoriasis variants, including pustulosis palmaris et plantaris and acrodermatitis continua (of Hallopeau), are discussed in Chap. 21.

SEBOPSORIASIS A common clinical entity, sebopsoriasis presents with erythematous plaques with greasy scales localized to seborrheic areas (scalp, glabella, nasolabial folds, perioral and presternal areas, and intertriginous areas). In the absence of typical findings of psoriasis elsewhere, distinction from seborrheic dermatitis is difficult. Sebopsoriasis may represent a modification of seborrheic dermatitis by the genetic background of psoriasis and is relatively resistant to treatment. Although an etiologic role of *Pityrosporum* remains unproven, antifungal agents may be useful.[225]

NAPKIN PSORIASIS Napkin psoriasis usually begins between the ages of 3 and 6 months and first appears in the diaper (napkin) areas as a confluent red area with appearance a few days later of small red papules on the trunk that may also involve the limbs. These papules have the typical white scales of psoriasis. The face may also be involved with red scaly eruption. Unlike other forms of psoriasis, the rash responds readily to treatment and tends to disappear after the age of 1 year.

LINEAR PSORIASIS Linear psoriasis is a very rare form. The psoriatic lesion presents as linear lesion most commonly on the limbs but may also be limited to a dermatome on the trunk. This may be an underlying nevus, possibly an inflammatory linear verrucous epidermal ne-



▲ **FIGURE 18-14** **A–C.** Generalized, von Zumbusch-type pustular psoriasis. Tiny pustules, 1 to 2 mm in diameter on erythematous skin.

vus (ILVEN), as these lesions resemble linear psoriasis both clinically and histologically. The existence of a linear form of psoriasis distinct from ILVEN is controversial.[226]

▲ **FIGURE 18-15** Pustular psoriasis. Panel **B** is a close-up of the cluster of pustules in the left half of panel **A**. (Photo used with permission from Drs. Trilokraj Tejasvi and Neena Khanna.)

Related Physical Findings

NAIL CHANGES IN PSORIASIS (See also Chap. 87) Nail changes are frequent in psoriasis, being found in up to 40 percent of patients,[27] and are rare in the absence of skin disease elsewhere. Nail involvement increases with age, with duration and extent of disease, and with the presence of psoriatic arthritis. Several distinct changes have been described and can be grouped according to the portion of the nail that is affected (Table 18-1).[227–229]

Nail pitting is one of the commonest features of psoriasis, involving the fingers more often than the toes (Fig. 18-16). Pits range from 0.5 to 2.0 mm in size and can be single or multiple. The proximal nail matrix forms the dorsal (superficial) portion of the nail plate, and psoriatic involvement of this region results in pitting due to defective keratinization. Other alterations in the nail matrix resulting in deformity of the nail plate (onychodystrophy) include leukonychia, crumbling nail, and red spots in the lunula. Onychodystrophy has a stronger association with psoriatic arthritis than other nail changes.[27] Oil spots and salmon patches are translucent, yellow-red discolorations observed beneath the nail plate often extending distally toward the hyponychium, due to psoriasiform hyperplasia, parakeratosis, microvascular changes, and trapping of neutrophils in the nail bed.[228,229] Unlike pitting, which is also seen in alopecia areata and other disorders, oil spotting is considered to be nearly specific for psoriasis. Splinter hemorrhages result from capillary bleeding underneath the thin suprapapillary plate of the psoriatic nail bed. Subungual hyperkeratosis is due to hyperkeratosis of the nail bed and is often accompanied by onycholysis (separation of the nail plate from the nail bed), which usually involves the distal aspect of the nail. Anonychia is total loss of the nail plate. Although nail changes are rarely seen in the localized pustular variant of pustulosis palmaris et plantaris, anonychia can be seen in other forms of pustular psoriasis.

GEOGRAPHIC TONGUE Geographic tongue, also known as *benign migratory glossitis* or *glossitis areata migrans*, is an idiopathic inflammatory disorder resulting in the local loss of filiform papillae. The condition usually presents as asymptomatic ery-

TABLE 18-1
Nail Changes in Psoriasis

Nail Segment Involved	Clinical Sign
Proximal matrix	Pitting, onychorrhexis, Beau's lines
Intermediate matrix	Leukonychia
Distal matrix	Focal onycholysis, thinned nail plate, erythema of the lunula
Nail bed	"Oil drop" sign or "salmon patch," subungual hyperkeratosis, onycholysis, splinter hemorrhages
Hyponychium	Subungual hyperkeratosis, onycholysis
Nail plate	Crumbling and destruction plus other changes secondary to the specific site
Proximal and lateral nail folds	Cutaneous psoriasis

Modified from Del Rosso JQ et al: Dermatologic diseases of the nail unit, in *Nails: Therapy, Diagnosis, Surgery,* edited by Scher RK, Daniel CR. Philadelphia, W.B. Saunders, 1997, p 172, with permission.

thematous patches with serpiginous borders, resembling a map. These lesions characteristically have a migratory nature. Geographic tongue has been postulated to be an oral variant of psoriasis, as these lesions show several histologic features of psoriasis, including acanthosis, clubbing of the rete ridges, focal parakeratosis, and neutrophilic infiltrate. In addition, the prevalence of geographic tongue is increased in psoriatic patients.[230] However, geographic tongue is a relatively common condition and is seen in many non-psoriatic individuals, so its relationship to psoriasis needs further clarification.

PSORIATIC ARTHRITIS Arthritis is a common extra-cutaneous manifestation of psoriasis seen in up to 40 percent of patients. It has a strong genetic component, and several overlapping subtypes exist. This condition is discussed in Chap. 19.

Laboratory Tests

Although histopathologic examination is rarely necessary to make the diagnosis, it can be helpful in difficult cases. The histopathologic findings of guttate and chronic plaque psoriasis have already been described (see Development of Lesions). In early lesions of pustular psoriasis, the epidermis is usually only slightly acanthotic, whereas psoriasiform hyperplasia is seen in older and persistent lesions. Neutrophils migrate from dilated vessels in the upper dermis into the epidermis where they aggregate beneath the stratum corneum and in the upper Malpighian layer to form the spongiform pustules of Kogoj.

Other laboratory abnormalities in psoriasis are usually not specific and may not be found in all patients. In severe psoriasis vulgaris, generalized pustular psoriasis, and erythroderma, a negative nitrogen balance can be detected, manifested by a decrease of serum albumin.[231]

Psoriasis patients manifest altered lipid profiles, even at the onset of their skin disease.[232] Patients had 15 percent higher levels of high-density lipoproteins, and their cholesterol-triglyceride ratio for very low-density lipoprotein particles was 19 percent higher. Furthermore, plasma apolipoprotein-A1 concentrations were 11 percent higher in psoriasis patients. Whether these differences in lipid profile can explain or are contributing to an increased incidence of cardiovascular events in psoriasis remains to be seen.

Serum uric acid is elevated in up to 50 percent of patients and is mainly correlated with the extent of lesions and the activity of disease. There is an increased risk of developing gouty arthritis. Serum uric acid levels usually normalize after therapy.

Markers of systemic inflammation can be increased, including C-reactive protein, α_2-macroglobulin, and erythrocyte sedimentation rate. However, such elevations are rare in chronic plaque psoriasis uncomplicated by arthritis. Increased serum immunoglobulin (Ig) A levels and IgA immune complexes, as well as secondary amyloidosis, have also been observed in psoriasis, and the latter carries a poor prognosis.[233]

Special Tests

Immunostaining techniques, fluorescence-activated cell sorting of dissociated cell suspensions, and assessment of

Box 18-1

Differential Diagnosis of Psoriasis

PSORIASIS VULGARIS

Most Likely

- Discoid/nummular eczema
- Cutaneous T-cell lymphoma (CTCL)
- Tinea corporis

Consider

- Pityriasis rubra pilaris
- Seborrheic dermatitis
- Subacute cutaneous lupus erythematosus
- Erythrokeratoderma (the fixed plaques of keratoderma variabilis and/or progressive symmetric erythrokeratoderma
- Inflammatory linear verrucous epidermal nevus
- Hypertrophic lichen planus
- Lichen simplex chronicus
- Contact dermatitis
- Chronic cutaneous lupus erythematosus/discoid lupus erythematosus
- Hailey-Hailey disease (flexural)
- Intertrigo (flexural)
- *Candida* infection (flexural)

Always Rule Out

- Bowen disease/squamous cell carcinoma in situ
- Extramammary Paget disease

GUTTATE

Most Likely

- Pityriasis rosea
- Pityriasis lichenoides chronica
- Lichen planus

Consider

- Small plaque parapsoriasis
- PLEVA
- Lichen planus
- Drug eruption

Always Rule Out

- Secondary syphilis

ERYTHRODERMIC

Most Likely

- Drug-induced erythroderma
- Eczema
- CTCL/Sézary syndrome
- Pityriasis rubra pilaris

PUSTULAR

Most Likely

- Impetigo
- Superficial candidiasis
- Reactive arthritis syndrome
- Superficial folliculitis

Consider

- Pemphigus foliaceus
- Immunoglobulin A pemphigus
- Sneddon-Wilkinson disease (subcorneal pustular dermatosis)
- Migratory necrolytic erythema
- Transient neonatal pustular melanosis
- Acropustulosis of infancy
- Acute generalized exanthematous pustulosis

T-cell receptor gene rearrangements have been of major importance in elucidating the pathogenesis of psoriasis and in characterizing the response to antipsoriatic therapies, but are generally not required for diagnosis or management.

DIFFERENTIAL DIAGNOSIS (Box 18-1)

COMPLICATIONS

Patients with psoriasis have an increased morbidity and mortality from cardiovascular events, particularly those with severe and long duration of psoriasis skin disease.[234,235] Risk of myocardial infarction is particulary elevated in younger patients with severe psoriasis.[236]

Psoriasis patients have also been shown to have increased relative risk of lymphoma, particularly in patients with more severe disease.[237]

Psoriasis is emotionally disabling, carrying with it significant psychosocial difficulties. Emotional difficulties arise from concerns about appearance, resulting in lowered self-esteem, social rejection, guilt, embarrassment, emptiness, sexual problems, and impairment of professional ability.[238] The presence of pruritus and pain can aggravate these symptoms. Psychological aspects can modify the course of illness; in particular, feeling stigmatized can lead to treatment noncompliance and worsening of psoriasis.[239] Likewise, psychological stress can also lead to depression and anxiety.[240] The prevalence of suicidal ideation and depression in patients with psoriasis is higher than that reported in other medical conditions and the general population.[241] Thus, although the disease is not threatening to life itself, psoriasis can very significantly impair quality of life.[242] A comparative study reported reduction in physical and mental functioning comparable with that seen in cancer, arthritis, hypertension, heart disease, diabetes, and depression.[243] According to a recent survey, 79 percent of patients with severe psoriasis reported a negative impact on their lives.[244]

PROGNOSIS AND CLINICAL COURSE

Natural History[205]

Guttate psoriasis is often a self-limited disease, lasting from 12 to 16 weeks without treatment.[205] It has been estimated that one-third to two-thirds of these patients later develop the chronic plaque type of psoriasis.[4,174] In contrast, chronic plaque psoriasis is in most cases a lifelong disease, manifesting at unpredictable intervals. Spontaneous remissions, lasting for variable periods of time, may occur in the course of psoriasis in up to 50 percent of patients. The duration of remission ranges from 1 year to several decades. In two separate studies, remission ranged from 17 percent to 55 percent. In another study of patients followed for 21 years, 71 percent had persistent lesions, 13 percent were free of the disease, and 16 percent had intermittent lesions.[205] The cause of spontaneous remission is unknown, but could reflect successful generation of self-tolerance under the model of immunologic self-reactivity discussed earlier (see Psoriasis as an Autoimmune Disease).

Erythrodermic and generalized pustular psoriasis have a poorer prognosis, with the disease tending to be severe and persistent.[205]

Modifying Factors

OBESITY It has been demonstrated that obese individuals are more likely to present with severe psoriasis (defined as > 20 percent body surface area involvement).[244] However, obesity does not appear to have a role in defining the onset of psoriasis.[245]

SMOKING Smoking (more than 20 cigarettes daily) has also been associated with more than a twofold increased risk of severe psoriasis.[246] Unlike obesity, smoking

TABLE 18-2
Topical Treatments for Psoriasis

	Topical Steroids	Vitamin D Analogues	Tazarotene	Calcineurin Inhibitors
Mechanism of action	Bind to glucocorticoid receptors, inhibiting the transcription of many different AP-1– and NF-κB–dependent genes, including IL-1 and tumor necrosis factor-α.	Bind to vitamin D receptors, influencing the expression of many genes. Promote keratinocyte differentiation.	Metabolized to tazarotenic acid, its active metabolite,[358] which binds to retinoic acid receptors. Normalizes epidermal differentiation, exhibits a potent antiproliferative effect, and decreases epidermal proliferation.	Bind to FK506-binding protein (FKBP) and inhibit calcineurin, decreasing the activation of the transcription factor, NF-AT, with resultant decrease in cytokine transcription, including IL-2.
Dosing	10,000-fold range of potency. High-potency steroids are applied to affected areas twice daily for 2–4 wk and then intermittently (weekends).	Calcipotriene, 0.005%, to affected areas twice daily. Often used alternating with topical steroids (i.e., vitamin D analogues on weekdays, topical steroids on weekends).	Available in 0.05% and 0.1% formulations, both as cream and gels. Apply every night to affected area.	Application to affected areas twice daily.
Efficacy	Very effective as short-term treatment.	Efficacy is increased by combination with topical steroids. Can be combined with various other therapies.	Efficacy is increased by combination with topical steroids.[359]	Effective for treatment of facial and flexural psoriasis[268] but minimally for chronic plaque psoriasis.[267]
Safety	Suppression of the hypothalamic-pituitary-adrenal axis (higher risk in children). Atrophy of the epidermis and dermis. Formation of striae. Tachyphylaxis.[257]	Development of irritation at the site of application is common.[257] Isolated reports of hypercalcemia in patients who applied excessive quantities.[360]	When used as monotherapy, significant proportion of patients develop irritation at the site of application.[361]	Burning sensation at the site of application. Case reports of development of lymphoma.
Contraindications	Hypersensitivity to the steroid, active skin infection.	Hypercalcemia, vitamin D toxicity.	Pregnancy, hypersensitivity to tazarotene.	Use only with caution for treatment of children younger than the age of 2 yr.
Remarks/long-term use	Long-term use increases risk of side effects.	Calcipotriol is well tolerated and continues to be clinically effective with minimum of adverse effects in long-term use.[362,363]	Combination of steroid with tazarotene may reduce atrophy seen with super-potent topical steroids.[359] If added during phototherapy, the ultraviolet doses should be reduced by one-third.[257]	Due to anecdotal reports of association with malignancy, this class of medications recently received a black-box warning by the U.S. Food and Drug Administration.
Pregnancy category	C	C	X	C

AP = activator protein; IL = interleukin; NF = nuclear factor; NF-AT = nuclear factor of activated T cells.

appears to have a role in the onset of psoriasis.[245] Recently, a gene-environment interaction has been identified between low activity of the cytochrome P_{450} gene CYP1A1 and smoking in psoriasis.[247]

INFECTION An association between streptococcal throat infection and guttate psoriasis has been repeatedly confirmed.[208,248] Streptococcal throat infections have also been demonstrated to exacerbate preexisting chronic plaque psoriasis.[175]

Severe exacerbation of psoriasis can be a manifestation of human immunodeficiency virus (HIV) infection.[249] Like psoriasis in general, HIV-associated psoriasis has a strong association with HLA-Cw6.[250] Interestingly, the prevalence of psoriasis in HIV infection is no higher than in the general population (1 percent to 2 percent of patients[249,250]), indicating that this infection is not a trigger for psoriasis but rather a modifying agent. Psoriasis is increasingly more severe with progression of immunodeficiency but can remit in the terminal phase.[251,252] This paradoxical exacerbation of psoriasis may be due to loss of regulatory T cells and increased activity of the CD8 T-cell subset.[171] Psoriasis exacerbation in HIV disease may be effectively treated with antiretroviral therapy.[253,254]

DRUGS Medications that exacerbate psoriasis include antimalarials, β blockers, lithium, nonsteroidal anti-inflammatory drugs, IFNs-α and -γ, imiquimod, angiotensin-converting enzyme inhibitors, and gemfibrozil.[255] Imiquimod acts on pDCs and stimulates IFN-α production,[107] which then strengthens both innate and Th1 immune responses. Lithium has been proposed to cause exacerbation by interfering with calcium release within keratinocytes, whereas β blockers are thought to interfere with intracellular cyclic adenosine monophosphate levels.[255] The mechanisms by which the remaining medications exacerbate psoriasis are largely unknown. Patients with active or unstable psoriasis should receive advice when traveling to countries where antimalarial prophylaxis is needed.

TREATMENT

General Considerations

A broad spectrum of anti-psoriatic treatments, both topical and systemic, is available for the management of psoriasis. As detailed in Tables 18-2 to 18-6, it is notable that most if not all of these treatments are immunomodulatory. When choosing

TABLE 18-3
Phototherapy of Psoriasis

	Narrowband UVB (NB-UVB; 310–331 nm)	Broadband UVB (BB-UVB)	Psoralen and UVA Light (PUVA)	Excimer Laser (308 nm)
Dosing	Determine MED. Initial treatment at 50% of MED followed by three to five treatments weekly. Lubricate before treatment. Advance treatment by at least 10% of the MED.[364] (Fitzpatrick skin types I–III, 10%–15%; skin types IV–VI, 15%–20%).[365]	Determine MED. Initial treatment often at 75% of MED. Advance treatment by at least 10% of MED (Fitzpatrick skin types I–III, 10%–15%; skin types IV–VI, 15%–20%).[365]	Dose based on MPD is recommended. If MPD testing is impractical, a regimen based on skin type may be used. Initial dose 0.5–2.0 J/cm^2, depending on skin type (or MPD). Treat twice weekly, increments of 40% per week until erythema, then maximum 20% per week. No further increments once 15 J/cm^2 is reached.[366]	Up to 6 MED (2–6 MED), twice weekly.
Efficacy	> 70% improvement in a split body study after 4 wk of treatment. Nine out of eleven patients showed clearance.[365] More effective than BB-UVB.[273,274,365]	47% improvement in a split body study after 4 wk, only 1 out of 11 patients showed clearance.[365]	Induces remission in 70%–90% of patients.[367–369] Less convenient than NB-UVB but may be more effective.[277]	Seventy-five percent improvement in Psoriasis Area and Severity Index in 72% of patients in an average of 6.2 treatments.[370]
Safety	Photodamage, polymorphic light eruption, increased risk of skin aging and skin cancers although lower than that for PUVA.[371]	Photodamage, polymorphic light eruption, increased risk of skin aging and skin cancers.	Photodamage, premature skin aging, increased risk of melanoma and nonmelanoma skin cancers, ocular damage. Eye protection required with oral psoralens.	Erythema, blisters, hyperpigmentation, and erosions. Long-term side effects not yet clear but likely similar to NB-UVB.
Contraindications	Absolute: Photosensitivity disorders. Relative: Photosensitizing medications, melanoma, and nonmelanoma skin cancers.	Absolute: Photosensitivity disorders. Relative: Photosensitizing medications, melanoma, and nonmelanoma skin cancers.	Absolute: Light-sensitizing disorder, lactation, melanoma. Relative: Age < 10 yr, pregnancy, photosensitizing medications, nonmelanoma skin cancers, severe organ dysfunction.	Absolute: Photosensitivity disorders. Relative: Photosensitizing medications, melanoma, and nonmelanoma skin cancers.
Remarks	Effective as a monotherapy, but coal tar (Goeckerman regimen), anthralin (Ingram regimen), or systemic therapies may increase effectiveness in resistant cases.[364]	Coal tar (Goeckerman regimen), anthralin (Ingram regimen), or systemic therapies may increase effectiveness in resistant cases.	< 200 total treatments (or < 2000 J/cm^2 UVA) are recommended.[372] Combination with oral retinoids can reduce cumulative UVA exposure.	Normal skin is spared from unnecessary radiation exposure, as therapy is selectively directed toward lesional skin.[282]

MED = minimal erythema dose; MPD = minimal phototoxic dose; UVB = ultraviolet B; UVA = ultraviolet A.

a treatment regimen (see Fig. 18-6) it is important to reconcile the extent and the measurable severity of the disease with the patient's own perception of his or her disease. In this context, it is notable that a recent study found that 40 percent of patients felt frustrated with the ineffectiveness of their current therapies, and 32 percent reported that treatment was not aggressive enough.[244] As psoriasis is a chronic condition, it is important to know the safety of a treatment during long-term use. In most treatments, the duration of a treatment is restricted because of the cumulative toxicity potential of an individual treatment, and, in some instances, treatment efficacy may diminish with time (tachyphylaxis). Some treatments, such as calcipotriol, MTX, and acitretin, can be regarded as appropriate for continuous use.[256] These treatments maintain efficacy and have low cumulative toxicity potential. In contrast, topical corticosteroids, dithranol, tar, photo(chemo)therapy, and cyclosporin are not indicated for continuous chronic use, and combinatorial or rotational treatments[256] are suggested. However, patients with stable chronic plaque psoriasis who respond well to local treatments may not require a change of treatment.[256] In cases of itchy/pruritic psoriasis, treatments with an irritative potential, such as dithranol, vitamin D_3 analogues, and photo(chemo)therapy, should be used cautiously, whereas treatments with potent anti-inflammatory effects, such as topical corticosteroids, are more appropriate.[256]

In patients with erythrodermic and pustular psoriasis, treatments with an irritant potential should be avoided, and acitretin, MTX, or short-course cyclosporin are the treatments of first choice.[256]

See Boxes 18-2 and 18-3 for special considerations in the treatment of women of child-bearing potential and pregnancy and children.

Topical Treatments (see Table 18-2)[257,258]

Most cases of psoriasis are treated topically. As topical treatments are often cosmetically unacceptable and time-consuming to use, non-compliance is on the order of 40 percent.[259] In most cases, ointment formulations are more effective than creams but are less cosmetically acceptable. For many patients, it is worth prescribing both cream and ointment formulations; cream for use in the morning and ointment for nighttime.[260]

CORTICOSTEROIDS Glucocorticoids exert many if not all of their myriad effects by stabilizing and causing nuclear translocation of glucocorticoid receptors, which are members of the nuclear hormone receptor superfamily. Topical glucocorticoids are commonly first-line therapy in mild to moderate psoriasis and in sites such as the flexures and genitalia, where other topical treatments can induce irritation. Improvement is usually achieved within 2 to 4 weeks, with maintenance treatment consisting of intermittent applications (often restricted to the weekends). Tachyphylaxis to treatment with topical corticosteroids is a well-estab-

TABLE 18-4
Systemic Treatments for Psoriasis

	Cyclosporin A	Methotrexate	Acitretin	Fumaric Acid Esters
Mechanism of action	Binds cyclophilin, and the resulting complex blocks calcineurin, reducing the effect of the NF-AT in T cells, resulting in inhibition of interleukin 2 and other cytokines.	Blocks dihydrofolate reductase, leading to inhibition of purine and pyrimidine synthesis. Also blocks AICAR transformylase, leading to accumulation of anti-inflammatory adenosine.[373]	Binds to retinoic acid receptors. May contribute to improvement by normalizing keratinization and proliferation of the epidermis.	Interferes with intracellular redox regulation, inhibiting NF-κB translocation. Skews the T-cell response toward a Th2-like pattern.[374]
Dosing	High-dose approach: 5 mg/kg daily, then tapered. Low-dose approach: 2.5 mg/kg daily, increased every 2–4 wk up to 5 mg/kg daily.[375] Tapering is recommended on discontinuation.	Start with a test dose of 2.5 mg and then gradually increase dose until a therapeutic level is achieved (average range, 10–15 mg weekly; maximum, 25–30 mg weekly).[375]	Initiate at 25–50 mg daily and escalate and titrate to response.[375]	Initiate at low dose, and escalate dose weekly. After treatment response is achieved, the dose should be individually adjusted. The maximum dose is 1.2 g/day.[299]
Efficacy	Very effective, up to 90% of patients achieve clearance or marked improvement.[376,377]	May reduce the severity of psoriasis by at least 50% in more than 75% of patients.[260]	Modestly effective as monotherapy.[260]	80% Mean reduction in Psoriasis Area and Severity Index.[378]
Safety	Nephrotoxicity, HTN, immunosuppression. Increased risk of malignancy if before PUVA.	Hepatotoxicity, chronic use may lead to hepatic fibrosis. Fetal abnormalities or death, myelosuppression, pulmonary fibrosis, severe skin reactions. Rarely, severe opportunistic infections.	Hepatotoxicity, lipid abnormalities, fetal abnormalities or death, alopecia, mucocutaneous toxicity, hyperostosis.	GI symptoms, including diarrhea. Flushing ± headaches. Lymphopenia, acute renal failure.[299,378]
Monitoring	BP. Obtain baseline CBC, CMP, magnesium, uric acid, lipids, UA. Repeat tests every 2–4 wk, then every month along with BP.[285]	Baseline CBC and LFTs. Monitor CBC and LFTs weekly until target dose is achieved, then every 4–8 wk.[285] Liver biopsy every 1.5 g of cumulative dose or use procollagen III assay.	Baseline LFTs, CBC, lipids, pregnancy test. Repeat LFTs, CBC, lipids every week for 1 mo then every 4 wk. Pregnancy test every month for females. Spinal x-rays if symptoms.	Baseline CBC, CMP, UA. Repeat tests every month for the first 6 mo and bi-monthly thereafter.[299]
Contraindications	Absolute: Uncontrolled HTN, abnormal renal function, history/current malignancy.	Absolute: Pregnancy, lactation. Relative: Hepatic dysfunction, hepatitis, renal insufficiency.	Absolute: Pregnancy during or within 3 years after termination of acitretin, lactation.	Absolute: Patients with chronic disease of the GI tract or renal disease. Pregnant or lactating women. Malignancy (or history of).[299]
Remarks/ long-term use	Intermittent short-course treatments appear to be safer than chronic long-term use.[377,379]	With appropriate monitoring, long-term use appears to be safe.	Retinoids have been combined with PUVA and occasionally with UVB in an attempt to minimize the side effects and to improve therapeutic response.[260]	Not U.S. Food and Drug Administration-approved for psoriasis but widely used in Europe. New formulations may reduce risk of GI symptoms.
Pregnancy category	C	X	X	C
	Hydroxyurea	**6-Thioguanine**	**Mycophenolate Mofetil**	**Sulfasalazine**
Mechanism of action	Inhibits ribonucleotide diphosphate reductase, which converts ribonucleotides to deoxyribonucleotides, thus selectively inhibiting DNA synthesis in proliferating cells.	Purine analog that interferes with purine biosynthesis, thereby inducing cell cycle arrest and apoptosis.	A noncompetitive inhibitor of inosine monophosphate dehydrogenase, blocking de novo purine biosynthesis. Selectively cytotoxic for cells that rely on de novo purine synthesis (i.e., lymphocytes).	Anti-inflammatory agent, inhibits 5-lipoxygenase, molecular mechanism unclear.
Dosing	500 mg daily, increased to 1.0–1.5 g daily based on response and tolerance.[285]	Starting dose is 80 mg twice weekly, with 20-mg increments every 2–4 weeks. Maximum dose, 160 mg three times weekly.[285]	Doses often initiated at 500–750 mg bid and then increased to 1.0–1.5 g bid.	Starting dose: 500 mg tid. If tolerated after 3 days, increase dose to 1 g tid. If tolerated after 6 wk, increase dose to 1 g qid.[285]

(continued)

TABLE 18-4
Systemic Treatments for Psoriasis (Continued)

	Hydroxyurea	6-Thioguanine	Mycophenolate Mofetil	Sulfasalazine
Efficacy	In a study of 85 patients with extensive chronic plaque psoriasis, 61% had satisfactory remission.[380]	A small retrospective cohort study demonstrated > 90% improvement in up to 80% of patients.[303]	Appears to be only moderately effective for treatment of psoriasis.[381,382]	Appears to be moderately effective treatment for severe psoriasis.[383]
Safety	Bone marrow suppression, macrocytosis. Teratogenicity and mutagenicity. Dermatologic side effects: lichen planus–like eruptions, exacerbation of post-irradiation erythema, leg ulcers, and dermatomyositis changes.	Bone marrow suppression; GI complaints, including nausea and diarrhea; hepatic dysfunction. Instances of hepatovenous-occlusive disease have been reported.[304]	GI, including constipation, diarrhea, nausea and vomiting, bleeding. Myelosuppression, leukopenia. Headaches, HTN, peripheral edema. Infectious disease, lymphoma.	Headache, nausea and vomiting, which occur in approximately one-third of patients. Rashes, pruritus, and hemolytic anemia (associated with G6PD deficiency).
Monitoring	Baseline CBC, CMP, LFTs. Repeat baseline tests weekly for 4 wk then every 2–4 wk for at least 12 wk. Then repeat tests every 3 mo.[285] Hold dosage if WBC $< 2.5 \times 10^9$/L, platelet count is $< 100 \times 10^9$/L or severe anemia.	Baseline CBC, CMP, LFTs. Repeat baseline tests weekly during dose escalation, then every 2 wk. Hold if WBC $\leq 4.0 \times 10^9$/L, platelet count is $< 125 \times 10^9$/L, or hemoglobin < 110 g/L.[285]	Baseline CBC and CMP. Repeat laboratory tests weekly × 6 wk, then every 2 wk × 2 mo, and then monthly. Monitor BP.	Baseline CBC, CMP, and G6PD. Repeat CBC and CMP weekly for 1 mo, then every 2 wk for 1 mo, then monthly for 3 mo, and then every 3 mo.
Contraindications	Absolute: Prior bone marrow depression (leukopenia, thrombocytopenia, anemia), pregnancy, lactation. Relative: Renal abnormalities.	Absolute: Patients with inherited deficiency of thiopurine methyltransferase enzyme have increased risk of myelosuppression. Liver toxicity. Pregnancy.	Absolute: Patients with severe infections, malignancy.[285]	Absolute: Hypersensitivity to sulfasalazine, sulfa drugs, salicylates, intestinal or urinary obstruction, porphyria. Precaution in patients with G6PD deficiency.
Remarks/ long-term use	Limited experience with long-term treatment.	Patients have been effectively maintained on treatment for up to 33 mo.[384]	Limited experience with long-term treatment.	Limited experience with long-term treatment.
Pregnancy category	D	D	C	B

AICAR = 5-Aminoimidazole-4-carboxamide ribonucleotide; BP = blood pressure; CBC = complete blood cell count; CMP = comprehensive metabolic panel; G6PD = glucose-6-phosphate dehydrogenase; GI = gastrointestinal; HTN = hypertension; LFTs = liver function tests; NF = nuclear factor; NF-AT = nuclear factor of activated T cells; PUVA = psoralen and UVA light; Th = T helper; UA = urinalysis; UV = ultraviolet; WBC = white blood cell count.

TABLE 18-5
Combination Treatments for Psoriasis

	Topical Vitamin D_3	Topical Corticosteroids	Dithranol	Coal Tar	Tazarotene	Ultraviolet B (UVB)	Psoralen and UVA Light (PUVA)	Methotrexate (MTX)	Cyclosporin A (CsA)
Acitretin	++	+	+	+	+	++	++	−	±
CsA	++	+	+	+	+	±	−	±

TABLE 18-6
Biologic Treatments for Psoriasis

	ALEFACEPT	EFALIZUMAB	ETANERCEPT	INFLIXIMAB	ADALIMUMAB
Mechanism	Binds CD2 on T cells, blocking the CD2-LFA3 interaction, thus interfering with T-cell activation and causing T-cell apoptosis.	Binds CD11a (α subunit of LFA-1). Blocks the interaction of LFA-1 with intercellular adhesion molecule-1. Inhibits T-cell activation, trafficking, and adhesion to keratinocytes.	Human recombinant, soluble TNF-α receptor. Binds TNF-α and neutralizes its activity.	Chimeric monoclonal antibody that has high specificity, affinity, and avidity for TNF-α.	Fully human recombinant monoclonal antibody that specifically targets TNF-α.
Dosing	15 mg IM once weekly.	Subcutaneous injections. Conditioning: 0.7 mg/kg. Maintenance: 1 mg/kg weekly.	25- to 50-mg injections subcutaneously twice weekly.	Intravenous infusions over 2 h. 5–10 mg/kg at weeks 0, 2, and 6.	40-mg injections subcutaneously every other week.
Efficacy	PASI-75 at 14 wk (2 wk after last dose) 24%. Patients who respond maintain improvement for extended periods of time. Repeat courses are safe and well tolerated.[385]	PASI-75 at 12 wk, 22%–41%;[386–388] at 24 wk, 44%;[389] and at 27 mo of extended treatment, 56%.[388]	PASI-75 at 12 wk, 34% and at 24 wk, 44%.[390]	PASI-75 at 10 wk, 82% (5 mg/kg) and 91% (10 mg/kg).[391] At wk 26 (following a single course), 57% of patients maintained PASI-50, and 50% maintained PASI-75.[391]	PASI-75 at 24 weeks 59%.[392]
Safety	Lymphopenia, malignancy, serious infections. Not recommended for human immunodeficiency virus–positive patients. Effects of live vaccines not studied.	Serious infections, thrombocytopenia, exacerbation of psoriasis. Live vaccinations not recommended.	Serious infections, exacerbation of MS, pancytopenia, malignancy. Worsening congestive heart failure. Lupus-like symptoms (anti-dsDNA positive). Live vaccinations should not be given.	Infusion-related reactions, infections, worsening of MS, malignancy or lymphoproliferative disease, worsening heart failure. Lupus-like symptoms (anti-dsDNA positive). Live vaccinations should not be given.	Injection site reactions, infections, lupus-like syndrome, worsening heart failure, cytopenias, neurologic events.[393] Live vaccinations should not be given.
Monitoring	$CD4^+$ T-cell counts every 2 wk during treatment.	Regular platelet counts.	Baseline PPD.	Baseline PPD.	Baseline PPD.
Long-term administration	Up to nine courses have been administered over 4–5 yr in small number of patients with incremental benefits.	PASI responses continue to increase to wk 24 and are maintained in patients receiving long-term continuous therapy (up to 24 mo).	PASI response continues to increase to wk 24. Large databases in patients with other immunologic diseases indicate safety.	As intermittent therapy. Large databases in patients with other immunologic diseases indicate relative safety.	Expected to be similar to other TNF-α inhibitors.
Pregnancy category	B	C	B	B	B

dsDNA = double-stranded DNA; LFA = lymphocyte function–associated antigen; MS = multiple sclerosis; PASI-50 = 50% improvement in Psoriasis Area and Severity Index; PASI-75 = 75% improvement in Psoriasis Area and Severity Index; PPD = purified protein derivative (of tuberculin); TNF = tumor necrosis factor.

lished phenomenon in psoriasis.[261] Long-term topical corticosteroids may cause striae (Fig. 18-17) and adrenal suppression. This class of agents is discussed in detail in Chap. 225.

VITAMIN D_3 AND ANALOGUES[262] Vitamin D exerts its actions by binding to the vitamin D receptor, another member of the nuclear hormone receptor superfamily. Vitamin D_3 acts to regulate cell growth, differentiation, and immune function, as well as calcium and phosphorous metabolism. Vitamin D has been shown to inhibit the proliferation of keratinocytes in culture and to modulate epidermal differentiation. Furthermore, vitamin D inhibits production of several pro-inflammatory cytokines by psoriatic T-cell clones, including IL-2 and IFN-γ.[263]

Analogues of vitamin D that have been used for the treatment of skin diseases are calcipotriene, (calcipotriol), tacalcitol, and maxacalcitol. In short-term studies, potent topical corticosteroids were found to be superior to calcipotriene. When compared with short-contact anthralin or 15 percent coal tar, calcipotriene was the more effective agent. The efficacy of calcipotriene is not reduced with long-term treatment.[264] Calcipotriene applied twice daily is more effective than once-daily use. Hypercalcemia is the only major concern with the use of topical vitamin D preparations. When the amount used does not exceed the recommended 100 g/week, calcipotriene can be used with a great margin of safety.[265] Vitamin D analogues are often used in combination with or in rotation with topical corticosteroids in an effort to maximize therapeutic effectiveness while minimizing steroid-related skin atrophy.

ANTHRALIN (DITHRANOL) Dithranol (1,8-dihydroxy-9-anthrone) is a naturally oc-

Box 18-2

Treatment of Women of Child-Bearing Potential and during Pregnancy

- Special caution needs to be exercised when treating women of child-bearing potential and during pregnancy.
- Medications such as methotrexate and oral retinoids should be avoided or used with extreme caution and then only along with appropriate contraception.
- In selected cases, isotretinoin rather than acitretin may be the preferred agent due to its much shorter half-life.
- As methotrexate is fetotoxic and an abortifactant and retinoids are potent teratotoxins, the use of these agents is absolutely contraindicated in pregnancy.
- Many women experience improvement or remission during periods of pregnancy, thus decreasing the need for the more potent agents.
- If treatment is needed, emollients and other topical agents are first line agents, often in association with ultraviolet B phototherapy.
- Many of the topical agents, such as topical steroids and calcipotriene, are pregnancy category C agents, and caution should be exercised with their use.
- Several of the biologic agents are category B and can be used in pregnancy. Likewise, cyclosporin A may be considered, as it is pregnancy category C and is nonteratogenic.
- Systemic psoralen and ultraviolet A light has been used on occasion in selected cases and appears to be safe.

curring substance found in the bark of the araroba tree in South America. It can also be synthesized from anthrone. Dithranol is made up in a cream, ointment, or paste.

Box 18-3

Treatment of Children

- Children represent a large fraction of psoriasis patients, as the disease commonly presents during childhood or adolescence.
- As for adults, first line treatment is with topical agents, often in association with ultraviolet B phototherapy.
- Due to its carcinogenic risk and opportunity for long-term exposure, psoralen and ultraviolet A light is generally contraindicated in childhood.
- Likewise, the decision to treat with systemic agents should be carefully assessed, as the long-term potential side-effect profile of many of the systemic agents is still unknown. However, many of the systemic agents have been used successfully in severe recalcitrant cases.

▲ **FIGURE 18-17** Positive and negative outcomes of psoriasis treatment. Panel **A** illustrates near-complete improvement of psoriasis after 10 weeks of infliximab therapy. Panel **B** illustrates marked improvement after 28 days of oral cyclosporin A treatment. Panel **C** illustrates marked reduction in nail dystrophy after 16 weeks of cyclosporin A treatment. Panel **D** illustrates severe atrophy with striae distensae after several years of treatment with potent topical steroid creams. (Photos used with permission from Mr. Harrold Carter.)

Dithranol is approved for the treatment of chronic plaque psoriasis. Its most common use has been in the treatment of psoriasis, particularly on plaques resistant to other therapies. It can be combined with UVB phototherapy with good results (the Ingram regimen). Most common side effects are irritant contact dermatitis and staining of clothing, skin, hair, and nails. Anthralin possesses antiproliferative activity on human keratinocytes along with potent anti-inflammatory effects. Classic anthralin therapy starts with low concentrations (0.05 to 0.1 percent) incorporated in petrolatum or zinc paste and given once daily. To prevent auto-oxidation, salicylic acid (1 percent to 2 percent) should be added. The concentration is increased weekly in individually adjusted increments up to 4 percent until the lesions resolve. Scalp psoriasis should be treated with great caution as anthralin can stain hair purple to green.

COAL TAR The use of tar to treat skin diseases dates back nearly 2000 years. In 1925, Goeckerman introduced the use of crude coal tar and UV light for the treatment of psoriasis. Tar is the dry distillation product of organic matter heated in the absence of oxygen. Its mode of action is not understood, and, because of its inherent chemical complexity, tar is not pharmacologically standardized, and the specific therapeutic activity of its components is not known. Tar appears to exert its action through suppression of DNA synthesis and consequent reduction of mitotic activity in the basal layer of the epidermis, and some components in tar appear to have anti-inflammatory activity. Coal tar, in concentrations up to 20 percent (5 percent to 20 percent) can be compounded in creams, ointments, and pastes. It is often combined with sali-

cylic acid (2 percent to 5 percent), which by its keratolytic action leads to better absorption of the coal tar.[205] Occasionally, patients become sensitive to the coal tar and develop allergic reactions. A folliculitis may occur after the use of coal tar. Furthermore, it has an unwelcome smell and appearance and can stain clothing and other items. Coal tar is carcinogenic.

TAZAROTENE Tazarotene is a third-generation retinoid for topical use that reduces mainly scaling and plaque thickness, with limited effectiveness on erythema. It is thought to act by binding to retinoic acid receptors, but its molecular targets are unknown. It is available in 0.05 percent and 0.1 percent gels, and a cream formulation has been developed. When this drug is used as a monotherapy, a significant proportion of patients develop local irritation. This retinoid dermatitis is worse with the 0.1 percent formulation. Efficacy of this drug can be enhanced by combination with mid- to high-potency glucocorticoids or UVB phototherapy. When used in combination with phototherapy, it lowers the minimal erythema dose (MED) for both UVB and UVA. It has been recommended that UV doses be reduced by at least one-third if tazarotene is added in the middle of a course of phototherapy.[266]

TOPICAL CALCINEURIN INHIBITORS (See Chap. 221) Tacrolimus (FK-506) is a macrolide antibiotic, derived from the bacteria *Streptomyces tsukubaensis* that, by binding to immunophilin (FK506 binding protein), creates a complex that interacts and inhibits calcineurin, thus blocking both T-lymphocyte signal transduction and IL-2 transcription. Pimecrolimus is also a calcineurin inhibitor and works in a manner similar to tacrolimus and CsA.

In a study of 70 patients with chronic plaque psoriasis treated with topical tacrolimus, there was no improvement beyond that seen for placebo.[267] However, for treatment of inverse and facial psoriasis, these agents appear to provide effective treatment.[268,269] The main side effect of these medications is a burning sensation at application site. Anecdotal reports of lymph node or skin malignancy require further evaluation in controlled studies, and these drugs have a U.S. Food and Drug Administration (FDA) "black box warning."

BLAND EMOLLIENTS Between treatment periods, skin care with emollients should be performed to avoid dryness. Emollients reduce scaling, may limit painful fissuring, and can help control pruritus. They are best applied immediately after bathing or showering. The addition of urea (up to 10 percent) is helpful to improve hydration of the skin and remove scaling of early lesions. The use of liberal bland emollients over a thin layer of topical prescription treatments improves hydration while minimizing treatment costs.

Phototherapy[270] (See Table 18-3) (See Chap. 238)

The mechanism of action of phototherapy appears to involve selective depletion of T cells, predominantly those that reside in the epidermis.[121,171] The mechanism of depletion appears to involve apoptosis[271] and is accompanied by a shift from a Th1 immune response toward a Th2 response in the lesional skin.[272]

ULTRAVIOLET B LIGHT (290 TO 320 NM) The initial therapeutic UVB dose lies at 50 percent to 75 percent of the MED. Treatments are given two to five times per week. As peak UVB erythema appears within 24 hours of exposure, increments can be performed at each successive treatment. The objective is to maintain a minimally perceptible erythema as a clinical indicator of optimal dosing. Treatments are given until total remission is reached or until no further improvement can be obtained with continued treatment. The main side effects of UVB phototherapy are summarized in Chap. 238.

Narrowband (312 nm) UVB (NB-UVB) phototherapy is superior to conventional broadband UVB (290 to 320 nm) with respect to both clearing and remission times[273,274] (see Table 18-3). Although early studies found NB-UVB to be as effective as psoralen and UVA light (PUVA),[275,276] a recent controlled trial found that PUVA was more effective, albeit less convenient.[277] On clearing, treatment is either discontinued or patients are subjected to maintenance therapy for 1 or 2 months. During this period, the frequency of UVB treatments is reduced while maintaining the last dose given at the time of clearing.[270]

Systemic drugs, such as retinoids, increase the efficacy of UVB light, particularly in patients with chronic and hyperkeratosis plaque–type psoriasis.[278,279] Because they are known to inhibit carcinogenesis in experimental animals, retinoids may possibly reduce the carcinogenic potential of UVB phototherapy.

PSORALEN AND ULTRAVIOLET A LIGHT (See Chap. 239) PUVA is the combined use of psoralens (P) and long-wave ultraviolet A radiation (UVA). The combination of drug and radiation results in a therapeutic effect, which is not achieved by the single component alone. Remission is induced by repeated controlled phototoxic reactions (see Table 18-3). A detailed account of PUVA therapy and its short-term and long-term side effects is to be found in Chap. 239.

EXCIMER LASER[280] (See Chap. 240) Supra-erythemogenic fluences of UVB and PUVA are known to result in faster clearing of psoriasis,[281] however, the limiting factor for the use of such high fluences lies with the intolerance of the uninvolved surrounding skin as psoriatic lesions can often withstand much higher UV exposures.[282] The monochromatic 308-nm excimer laser can deliver such supra-erythemogenic doses of light (up to 6 MED, usually in the range of 2 to 6 MEDs) focally to lesional skin (see Table 18-3). In a study on 124 patients, 72 percent of study subjects achieved at least 75 percent clearing in an average of 6.2 treatments delivered twice weekly.[282] The role of this treatment seems to be indicated for patients with stable recalcitrant plaques particularly in the elbows and knee region.

PHOTODYNAMIC TREATMENT[283] (See Chap. 239) Photodynamic therapy has been tried for several inflammatory dermatoses, including psoriasis. In a randomized study on the effect of topical aminolevulinic acid–based photodynamic therapy, 29 patients demonstrated unsatisfactory clinical response and frequent occurrence of pain during and after treatment, prompting the authors to declare this as an inadequate treatment option for psoriasis.

CLIMATIC THERAPY[284] It is well known that going to a sunny climate can improve psoriasis, although a small proportion of patients actually deteriorate. Patients should be warned not to overexpose themselves in the first few days, as sunburn may actually progress to psoriasis (Koebner phenomenon). The best-studied effects are from the Dead Sea area, and those therapeutic effects may be attributed, at least partially, to the unique climatic characteristic of that location. As it is situated 400 m below sea level, the evaporation of the sea forms an aerosol that stays in the atmosphere above the sea and surround-

ing beaches. This aerosol screens out the majority of the UVB rays but not the UVA. This mixture of UV light appears to be sufficient to clear psoriasis but without sunburn. Thus, patients can stay on the shores of the Dead Sea for long periods of time with greatly reduced risk of sunburn. This treatment is carried out over a period of 3 to 4 weeks, and improvements comparable to NB-UVB or PUVA treatments are observed. The main disadvantages of this treatment are time and expense.

Systemic Oral Agents[285,286] (See Table 18-4)

METHOTREXATE MTX is highly effective for chronic plaque psoriasis[286] and is also indicated for the long-term management of severe forms of psoriasis, including psoriatic erythroderma and pustular psoriasis[285] (see Table 18-4). For mechanisms of action, see Chap. 228. When first used for the treatment of psoriasis, MTX was thought to act directly to inhibit epidermal hyperproliferation via inhibition of dihydrofolate reductase (DHFR). However, it was found to be effective at much lower doses (0.1 to 0.3 mg/kg weekly) in the management of psoriasis, psoriatic arthritis, and other inflammatory conditions such as rheumatoid arthritis. At these concentrations, MTX inhibits the in vitro proliferation of lymphocytes, but not proliferation of keratinocytes.[286] It is now thought that the inhibition of DHFR is not the main mechanism of anti-inflammatory action of MTX, but rather the inhibition of an enzyme involved in purine metabolism [AICAR (5-aminoimidazole-4-carboxamide ribonucleotide) transformylase]. This leads to accumulation of extracellular adenosine, which has potent anti-inflammatory activities, particularly for neutrophils.[287] Consistent with a DHFR-independent mechanism of action, concomitant administration of folic acid (1 to 5 mg/day) reduces certain side effects, such as nausea and megaloblastic anemia, without diminishing the efficacy of antipsoriatic treatment.[288] The cellular targets of MTX action in psoriasis are still under investigation, but its mechanism of action may involve modulation of adhesion molecules, such as intercellular adhesion molecule 1, rather than induction of lymphocyte apoptosis.[289]

The very long half-life of MTX may account for its efficacy after weekly administration and may also help to explain why its onset of action is rather slow (therapeutic effects usually require 4 to 8 weeks to become evident). MTX is renally excreted and should therefore not be administered to patients with impairment in renal function, as MTX side effects are generally dose-related. Short-term toxicity and long-term concerns are discussed in Chap. 228.

In the most recent guidelines,[290] patients with normal liver function tests and without a history of liver disease or alcoholism are not asked to undergo liver biopsy until they have been treated with a cumulative MTX dose of 1.0 to 1.5 g. Repeat biopsies are done approximately 1.0 to 1.5 g thereafter if liver function test and biopsy findings are normal. Some groups have recommended the use of amino terminal type III procollagen peptide (PIIINP) assay for screening of liver fibrosis.[291] Specific guidelines have been developed for monitoring PIIINP levels in psoriatic patients,[291] but the FDA has not yet approved the use of this assay for diagnostic use within the United States.

Another well-known side effect of MTX is myelosuppression, especially pancytopenia, which usually occurs in the setting of folate deficiency. Leucovorin calcium (folinic acid) is the only antidote for the hematologic toxicity of MTX. When an overdose is suspected, an immediate leucovorin dose of 20 mg should be given parenterally or orally, and subsequent doses should be given every 6 hours.[292] Pneumonitis can develop, and mucosal and skin ulcerations have also been reported in patients treated with MTX.[293,292]

Discontinuation of MTX treatment is required in the event of hepatotoxicity, hematopoietic suppression, active infections, nausea, and pneumonitis. MTX is also teratogenic and should therefore not be prescribed for women who are pregnant. Several classes of drugs, including nonsteroidal anti-inflammatory drugs and sulfonamides, may interact with MTX to increase toxicity.

ACITRETIN[294] Acitretin is a second-generation, systemic retinoid that has been approved for the treatment of psoriasis since 1997 and is discussed in Chap. 229.

The clinical forms most responsive to etretinate or acitretin as monotherapy include generalized pustular and erythrodermic psoriasis. Acitretin induces clearance of psoriasis in a dose-dependent fashion. Overall, higher starting doses appeared to clear psoriasis faster.[295] The mechanism of action of retinoids for psoriasis is not fully understood.

The optimal initial dose of acitretin for psoriasis is reported at 25 mg/day, with a maintenance dose of 20 to 50 mg/day (see Table 18-4). Adverse effects, such as hair loss and paronychia, occur more frequently with higher initial dose (i.e., ≥ 50 mg/day). Most patients relapse within 2 months after discontinuing etretinate or acitretin. Acitretin should be discontinued if liver dysfunction, hyperlipidemia, or diffuse idiopathic hyperostosis develops.

CYCLOSPORIN A CsA is a neutral cyclic undecapeptide derived from the fungus *Tolypocladium inflatum gams*. Its mechanism of action and side effects are discussed in Chap. 234. The only formulation approved for treatment of psoriasis is available as an oral solution or in capsules. It is highly effective for cutaneous psoriasis and can also be effective for nail psoriasis (see Fig. 18-17). CsA is particularly useful in patients who present with widespread, intensely inflammatory, or frankly erythrodermic psoriasis. Dosage ranges from 2 to 5 mg/kg/day (see Table 18-4).[296] Because the nephrotoxic effects of CsA are largely irreversible, CsA treatment should be discontinued if kidney dysfunction and/or hypertension occur. CsA-induced hypertension may be treated with calcium antagonists such as nifedipine.[297] The most common adverse effects noted in patients using CsA for short periods of time are neurologic, including tremors, headache, paresthesia, and/or hyperesthesia. Long-term treatment of psoriasis with low-dose CsA was found to increase risk of non-melanoma skin cancers.[298] However, unlike organ transplant patients treated with higher doses of CsA, there is little or no increased risk of lymphoma.

FUMARIC ACID ESTERS Fumaric acid was first reported in 1959 to be beneficial in the systemic treatment of psoriasis[299] and is licensed in Germany for treatment of psoriasis. Because fumaric acid itself is poorly absorbed after oral intake, esters are used for treatment. The esters are almost completely absorbed in the small intestine, and dimethylfumarate is rapidly hydrolyzed by esterases to monomethylfumarate, which is regarded as the active metabolite. The mode of action of fumaric acid esters (FAEs) in the treatment of psoriasis is not fully understood, but experimental data point toward a skewing of the Th1-dominated T-cell response in psoriasis to a Th2-like pattern and inhibition of keratinocyte proliferation.[299] Patients with severe concomitant disease, chronic disease of the

gastrointestinal tract, chronic kidney disease, or with bone marrow disease leading to leukocytopenias or leukocyte dysfunction should not be treated. Likewise, pregnant or lactating women and patients with malignant disease (including positive history of malignancy) should be excluded from treatment. Prolonged therapy (up to 2 years) to prevent relapse in psoriasis patients with high disease activity is possible. Another therapeutic option is short-course intermittent therapy. FAEs are given until a major improvement is achieved and are then withdrawn (see Table 18-4). If a patient remains lesion-free during prolonged treatment, the FAE dose should be gradually decreased to reach the individual's threshold.[299] Therapy with FAEs can be stopped abruptly. Rebound phenomena have not been observed.[299]

SULFASALAZINE Sulfasalazine is an uncommonly used systemic agent in the management of psoriasis. In the only prospective double-blind study on the efficacy of sulfasalazine in psoriasis, moderate effects were seen, with 41 percent of the patients showing marked improvement, 41 percent with moderate, and 18 percent with minimal improvement after 8 weeks of treatment.[300]

SYSTEMIC STEROIDS (See Chap. 225) In general, systemic steroids should not be used in the routine care of psoriasis. When systemic steroids are used, clearance of psoriasis is rapid, but the disease usually breaks through, requiring progressively higher doses to control symptoms. If withdrawal is attempted, the disease tends to relapse promptly and may rebound in the form of erythrodermic and pustular psoriasis.[301] However, systemic steroids may have a role in the management of persistent, otherwise uncontrollable, erythroderma and in fulminant generalized pustular psoriasis (von Zumbusch type) if other drugs are ineffective.

MYCOPHENOLATE MOFETIL (See Chap. 228) Mycophenolate mofetil is a prodrug of mycophenolic acid, an inhibitor of inosine-5′-monophosphate dehydrogenase. Mycophenolic acid depletes guanosine nucleotides preferentially in T and B lymphocytes and inhibits their proliferation, thereby suppressing cell-mediated immune responses and antibody formation. The drug is usually well tolerated with few side effects. Few studies have been done on this medication for psoriasis, but, in a prospective open-label trial on 23 patients with dosage between 2 to 3 g daily, a 24 percent reduction of the Psoriasis Area and Severity Index (PASI) was seen after 6 weeks, with 47 percent improvement at 12 weeks.[302]

6-THIOGUANINE 6-Thioguanine is a purine analog that has been highly effective for psoriasis.[303] Apart from bone marrow suppression, gastrointestinal complaints including nausea and diarrhea can occur, and elevation of liver function tests is common.[285] Isolated instances of hepatic veno-occlusive disease have been reported.[304]

HYDROXYUREA Hydroxyurea is an antimetabolite that has been shown to be effective as monotherapy, but nearly 50 percent of patients who achieve marked improvement develop bone marrow toxicity with leukopenia or thrombocytopenia. Megaloblastic anemia is also common but rarely requires treatment.[285] Cutaneous reactions affect most patients treated with hydroxyurea, including leg ulcers, which are the most troublesome.[305]

Combination Treatments (See Table 18-5)

Combination treatment may increase efficacy and reduce side effects, and so may result in a more substantial improvement, or alternatively, may permit reduced doses to reach the same improvement as compared with monotherapy.[256] Data on combination of biologics with other systemic or topical agents are not yet widely available, but some combinations commonly used in the treatment of inflammatory arthritides, such as a combination of MTX and anti-TNF agents,[306] may be appropriate for treatment of recalcitrant psoriatic disease.

Biologic Treatments[307–310] (See Table 18-6) (See also Chap. 235)

Based on the continuous progress in psoriasis research and advances in molecular biology, a new class of agents—targeted biologic therapies—has emerged.[307,308] These agents are designed to block specific molecular steps important in the pathogenesis of psoriasis or have been transferred to the psoriasis arena after being developed for other inflammatory diseases. Currently, three types of biologics are approved or are in development for psoriasis: (1) recombinant human cytokines, (2) fusion proteins, and (3) monoclonal antibodies, which may be chimeric or humanized (see Table 18-6). Due to the risk of the development of antibodies to mouse sequences, humanized or fully human antibodies are preferred for clinical use.

Using internationally acknowledged safety and efficacy endpoints, the overall utility and benefit of biologics have been demonstrated based on the percentage of patients achieving at least a 50 percent improvement in PASI (PASI-50), a 75 percent improvement in PASI (PASI-75), the impact of treatment on quality of life, and safety and tolerability.[310] In general, these agents have antipsoriatic activity roughly comparable to that of MTX and lack its risk of hepatotoxicity. However, they are far more expensive, carry risks of immunosuppression, infusion reactions, and antibody formation, and their long-term safety remains to be evaluated. In the opinion of the authors, use of biologic agents should be reserved for treatment of severe psoriasis that is either unresponsive to MTX or in patients for whom the use of MTX is contraindicated.

ALEFACEPT Alefacept is a human lymphocyte function–associated antigen (LFA)-3-IgG1 fusion protein designed to prevent the interaction between LFA-3 and CD2. The LFA-3-CD2 signal plays an important role in activation of T cells. The LFA-3 portion of alefacept binds to the CD2 receptor on T cells, blocking the interaction between LFA-3 and CD2, thus interfering with the activation of T cells, inducing apoptosis and modifying the inflammatory process. CD2 is upregulated on memory effector T cells, explaining the preferential depletion of these cells by alefacept.[311] One-third to one-half of psoriatic patients do not respond to alefacept; the reasons for this remain unclear. However, evidence indicates that repeated administration of alefacept leads to improved response, and that responses to alefacept are durable.[308]

EFALIZUMAB Efalizumab (anti-CD11a) is a humanized monoclonal antibody developed for treatment of plaque psoriasis. It is directed against CD11a, the α subunit of LFA-1, and thus blocks the interaction of LFA-1 with its ligand intercellular adhesion molecule 1. This blockade inhibits T-cell activation, cutaneous T-cell trafficking, and T-cell adhesion to keratinocytes.[312,313] Some patients have shown evidence of exacerbation of the disease at the end of the dosing period.[314] Studies are currently evaluating

the safety and tolerability of long-term treatment with efalizumab.

TUMOR NECROSIS FACTOR-α ANTAGONISTS

The clinical application of TNF antagonists in inflammatory diseases has exploded on the clinical realm in a manner reminiscent of the discovery of the activity of corticosteroids.[315] TNF-α is a homotrimeric protein that exists in both transmembrane and soluble forms, the latter resulting from proteolytic cleavage and release. It is still unclear which form is more important in mediating its pro-inflammatory activities or the relative importance of the two p55- and p75-kd TNF-α–binding receptors.[316]

Currently, three anti-TNF biologics are available in the United States. Infliximab is a chimeric monoclonal antibody that has high specificity, affinity, and avidity for TNF-α. An example of an excellent treatment outcome with infliximab is shown in Fig. 18-17. Etanercept is a human recombinant, soluble, TNF-α receptor-FcIgG fusion protein that binds TNF-α and neutralizes its activity. Adalimumab is the first fully human recombinant IgG1 monoclonal antibody and specifically targets TNF-α. Currently, infliximab and adalimumab are only FDA-approved for psoriatic arthritis. However, clinical trials have shown that each of these agents is well tolerated and appears suitable for long-term use in chronic plaque psoriasis. However, like all the targeted biologic therapies, they carry risks of immunosuppression (see Table 18-6), and their long-term safety requires further study.

Clinical studies have found infliximab and adalimumab to be slightly more effective than etanercept in the treatment of psoriasis (see Table 18-6). It is likely that the differential effects of these agents are associated with selectivity in their ability to perturb these receptor ligand interactions. It is known that infliximab, adalimumab, and etanercept bind TNF differently; infliximab and adalimumab bind to both soluble and membrane-bound TNF, whereas etanercept binds primarily to soluble TNF.[317] Binding to membrane-bound TNF can induce a dose-dependent increase in apoptosis of T cells, but the relevance of this mechanism in psoriasis has not been evaluated.

ANTI-INTERLEUKIN 12/INTERLEUKIN 23 P40

A recently developed agent has been developed and tested for treatment of chronic plaque psoriasis and has shown promising efficacy in phase I trials. This agent is a human IgG1 κ monoclonal antibody that binds to the common p40 subunit of human IL-12 and IL-23 and prevents its interaction with its receptor.[318] Besides blocking IL-12, which is critical for Th1 differentiation of T cells, blockade of IL-23 may be even more important in the treatment of chronic plaque psoriasis, as this cytokine supports chronic inflammation by maintaining a separate $CD4^+$ T-cell subset characterized by IL-17 production.[80–82] A phase I trial testing various treatment doses showed clear correlation between the anti-IL-12 p40 dose and the proportion of subjects achieving at least a 75 percent improvement in PASI score.[318]

Numerous new drugs are currently in clinical trials for treatment of psoriasis as outlined in a comprehensive review.[319]

PREVENTION

There is no known prevention for psoriasis.

CHAPTER 19

Psoriatic Arthritis

Robert Winchester

DEFINITION AND CLASSIFICATION

Psoriatic arthritis is a clinically distinctive autoimmune inflammation of the musculoskeletal system that occurs in persons with psoriasis or with a strong family history of psoriasis. The inflammation underlying psoriatic arthritis is apparently driven by CD8 T cells and is based on the entrance and activation of T cells in three target sites: the entheses (fibrocartilage insertions of ligaments, tendons, and fascia), the synovium of peripheral synovial joints, and the spine and sacroiliac joints. The activated T cell releases cytokines and chemokines that directly affect target tissues, activate macrophages to secondarily release additional cytokines and chemokines and, result in the recruitment of additional inflammatory leukocytes.

Of the three target sites, the inflammation of the entheses, enthesitis,[1] and the spine, spondyloarthritis, are distinctive features of psoriatic arthritis. In contrast, the development of arthritis, synovitis, or non-specific musculoskeletal symptoms in a person with psoriasis does not, per se, make the diagnosis of psoriatic arthritis and requires exclusion of the coincident occurrence of psoriasis with other inflammatory arthritides or musculoskeletal conditions such as fibromyalgia, seronegative or seropositive rheumatoid arthritis, Lyme disease, repetitive motion injuries, or osteoarthritis. Although the large majority of cases of psoriatic arthritis are readily identified, precise and sensitive diagnostic criteria for psoriatic arthritis are not yet fully developed and validated, which complicates the study of the disease. The criteria for case classification for study purposes also are improving. Table 19-1 summarizes some distinguishing features of psoriatic arthritis that are useful for its diagnosis. These distinguishing features reflect increased emphasis on the presence of enthesitis and spondyloarthritis as specific elements of psoriatic arthritis.

Psoriatic arthritis develops in approximately 10 percent to 15 percent of those with psoriasis. In approximately one-half of those affected with psoriatic arthritis, the musculoskeletal involvement appears an average of a decade after the onset of psoriasis, whereas in the remainder the onset is roughly contemporaneous or even precedes the development of skin disease.[2] Psoriatic arthritis is, intriguingly, more likely to be found in individuals with psoriasis who lack HLA-Cw6, *Psors 1*, consistent with some genetic heterogeneity. Unlike most autoimmune diseases, psoriatic arthritis does not appear to involve B cells or autoantibody production or be critically dependent on CD4 T cells as is indicated by the increase in prevalence and severity of psoriatic arthritis in those with advancing and poorly treated human immunodeficiency virus-1 (HIV-1) infection, where special concerns exist about its therapy.

The rapid development of potent new pharmacologic agents and improved regimens for their use has substantively improved the treatment of psoriatic arthritis. This is particularly the case in more severe forms of psoriatic arthritis where in view of the role of T cells and macrophages in disease pathogenesis, new immunobiologics, such as tumor necrosis factor (TNF) blockers, offer the potential of targeting and interdicting specific stages or events in the mechanism of disease, and indeed are very effective disease-modifying antirheumatic drugs (DMARDs), at least in subsets of individuals.

TABLE 19-1
Diagnostic Clinical Features of Psoriatic Arthritis

- Characteristic features
  - Psoriasis present
  - Enthesitis
  - Dactylitis
  - Onychodystrophy
  - Distal interphalangeal joint involvement
  - Juxta-articular new bone formation
  - Sacroiliitis and/or spondyloarthritis
  - Isolated involvement of the joints of one ray (e.g., distal interphalangeal, proximal interphalangeal, monocyte chemotactic protein)
  - Insidious appearance of ankylosed joints (e.g., hallux rigidus)
- Supporting features
  - In the absence of documented psoriasis, a convincing history of psoriasis and/or a family history positive for psoriasis
  - Peripheral arthritis, often asymmetrical or oligoarticular at onset
- Exclusions
  - Fibromyalgia
  - Seronegative or seropositive rheumatoid arthritis
  - Intercurrent arthritides (e.g., Lyme disease)
  - Repetitive motion–induced musculoskeletal syndromes

PSORIATIC ARTHRITIS AT A GLANCE

- Psoriatic arthritis is a member of the seronegative spondyloarthritis group of disorders and affects three principal target sites: the entheses, the synovium, and the spine and sacroiliac joints.
- Occurs in 10 percent to 15 percent of those with psoriasis. In one-half, psoriasis appears an average of a decade earlier than the arthritis; in the rest arthritis is roughly contemporaneous or even precedes the skin disease.
- Strong genetic predisposition: susceptibility associated with HLA-Cw6 and other class I major histocompatibility complex alleles including HLA-B27 and HLA-B39.
- The pathogenesis appears to involve activation of CD8 T cells, which release inflammatory mediators that affect the target tissues.
- The most distinctive features of psoriatic arthritis are distal interphalangeal joint arthritis, dactylitis, enthesitis, periosteal new bone formation, and asymmetric oligoarthritis and spondylitis.
- A severe syndrome with features of psoriasis, psoriatic arthritis, and reactive arthritis may occur with advanced fulminant untreated human immunodeficiency virus-1 infection.
- Therapy is determined by the balance of the severity of the skin and musculoskeletal disease. Nonsteroidal anti-inflammatory drugs are the mainstay of therapy in concert with physical therapy; methotrexate is usually the initial choice for more severe involvement. In the event of failure, a growing number of second-line disease-modifying agents are often effective, but with an attendant increased risk of untoward effects.

Psoriatic arthritis is classified as one of the seronegative spondyloarthritis group of disorders that also includes ankylosing spondylitis, undifferentiated spondylitis, Reiter syndrome, reactive arthritis, and enteropathic arthritis. The term *seronegative* refers to the absence of rheumatoid factor or other autoantibodies, and the

absence of these autoantibodies is one of the essential laboratory features of psoriatic arthritis. The seronegative spondyloarthritis disorders share involvement of the spine (spondylo), sacroiliac joints, and some degree of genetic susceptibility associated with HLA-B27. In addition, each of the entities in the spondyloarthritis group of disorders has the singularly distinctive feature of enthesitis that may either involve peripheral joints or the spine. This results in tendinitis, fasciitis, and some of the deep inflammatory back pain of spondyloarthritis. Common to the spondyloarthritis group of disorders is juxta-articular new bone formation, which results from the cytokine-induced activation and modulation of mesenchymal or periosteal cells to an osteogenic program. It is typically found around the entheses and accounts for bone spurs. Perhaps related to this pattern of mesenchymal cell activation is the characteristic development of joint fibrosis and ankylosis (see Table 19-1).

Some clinical and pathogenic features of psoriatic arthritis are similar to those of Reiter syndrome and reactive arthritis. In the setting of advancing HIV-1 infection, the arthrocutaneous syndrome that may develop often has considerable clinical overlap in both the skin and musculoskeletal findings of psoriatic arthritis and Reiter syndrome.

Psoriatic arthritis is distinguished from ankylosing spondylitis by the confinement of spinal involvement to a few vertebrae and from all the other spondyloarthritides by the predominance of more distal peripheral joint involvement. A distinctive and diagnostically specific feature of psoriatic arthritis is acral inflammatory involvement of the skin, nail matrix, periosteum, enthuses, and synovium of one or more digits with the complex of onychodystrophy, periungual erythrodermia, and distal interphalangeal joint (DIP) involvement (Fig. 19-1; see Table 19-1). Dactylitis, sometimes graphically termed *sausage digits*, is a characteristic inflammation of one or more digits with a high specificity for psoriatic arthritis characterized by inflammatory edema of the entire digit due to extensive enthesitis, DIP and proximal interphalangeal synovitis, tenosynovitis often focused on flexor tendons, and periosteitis. Similar to the acral dystrophy, dactylitis is also a diagnostic feature of psoriatic arthritis.

The relationship to the presence of psoriasis is of course a hallmark of psoriatic arthritis. However, the presence of psoriasis is not an absolute requirement

▲ **FIGURE 19-1** Psoriatic arthritis. Striking joint swelling of the distal interphalangeal joints with associated psoriasis of the skin and psoriatic nail involvement reflecting acral inflammatory involvement.

for the diagnosis of psoriatic arthritis and a history of prior psoriasiform lesions or a family history of psoriasis suffices (see Table 19-1). Except for the absence of psoriasis, some cases of the spondyloarthritis disorder undifferentiated spondylitis are indistinguishable from the joint involvement of psoriatic arthritis and this has sometimes been termed *psoriatic arthritis sine psoriasis*.

In psoriatic arthritis, the peripheral joints are involved in a variety of patterns of arthritic involvement at presentation, often affecting only one or a few joints in an asymmetric manner (Table 19-2). These patterns are sometimes useful diagnostically as originally emphasized by Moll and Wright in their classic paper on patterns of joint involvement.[3] For example, DIP arthritis in an individual with psoriasis immediately suggests the diagnosis of psoriatic arthritis and essentially requires only the exclusion of osteoarthritis, the other entity that commonly affects the DIP joint. However, it is now recognized that some of these patterns of arthritis onset are neither stable nor highly specific for psoriatic arthritis. Over time with the accumulative involvement of different peripheral joints by the disease, the asymmetric features of psoriatic arthritis often become less apparent. For these reasons, with the exception of the characteristic DIP arthritis or spondyloarthritis, less emphasis is now being placed on the other patterns of arthritis for diagnosis, other than classifying the arthritis as axial or peripheral.

TABLE 19-2
Patterns of Psoriatic Arthritis Joint Involvement

- Asymmetric or symmetric peripheral joint involvement
  - Distal interphalangeal joint involvement
  - Small joints of hands and feet
  - Large joints
- Axial disease
  - Spondyloarthritis with vertebral squaring affecting one or a few vertebrae, often asymmetrically
  - Sacroiliitis

HISTORICAL ASPECTS

The recent identification of psoriatic arthritis in skeletal remains of individuals who sought refuge in ancient Middle Eastern Byzantine monasteries in Biblical times suggests that psoriasis with psoriatic arthritis was one of the forms of biblical leprosy, attesting to the severe and ancient nature of this condition. The association of arthritis with psoriasis was first formally described in 1818 by Alibert and was designated *psoriasis arthritique* by Bazin in 1860. The notion of a distinctive arthritis associated with psoriasis became widely accepted, but in the decades after World War II psoriatic arthritis was grouped with rheumatoid arthritis as a "rheumatoid variant" or "rheumatoid spondylitis." Subsequently, the distinct nature of psoriatic arthritis was again emphasized, using as criteria the clinical pattern of joints affected, spondylitis, and the absence of rheumatoid factor. The observation of an elevated frequency of HLA-B27 provided a strong immunogenetic basis for the entity. The central importance of enthesitis has been recognized, along with the development of more prevalent and intense disease with advancing HIV infection.

EPIDEMIOLOGY

Despite the problems in diagnostic and classification criteria of psoriatic arthritis, considering the frequency of psoriasis to be between 1 percent and 3 percent, and using the 10 percent to 15 percent value for the prevalence of psoriatic arthritis in those with psoriasis, the prevalence of psoriatic arthritis in the different populations would be expected to range from 0.10 percent to 0.45 percent, a value approaching half that of the prevalence of seropositive rheumatoid arthritis and in agreement with recent prevalence studies.[4,5] Reports of much higher prevalence in some series ascertained clinically or by newer imaging modalities, such as magnetic resonance imaging (MRI), may reflect the absence of specific or fully developed criteria for excluding other forms of common joint or musculoskel-

etal diseases, and one should await their full validation.

PATHOGENESIS AND PATHOLOGY

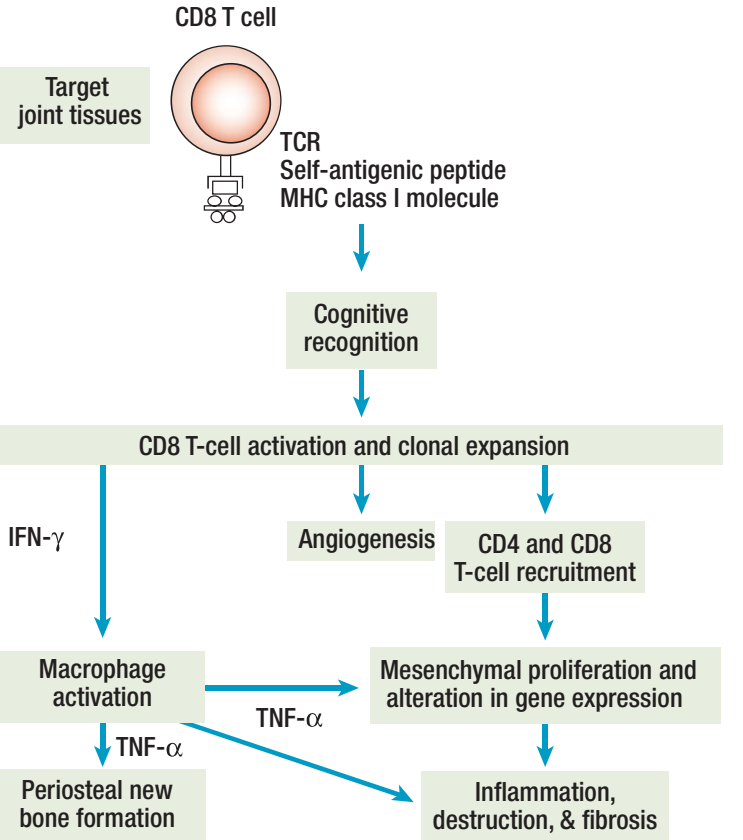
Two lines of evidence strongly implicate lymphocytes in the pathogenesis of psoriatic arthritis: the presence and activated state of both CD8 T cells and natural killer (NK) cells in lesional sites and the response of the disease to immunomodulatory therapy directed at these cells or pathways triggered by them. The inflammatory infiltrate in the synovitis of fully developed psoriatic arthritis has been well studied because of its accessibility and contains a small number of very large CD8 T-cell clonal expansions.[6,7] The T-cell receptors of these clones often appear structurally related and manifest the same CDR3 length and the same or homologous CDR3 amino acid sequences, structural features that strongly imply the clones are driven by an antigen, the identity of which remains unknown. The CD8 T-cell clones in the synovial tissue and fluid are derived from clonal precursor pools that are also highly expanded in blood (> 20 cell divisions). Their activation in the tissue is presumably the basis of the arthritis and enthesitis through the release of chemokines and cytokines as illustrated by the hypothetical scheme in Fig. 19-2. Their phenotype is predominantly that of memory effector CD8 T cells that have lost the co-stimulatory CD28 molecule, but gained various receptors that are typically expressed on, and regulate the activation of, NK cells.

The synovium in active psoriatic arthritis also contains a preponderant infiltrate of polyclonal, non-antigen–specific CD4 T cells, as shown by analysis of the T-cell repertoire.[6,7] These appear to arise via a chemokine-mediated recruitment of non-antigen specific T cells. Other types of bystander type clonal expansions are also found in the joint fluid and synovium, which appear to be directed to diverse viral and other antigens unrelated to the presumed autoantigens driving the joint disease. These are presumably attracted to the inflammatory milieu and by their activation in the tissue may secondarily contribute to the intensification of arthritis.

Cytokines that have been implicated in the pathogenic process of psoriatic arthritis include macrophage-derived TNF-α, interleukin (IL)-6, IL-1α, and lymphocyte-derived IL-2 and interferon-γ, although compared with rheumatoid arthritis synovium, the psoriatic arthritis synovium has less interferon-α and IL-1.[8–10] Infiltrating T cells elaborate chemokines, including RANTES (regulated on activation, normal T cell expressed and secreted). The chemokine IL-8 is expressed at a high level by the synovial lining cells and to a lesser extent in cells located in the perivascular areas and likely mediates attraction of neutrophils to the joint fluid, a characteristic feature of psoriatic arthritis. Lining cells also elaborate the chemokine monocyte chemotactic protein 1 (CCL2), a chemotactic factor that attracts and activates monocytes but not neutrophils. Macrophages in the lining produce chemokines such as GRO-α (growth-regulated protein α precursor, CXCL1), which also has chemotactic activity for neutrophils. Vascular abnormalities are prominent in the psoriatic synovium both at the gross level and immunopathologically with a transformation to an activated endothelium. These changes are likely to reflect specific cytokine profiles augmented in the psoriatic patient. The destruction of cartilage differs from that seen in rheumatoid arthritis by minimally elevated levels of aggrecan and greatly increased concentrations of cartilage oligomeric matrix protein.[11]

The role of dendritic cells in the initiation of the inflammation has not been well delineated. These are the likely candidate cells to mediate the response to physical stress, microbial infection, cytokines including interferon-α, and other danger signals that can initiate the process of arthritis in predisposed individuals.

Theoretic scenarios to explain the immune drive underlying inflammation: The nature of the immunologic recognition events responsible for the CD8 clonal expansion remains completely unknown. Two potential scenarios could account for the immune drive in psoriatic arthritis because they each illuminate dif-



▲ **FIGURE 19-2** A scheme for pathogenesis of inflammation and tissue destruction summarizing the mechanisms of inflammation in psoriatic arthritis. The process is driven by cognitive recognition of a self-peptide presented to a CD8 T cell by a major histocompatibility complex (MHC) class I molecule on a joint cell. The ensuing T-cell activation and clonal expansion initiates non-antigen–specific recruitment of CD4 and CD8 T cells, angiogenesis, and monocyte recruitment by the release of cytokines and chemokines. Activation of macrophages occurs through cytokines such as interferon (IFN)-γ. The activated macrophages release cytokines such as tumor necrosis factor (TNF)-α, interleukin-1, and interleukin-6. These products alter patterns of gene expression in cells comprising the joint and related structures, resulting in inflammation, fibrosis, new bone formation, erosions, and osteolysis. TCR = T-cell receptor.

ferent aspects of immune response mechanisms relevant to psoriatic arthritis.

Scenario 1, adaptive immune drive (see Fig. 19-2): The first and more classic view is that the clonal expansion reflects a typical specific peptide antigen-triggered adaptive immune response mediated by CD8 T cells to a particular autoantigen. Ongoing activation of the CD8 T-cell clones by the unlimited reservoir of self-antigen drives the clonal expansion and sustains the attack on the target cells expressing the autoantigen. The primary defects responsible for this scenario are expression of the autoantigen, binding of autoantigen peptides by major histocompatibility complex (MHC) class I allelic molecules associated with susceptibility, and provision of initial clonal activation in an adaptive immune response by activated dendritic cells.

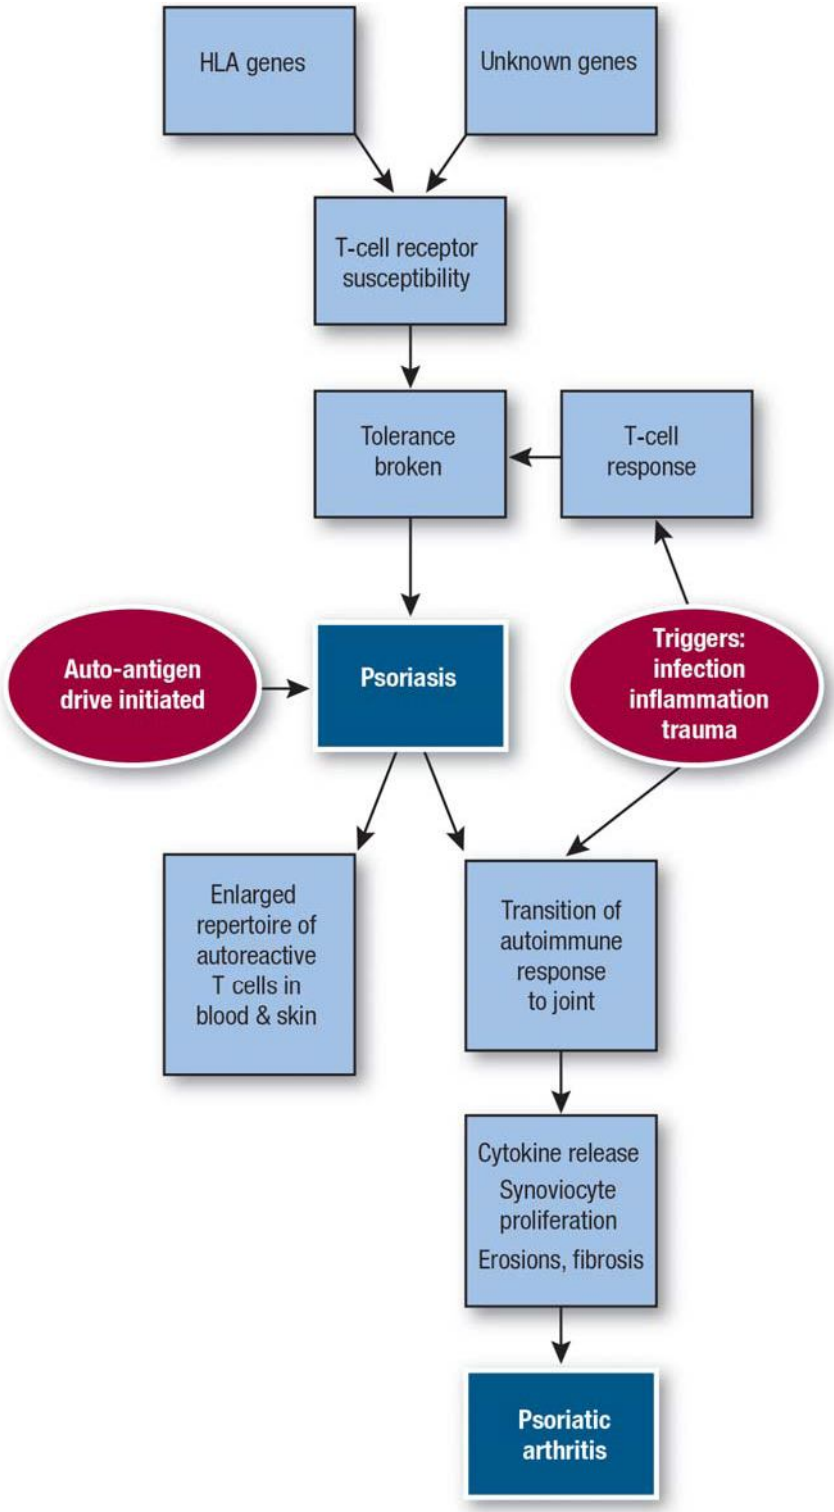
Scenario 2, innate immune activation of preexisting memory/effector T cells: This alternative scenario is based on the predominant memory-effector phenotype of the expanded CD8 T cells in the inflammatory sites. Their CD28-negative status reflects the fact that as memory effector cells they do not require engagement of this receptor by counter-receptors on activated dendritic cells to provide a signal two by this pathway, and instead, the activating NK receptors expressed by these cells provide a surrogate signal two on recognition of molecules expressed on stressed or injured cells. In this scenario, the engagement of receptors that recognize innate immune response ligands is the central recognition event, and the clonal specific adaptive immune response T-cell receptors provide a low affinity recognition signal.

DISEASE PATHOGENESIS AND STAGES

In common with other autoimmune diseases, the development of psoriasis and subsequently psoriatic arthritis can be considered to occur in stages, beginning with a genetically defined predisposition and ending with a final stage of overt joint disease (Fig. 19-3). The following sections group some of the information about the predisposition and pathogenesis of psoriatic arthritis according to these stages and the preceding two scenarios.

Genetic Predisposition: Stage 1

FAMILIAL AGGREGATION The family history of the patient provides an important clue to diagnosis. More than 40 percent of patients with psoriatic arthritis have a



▲ **FIGURE 19-3** Hypothetical stages in the development of psoriasis or psoriatic arthritis. The first stage is one of genetically defined susceptibility illustrated in the first compartment. Major histocompatibility complex class I molecules, self-peptides, and other still unknown genes interact to select a T-cell repertoire that has the property of recognizing a self-peptide critical to pathogenesis of psoriasis or psoriatic arthritis. The second compartment depicts several possible initiation events in which the T-cell clones selected in stage one are triggered to recognize a self-peptide. This physiologic adaptive immune response is initiated by a specific microorganism or by non-antigen–specific inflammation or trauma. In the third stage, the unlimited amount of self-peptide autoantigen drives the immune response to clonal expansion and an effector phenotype that results in psoriasis. In the fourth phase, these T-cell clones acquire the ability to respond to a self-antigen of the joint. In a final phase, these clones acquire the potential to injure the joint by the release of chemokines that recruit and activate monocytes and non-antigen–specific T cells. Multiple inflammatory mechanisms characterize this stage.

family history that includes one or sometimes multiple cases of psoriatic arthritis, psoriasis, or seronegative spondyloarthritis in their blood relatives, a likelihood 40-fold greater than that of their unaffected spouses.[12–14] This, along with high twin concordance rates, establishes that germline genes importantly contribute to the definition of the predisposition to develop psoriatic arthritis. Despite this strong familial aggregation, a little more than one-half of patients with psoriatic arthritis are sporadic cases with a negative family history. In the classic studies of Moll and Wright,[3] among 88 probands that fulfilled their criteria for psoriatic arthritis, 12.5 percent had at least one first- or second-degree relative with psoriatic arthritis that also met these criteria, with a psoriatic arthritis prevalence of 5.5 percent among 181 first-degree relatives. Rahman and Elder[2] reanalyzed these data and estimated the magnitude of the genetic contribution for psoriatic arthritis from the relative proportion of disease in the first-degree relatives compared with the prevalence of disease in the general population using the λ_R formulation by Risch.[15] Assuming the prevalence of psoriatic arthritis is 0.1 percent, this yields a risk λ_R for first-degree relatives of 55. Even assuming a highest prevalence of psoriatic arthritis in the population of 0.45 percent, the λ_R would decrease only to 12.2, a notably high recurrence ratio for a complex disease, implying a very strong genetic contribution to susceptibility. In a more recent study, Myers et al.[16] reported essentially similar findings. The concordance rate among siblings for all types of psoriatic arthritis was 14 percent including enthesitis and for psoriasis 21 percent. If enthesitis is excluded, the resulting values resemble the 12.5 percent frequency of affected siblings observed by Moll and Wright, who did not include enthesitis in their original criteria. The inheritance of psoriatic arthritis has a mixed multifactorial pattern found in many autoimmune diseases that either simulates a partially dominant mode of inheritance that is incompletely penetrant,[3] or a recessive mode.[17] As might be expected, affected sibling pairs are usually discordant for their patterns of joint involvement. The most common symptom in affected siblings was enthesitis.

HLA CLASS I GENES INVOLVED IN DETERMINING SUSCEPTIBILITY Because the highly polymorphic MHC genes have an important role in regulating immune responsiveness, they were the first candidate genes to be examined for a role in determining genes involved in psoriatic arthritis susceptibility. Association studies with candidate genes with psoriatic arthritis began with Brewerton's identification of a significantly increased frequency of HLA-B27 in individuals with psoriatic arthritis.[18] There is considerable heterogeneity in the reported frequency of HLA-B27 in psoriatic arthritis, ranging from 39 percent in Taiwan,[19] 17 percent to 34 percent in different studies from northern Spain,[20,21] through 20 percent in Great Britain,[22–24] 4 percent in Israel,[25] and to series in which HLA-B27 was not detected.[26] These variations partially reflect the diagnostic criteria used and the geographic distribution of HLA-B27 alleles that increase in circumpolar populations. In addition, the influence of immunogenetic factors on the pattern of joint involvement in psoriatic arthritis was shown by an increase of the frequency of HLA-B27 to approximately 70 percent with spine involvement. HLA-B39 and to a lesser extent HLA-B38 (both splits of the specificity termed *HLA-B16* in the very old nomenclature) have been identified as elevated in psoriatic arthritis in multiple independent studies, but with divergence between different reports, in part because of the differences in ethnic distribution. HLA-B*3801 differs from HLA-B*3901 because the former, similar to HLA-B27, bears a strong ligand for the KIR3DL1 NKR receptor, whereas the latter is nonreactive. HLA-B38 and HLA-B39 do not share ancestral haplotypes or HLA-C alleles with HLA-B27 alleles.

As anticipated from the relationship of psoriatic arthritis to psoriasis, psoriatic arthritis is also associated with an elevated frequency of *HLA-Cw6* as first reported in a study using serologic techniques by Murray et al.,[25] where it was identified in 34.6 percent of psoriatic arthritis, 50.0 percent of psoriasis, and 13.5 percent of controls. Interestingly, the HLA-Cw6 allele, related to *Psors1*, is found in strong linkage disequilibrium with HLA-B57 and HLA-B13, but not with HLA-B27, HLA-B38, or HLA-B39. Alleles encoding HLA-B13 and HLA-B57 are also in strong linkage disequilibrium with the HLA-DR7 and the DQA1*0201 alleles, emphasizing the large genomic distances over which these ancestral haplotypes extend, and as expected HLA-DR7 and the DQA1*0201alleles have also been reported at increased frequency in psoriatic arthritis and psoriasis.[27,28]

There are four general lessons about HLA associations in psoriatic arthritis: First, the genetic effect of HLA susceptibility alleles is evident in both simplex "sporadic" psoriatic arthritis as well as in multiplex families, demonstrating that both sporadic and multiplex forms of psoriatic arthritis are likely determined by the same genes. Second, even in multiplex families the inheritance of HLA alleles associated with susceptibility does not account for all affected individuals. Third, the greater increase in the frequency of the HLA-Cw6 allele in psoriasis without psoriatic arthritis and the greater increase in HLA-B27, HLA-B38, or HLA-B39 in psoriatic arthritis provide molecular evidence of genetic heterogeneity in psoriatic arthritis and psoriasis. Fourth, in comparison to psoriasis, the role of HLA alleles in determining susceptibility to psoriatic arthritis is less conclusively etched and seemingly more intricate. These findings strongly suggest that other non-MHC genes play an important role in specifying psoriatic arthritis susceptibility.

Triggering of T Cells: Stage 2

HLA class I molecules have two different functions. First, they specifically bind and present peptides that are recognized by the clonally specific T-cell receptors on CD8 T cells, a recognition event central to the adaptive immune response to intracellular pathogens. Second, they engage a variety of NK receptors expressed by NK cells or memory/effector CD8 T cells in an innate immune system surveillance process that in part detects reduction in expression of self-MHC, missing self, found on transformed or pathogen-infected cells, and also detects aberrant increases in class I or related molecules induced by stress and injury. One set of either activating or inhibiting NK receptors that interact with particular allelic HLA-B or HLA-C allelic molecules is the killer inhibitor receptor (KIR) system. Alleles of the KIR system have been shown to interact epistatically with HLA alleles in determining susceptibility to psoriatic arthritis.[29,30] The interpretation of the meaning of the association of HLA-B27 and the second group of HLA class I alleles including HLA-B13, HLA-B57, and HLA-Cw6 with susceptibility to develop psoriatic arthritis is compatible with both scenarios of pathogenesis described above. In the first scenario, these HLA molecules are envisioned to act to select a particular repertoire of CD8 T cells by binding and presenting certain self-peptides during the phase of positive thymic selection of the T-cell repertoire. In

the second scenario, these particular allelic HLA molecules interact differently with various NK receptors (e.g., KIR receptors on the memory-effector population).

The second stage of the disease involves activation of the CD8 T-cell clones and the pathways involved differ in each of the two potential scenarios. In the first scenario, during T-cell repertoire formation all T cells are selected on self-peptides and the individuals with psoriatic susceptibility alleles are left with certain potentially self-reactive CD8 T-cells in their repertoire. These may be in a state termed *clonal ignorance* rather than tolerance, and the provision of appropriate co-stimulatory signals to the T-cell by accessory molecules on activated dendritic cells is the critical event that results in the activation of these T-cell clones. In the innate immune scenario, activation is accomplished by either self- or non-self-antigens that are not identical to peptides found in the entheses or joints. The CD8 T cells directed to putative keratinocyte peptides that expand for a decade while mediating psoriasis until the phase of overt psoriatic arthritis appears might suffice to account for this clonal expansion. Alternatively, the clones may expand in an adaptive immune response to a pathogen. The HLA susceptibility alleles could play a role in developing a primed memory–effector cell repertoire.

Events Resulting in Overt Joint Inflammation and Injury: Stage 3

The development of joint inflammation requires a pool of expanded antigen-reactive CD8 T-cell clones with an effector cell phenotype that can be triggered by the joint environment. In the adaptive immune response scenario, there is a phase of substantive CD8 T-cell clonal expansion and differentiation to an effector phenotype driven by psoriatic self-antigens as depicted in the third compartment in Fig. 19-3. In the second scenario, this expansion has been accomplished. The critical event in the innate immune scenario is the provision of a clonal attracting and activating stimulus in the joint that initiates the localization and in situ activation of the memory-effector T cells through engagement of their NK and other receptors acquired as the cell enters the memory-effector stage of development. It is the analogue of the activation of the dendritic in the innate scenario. Engagement of these NK receptors by ligands induced in the joint tissues provides abundant co-stimulation to activate the memory-effector CD8 T-cell clone with minimal clonal T-cell receptor engagement.

Both scenarios then merge in terms of the consequence of T-cell activation. A cascade of secondary immune responses occurs in the joint tissue as a result of this drive. Chemokines and cytokines, including interferon-γ released by T-cell activation (see Chaps. 11 and 12), activate vascular endothelium and monocyte-macrophages. The activated macrophages release additional chemokines and cytokines such as IL-1, IL-6, and TNF-α. The cytokines affect the pattern of gene expression in target mesenchymal cells resulting in injury and loss of function, whereas the chemokines instigate the non-antigen–specific recruitment of other CD8 T cells and CD4 T cells into the site of inflammation, as well as additional leukocytes. These recruited bystander T cells, in turn, release additional cytokines that act on synovial lining cells, cells of the entheses, and other cells in the fibroblast lineage to alter their pattern of gene expression, proliferate, and preside over cartilage erosion or induce new bone formation. Similarly, these immunoreactants act on vascular endothelium to alter its functional state toward one that supports inflammation and recruits additional leukocytes. The combination of cytokines, chemokines, and other pro-inflammatory factors from all of these cell types results in the distinctive picture of joint and tendon inflammation, cartilage destruction, and mesenchymal activation characterized by fibrosis and new bone formation.

CLINICAL MANIFESTATIONS

Onset and Occurrence

Psoriatic arthritis characteristically develops between 25 and 45 years of age, an average of 10 years after appearance of psoriasis, but can occur at nearly any age. Onset earlier in adulthood or in childhood is associated with a heightened likelihood of developing destructive arthritis. Typically, early onset psoriatic arthritis occurs in a setting of a strong family history of the disease.[31] The sex ratio parallels that of psoriasis, with an excess of females in early childhood but an essentially equivalent incidence in both sexes in adults.

The onset of arthritis is usually insidious, but occasionally is abrupt, sometimes seeming to following a joint injury. Whether the injury precipitates the process or simply draws attention to an ongoing process is unclear. The intensity of the disease and the abrupt onset may suggest reactive arthritis (see Chap. 20) syndrome or gout (see Chap. 161). Dactylitis and pitting edema of the hands or feet, sometimes asymmetric, secondary to enthesitis and tenosynovitis may be the first manifestation of psoriatic arthritis and emphasizes the tendency for acral involvement of the limbs in psoriatic arthritis. The development of insidious inflammatory back pain is an important clue to the recognition of axial disease and this may be the initial manifestation of psoriatic arthritis (Table 19-3). Constitutional features, including fever and malaise, are uncommon, usually evident only in a fulminant onset with widespread joint disease. However, the erythrocyte sedimentation rate, C-reactive protein, and the serum complement levels are commonly elevated, reflecting activation of acute phase reactants by cytokines.

TABLE 19-3
Inflammatory Back Pain from Initial Inflammation of Spondylitis, Sacroiliitis, or Axial Enthesitis

- Onset before age 40 yr
- Insidious dull deep buttock or low back pain
- Poorly localized, does not follow nerve root
- Persists > 3 mo
- Stiffness/pain on arising in the morning, or during sleep
- Improvement with exercise
- Differential diagnosis from mechanical or degenerative spine disease

Skin Disease

Susceptibility to the development and severity of arthritis loosely correlates with the severity of cutaneous involvement. However, remissions and exacerbations of the joint disease correlate only poorly with similar changes in the skin disease.

Tenosynovitis and Enthesitis

Enthesitis and dactylitis are hallmarks of psoriatic arthritis. Enthesitis may be quite subtle and can sometimes be relatively easy to overlook, or it may be fulminant with intense tenosynovitis. Enthesitis may present only as non-specific foot pain, tennis elbow in the non-dominant hand, or isolated posterior tibial tendonitis; these symptoms are not considered by the patient to be part of the illness. Enthesitis is sometimes widespread and symmetric, a distribution that differentiates it from post-traumatic or

occupational tendon injury that tends to affect the dominant hand and arm. Advances in imaging greatly aid in the identification of enthesitis and other features of psoriatic arthritis.[32,33] The property of magnetic resonance to image ligaments and cartilage is a particular strength, as is its ability to identify tissue edema or small effusions by various types of signal weighting. MRI showed the inflammation of the bone adjacent to the insertion as well as the soft tissue changes. Ultrasonography was shown to delineate the swelling of the entheses and the peritendinous soft tissues as well as the distension of adjacent bursae by fluid collections. Bone scintigraphy is often useful in identifying the precise nature and location of the sometimes confounding development of enthesitis that may simulate infection.

Nail Disease

The nail matrix is frequently affected in psoriatic arthritis, resulting in a variety of manifestations, including nail pitting, subungual hyperkeratosis and onycholysis, nail crumbling, Beau's lines (ridging), leukonychia, salmon patches, erythematous patches of the lunula, and ectatic tortuous capillaries that resemble splinter hemorrhages. Nail matrix disease is more strongly associated with psoriatic arthritis than with psoriasis alone, being found in 80 percent to 85 percent of those with arthritis versus 20 percent to 30 percent of those with the isolated cutaneous form of the disease.[34] Nail disease and paronychia is especially related to involvement of the DIP of the same digit reflecting the acral dystrophic state (see Fig. 19-1).

JOINT DISEASE PATTERNS AND RADIOLOGY The pattern of peripheral joint involvement[35] and the associated findings of nail disease, tenosynovitis, enthesitis, ankylosis, periosteal new bone formation, erosions, osteolysis, and axial involvement provide radiologic hallmarks for the recognition of psoriatic arthritis (see Tables 19-1 and 19-2). Approximately 75 percent of persons diagnosed with psoriatic arthritis manifest peripheral, usually asymmetric, oligoarthritis that involves the small joints of the hands and feet (Fig. 19-4), the large joints of the legs, or a combination of both small and large joints. When only a few joints are involved, the distribution often appears asymmetric. The hand involvement can include stiffness and dactylitis that are attributable to enthesitis

▲ **FIGURE 19-4** Radiograph revealing juxta-articular osteoporosis and erosions at all metacarpophalangeal, distal, and proximal interphalangeal joints in a 30-year-old man with human immunodeficiency virus-1–associated psoriatic arthritis.

as well as synovitis. Deformity secondary to fibrosis and contractures may occur. The classic pencil-in-cup joint of psoriatic arthritis is sometimes seen, consisting of symmetric and conical osteolysis of the proximal head, with enlargement of the base of the distal head by new bone formation. Acral osteolysis and erosions at the tip of the tuft of the digit are characteristic, especially when they involve the hallux. Ankylosis of one or more isolated joints is another distinctive feature due to fibrosis and new bone formation. Sometimes the initial or only manifestation of psoriatic arthritis is hallux rigidus, implying the subtle nature of joint inflammation and the need for its earlier recognition.

Inflammation of one or many of the DIPs is virtually pathognomonic for psoriatic arthritis or reactive arthritis; it need only be distinguished from Heberden's nodes, which occur in a form of osteoarthritis infection, or, rarely, crystalline arthritides such as gout. The points of distinction concerning rheumatoid arthritis versus psoriatic arthritis are summarized in Table 19-4, and it is important to emphasize that the DIP is rarely, if ever, affected by rheumatoid arthritis. In some instances, the joint involvement in the hands and feet is widespread (see Fig. 19-4).

The large joints that are affected in psoriatic arthritis include the hips, knees, and ankles. Often only a single hip or knee joint is involved; the dominant diagnostic considerations in adults include degenerative osteoarthritis or post-traumatic arthritis rather than psoriatic arthritis. Post-traumatic forms of psoriatic arthritis in athletes are particularly challenging to distinguish from purely mechanical injuries. In approximately 5 percent of persons with psoriatic arthritis, the character of the joint injury becomes profoundly destructive with marked osteolysis, resulting in what is sometimes referred to as *arthritis mutilans*. In rare instances, this process is generalized, but much more commonly one or a few joints in the hands or feet are characterized by destruction out of proportion to the remainder of the illness. *Opera glass hand* refers to the osteolytic shortening of digits or the wrist

TABLE 19-4
Contrasts between Psoriatic Arthritis and Rheumatoid Arthritis

	Psoriatic Arthritis	Rheumatoid Arthritis
Elevated erythrocyte sedimentation rate, C-reactive protein	Yes	Yes
Susceptibility alleles	MHC class I	MHC class II
Amelioration with progressive HIV infection	No	Yes
Implied class of lymphocytes driving inflammation	CD8	CD4
Autoantibodies (e.g., rheumatoid factor)	No	Yes
Immune complexes	No	Yes
Small vessel vasculitis	No	Yes
Fibroblastic response	Yes	Rare
Sacroiliitis	Yes	No
Enthesitis, dactylitis	Yes	No
Erosions	Yes	Yes
Juxta-articular osteopenia on x-ray	Uncommon	Yes
Juxta-articular new bone	Yes	No

HIV = human immunodeficiency virus; MHC = major histocompatibility complex.

bones surrounded by redundant folds of skin. Pustular psoriasis or erythroderma is more common among this group.[36] In occasional patients the sternomanubrial and temporomandibular joints may become involved, in association with extensive typical psoriatic arthritis.

The synovitis of psoriatic arthritis is accompanied by the formation of joint fluid with features that reflect the pathogenesis of the disease. The fluid is dominated by polymorphonuclear leukocytes, with levels that may reach 25,000 per mm^3, presumably recruited by IL-8. The number of lymphocytes is often substantially elevated and consists mainly of T cells and NK cells, with a preponderance of CD8 T cells.[37] The T-cell phenotype reflects their activated state with expression of HLA-DR, CD25, and CD69 and their predominant memory-effector differentiation, being $CD28^-$, $CD45RA^+$, and expressing various NK receptors.

Certain syndromes simulate psoriatic arthritis but increasingly appear to be distinct entities; these include the anterior chest wall syndrome of sternomanubrial or costoclavicular involvement, where sternomanubrial disease occurs in isolation; the so-called *SAPHO syndrome* and recurrent multifocal osteomyelitis. See reference 38 for a brief review of these entities.

The axial involvement occurs in just over one-third of cases and is often most evident in the lower spine and sacroiliac joints. The predisposition to axial involvement is strongly influenced by the presence of HLA-B27. The axial involvement is often heralded by inflammatory back pain (see Table 19-4). The spinal involvement differs from the uniform ascending pattern that characterizes ankylosing spondylitis. Scattered submarginal syndesmophytes and apophyseal or odontoid erosions are found without widespread vertebral squaring, apophyseal joint involvement, or ligamentous calcification. Sometimes the nonmarginal syndesmophytes become bulky broad paravertebral excrescences that contrast with the vertically oriented outgrowths of bone in the outer margins of the annulus fibrosus in ankylosing spondylitis.[39,40] Vertebral squaring from new bone formation, apophyseal joint involvement, and ligamentous calcification in the lumbar spine are similar to that found in ankylosing spondylitis. Sacroiliitis is more often asymmetric rather than the symmetric involvement of ankylosing spondylitis. MRI is the most sensitive and specific modality for identifying sacroiliitis and other changes in the axial skeleton.[41]

Whether current ascertainment of joint involvement by clinical and classic x-ray procedures in those with psoriasis is adequate has been the subject of several studies using newer imaging modalities such as radionuclide scanning, ultrasonography, or nuclear MRI. In a study using MRI to examine the frequency of hand involvement in patients with nummular psoriasis, plaque psoriasis, or both, free from arthritic symptoms, Offidani et al. found 68 percent of psoriasis patients had at least one arthritic sign by MRI, such as soft tissue swelling, periarticular effusion, joint effusion-synovial pannus, tendon sheath effusion, bone erosion, subluxation, bone cysts, and subchondral signal intensity abnormalities, whereas standard x-rays revealed joint abnormalities in 32 percent.[32] Further investigation of these observations is warranted, including the determination of the specificity of these findings.

Other Manifestations

Apart from cutaneous and musculoskeletal involvement, ocular involvement occurs in approximately one-fourth of those with psoriatic arthritis. Conjunctivitis is the most prevalent condition and usually responds to symptomatic therapy. Iritis develops in approximately 5 percent of those with psoriatic arthritis. It is uncertain whether this reflects the presence of HLA-B27, because uveal tract inflammation is strongly associated with the presence of this allele, or whether it is an intrinsic feature of psoriatic arthritis. Because of the serious inflammatory consequences of synechiae and glaucoma, it is important to detect the development of iritis and initiate appropriate therapy. Cutaneous vasculitis, a feature of many autoimmune rheumatic diseases, is absent from psoriatic arthritis.

PEDIATRIC PSORIATIC ARTHRITIS There are two syndromes currently classified as juvenile psoriatic arthritis distinguished by age of onset and other features. The onset of juvenile psoriatic arthritis shows a peak incidence, with female preponderance, between 2 and 4 years and a second peak beginning at age 11 to 12 years in both sexes that extends into adulthood and in most respects resembles the disease in adults. The subset of children between 2 and 4 years of age currently diagnosed with juvenile psoriatic arthritis is predominantly female, has positive anti-nuclear antibodies, and has potentially ominous chronic anterior uveitis, indistinguishable from that seen in young (2 to 4 years of age) girls with pauciarticular juvenile arthritis.[42] They have much lower frequencies of HLA-B27 and HLA-Cw6 than the older onset subset. This interesting early onset form of juvenile psoriatic arthritis may be a variant form of pauciarticular juvenile arthritis that is characterized by psoriasis and dactylitis and be a fundamentally different entity from psoriatic arthritis as it is currently understood. In contrast to the usual sequence in adults, almost one-half of juvenile patients presented with arthritis before skin disease, with the interval between the onset of arthritis and psoriasis as long as 8 years.[43] Psoriasis, or a positive family history of psoriasis, usually provides the diagnosis, but if it is absent diagnosis is often delayed due to the similarities of the disorder with pauciarticular or oligoarticular juvenile arthritis. Axial involvement, when found, is usually associated with the presence of HLA-B27. Therapy is analogous to that of the adult disease, with the added concern that chronic inflammation in a joint may enhance the maturation of the epiphyses resulting in limb asymmetry and deformity. Additionally, management is complicated because Reye syndrome in young children may be seen with salicylate administration.

The long-term course of juvenile psoriatic arthritis results in a polyarticular pattern with asymmetric involvement of both upper and lower extremities and prominent digital involvement. Criteria have been developed for the classification of childhood psoriatic arthritis where, in addition to the presence of arthritis and psoriasis or a positive family history thereof, emphasis is placed on dactylitis, nail pitting, symmetry of arthritis, disease course (oligoarthritis or polyarthritis), anti-nuclear antibodies, and uveitis.[44] Interestingly, emphasizing the interplay between various events that precipitate reactive arthritis or reactive arthritis syndrome and the development of psoriatic arthritis of five HLA-B27–positive children reported with what was termed *juvenile reactive arthritis* following *Salmonella enteritidis* infection, three developed typical psoriasis in the months after the arthritis.[45]

PSORIATIC ARTHRITIS AND HUMAN IMMUNODEFICIENCY VIRUS INFECTION In North America and most of Europe, the con-

siderable earlier problem of extraordinarily severe psoriasis, psoriatic arthritis, and reactive syndrome occurring in the setting of advanced fulminant HIV-1 infection has abated due to better antiretroviral therapy and management of other infections, but in some regions of the world these complications of HIV remain a very substantive problem.[38] The onset of de novo psoriasis and psoriatic arthritis in HIV-infected individuals may be explosive with many features indistinguishable from Reiter syndrome. It can be triggered by an antecedent infection with an arthritogenic Gram-negative organism or appear in a more insidious manner.[46–49] Almost invariably, the psoriasiform skin disease is very severe with pronounced acral involvement (see Fig. 19-1). Alternatively, in an individual with pre-existing mild psoriasis, the development of acquired immunodeficiency syndrome (AIDS) can be signaled by an abrupt increase in severity of the skin disease and development of psoriatic arthritis.

The progression of the arthritis takes two general forms: an accumulative pattern evolving to full intensity over several weeks to months, or the more common milder, intermittent pattern of recrudescences and remissions. The accumulative form is often associated with widespread polyarticular (but asymmetric) arthritis and is characterized by synovial thickening, erosions, and juxtaarticular osteoporosis. Hand and upper extremity involvement predominates in the accumulative pattern. The intermittent form usually has oligoarticular knee or ankle joint involvement. Severe enthesopathy of the Achilles tendon, plantar fascia, and anterior or posterior tibial tendons may cause some patients to exhibit a characteristic broad-based "AIDS" gait, walking with the feet in inversion and extension in an attempt to diminish pain by distributing weight on the lateral margins. Multidigit dactylitis frequently occurs and, in combination with plantar fasciitis and extensor tenosynovitis, may simulate cellulitis or pedal edema. Although synovitis of the knee is prominent, hip disease and shoulder-girdle involvement are uncommon, emphasizing the acral component of involvement. The prevalence of axial involvement appears to be distinctly uncommon, with sacroiliitis only occasionally seen.

The cutaneous manifestations of HIV-associated psoriatic arthritis overlap with those of HIV-associated reactive arthritis syndrome. The eruption often resembles widespread pustular psoriasis with a greater tendency for involvement of the groin and intertriginous regions (inverse or sebopsoriasis). A progressive intensification of changes in the distal digits is often very prominent. Acrokeratosis is very common, often associated with erythema and periungual pseudoparonychia formation. Severe alterations in the nails of the hands and feet often accompany DIP joint involvement and are manifested clinically as onychodystrophy with or without subungual hyperkeratoses.

COURSE AND PROGNOSIS

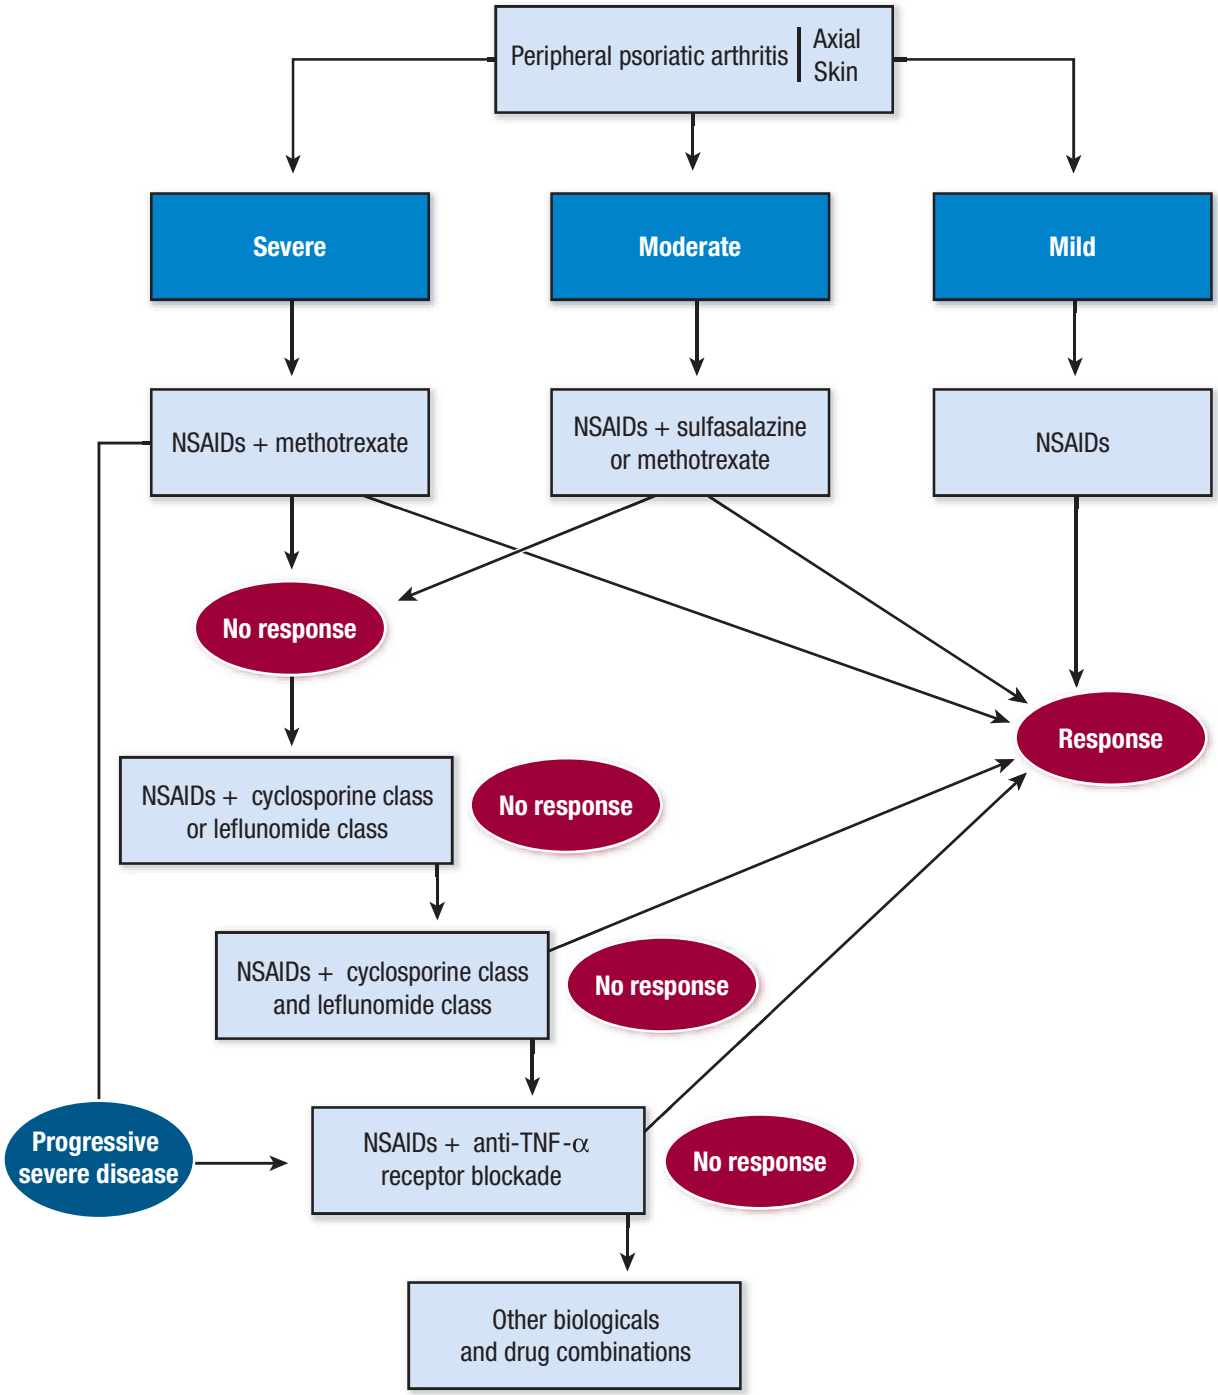
For most patients with psoriatic arthritis, the musculoskeletal manifestations are relatively milder than those of rheumatoid arthritis. However, the subset of psoriatic arthritis cases with arthritis mutilans have catastrophic joint destruction that often proceeds more rapidly than joint injury in rheumatoid arthritis. After 8 years of disease, two-thirds of patients with psoriatic arthritis are effectively employed,[50,51] roughly one-half develop significant deformity of one or more joints, and approximately 1 in 10 progress to an advanced stage of musculoskeletal impairment.[52] Severe and sustained joint involvement or enthesitis is especially evident in the HIV-associated form. Persons with hip or knee involvement may ultimately require joint replacement. However, despite a much greater degree of vitality among the majority of those with psoriatic arthritis, quality of life evaluation was equivalently diminished to that of rheumatoid arthritis.[53]

Several patterns of disease progression are evident. For most, the enthesitis arthritis waxes and wanes in severity, but remains persistently active. Approximately one-fifth of prospectively followed patients experience sustained remissions that last an average of 2.6 years.[54] Among the remainder with persistently active disease, mild but sometimes troublesome localized disease, such as the foot pain or recurrent tendinitis of enthesitis, forms a dominant pattern of involvement. For these individuals the overall prognosis is very good. Other patients with psoriatic arthritis progress to fibrous or bony ankylosis of one or a few joints, which may be unnoticed if there are no occupational demands. In yet another pattern, largely asymptomatic axial joint involvement not ameliorated by any of the specific therapeutic measures progresses independently of the state of the skin or peripheral joint disease.[55]

TREATMENT

The induction treatment algorithm summarized in Fig. 19-5 is a modification of the algorithm initially proposed by the British Society of Rheumatology.[56] This is an idealized way of approaching treatment choices that apply to an average patient, but certainly not to all patients. Because either skin or musculoskeletal disease may be the dominating feature, the choices summarized in the algorithm should be further modified for treating the skin lesions if they are the preponderant process. For example, an individual with mutilans arthritis would likely be a candidate for immunobiologic therapy in combination with a DMARD and move directly to the bottom of the algorithm. In the algorithm, patients with peripheral psoriatic arthritis involving entheses, joints, or both are subsetted according to disease severity into three initial treatment groups, mild, moderate, and severe, that receive nonsteroidal anti-inflammatory drugs (NSAIDs) alone or in combination with the first line DMARDs, sulfasalazine or methotrexate (MTX), with those at the more severe end of the spectrum begun on a combination of MTX and sulfasalazine. The following section expands on the nature and effects of these and related agents. Each of these therapies may be combined as appropriate with administration of local corticosteroids into one or a few sites of enthesitis or synovitis. Local therapy of a localized disease process is preferable to systemic therapy. Objective failure of an adequate trial of this regimen moves the patient to the second-line DMARDs such as the cyclosporine class of calcineurin blockers and the leflunomide class of DNA/RNA antimetabolites including azathioprine (Imuran), with an attendant increased risk from side and untoward effects. Objective failure is a difficult concept to define comprehensively, but should include both worsening of patient and physician global assessment and documented evidence of persisting or progressive synovitis or enthesitis; development of cartilage or bone erosions; and progression of joint fibrosis or ankylosis. The British Society of Rheumatology criterion for treatment failure is ≥ 3 tender and ≥ 3 swollen joints on two occasions 1 month apart. Objective failure of an adequate trial of second-line DMARDs moves the patient to the use of immunobiologics, such as a TNF blocker. Response moves the patient to a maintenance regimen.

In the case of mild disease, a maintenance regimen is a continuation of the



▲ **FIGURE 19-5** An algorithm summarizing choices for the induction of treatment of psoriatic arthritis involving the peripheral joints according to response or no response. NSAIDs = nonsteroidal anti-inflammatory drugs; TNF = tumor necrosis factor.

NSAID administration. For more severe psoriatic arthritis, the choices of maintenance therapy are more complex and guidelines less established, though based on the principles of drug action as outlined below for induction, and involve stepping back through the scheme.

Mild Joint Involvement

For most patients with mild joint involvement or enthesitis, the goals of therapy are the control of pain and inflammation by using traditional NSAIDs or analgesics, the maintenance of joint range of motion and function by physical therapy, local therapy for isolated areas of involvement, and the avoidance of potentially injurious extreme joint stress through counseling against repetitive injury. The patient should be monitored for progression in the severity of joint involvement.

NSAIDs act late in the inflammatory cascade by altering lipid remodeling in prostaglandin and leukotriene pathways and do not greatly alter the natural history of psoriatic arthritis. However, they do lessen stiffness, tissue edema, overall inflammation and pain, and thus increase mobility and function. Several biochemical families of NSAIDs or analgesics are available for therapy and although they have some differences in anti-inflammatory efficacy and toxicity, choosing which NSAID to start is mainly dictated by physician experience

and the individual response of a patient. Naproxen and indomethacin are traditionally considered representative of NSAIDs with the greatest efficacy in treating spondyloarthritis. Adverse effects shared by all NSAIDs include gastric and renal toxicity; hypersensitivity reactions; central nervous system effects, in particular tinnitus and headache; and coagulation abnormalities. In some patients with psoriasis the use of NSAIDs induces an idiosyncratic flare of the psoriatic skin lesions, the result of enhanced production of leukotrienes that occurs with cyclooxygenase inhibition. Most patients have had experience of self-prescribed drugs of this class and before initiating NSAID therapy patients should be asked whether aspirin or other NSAIDs caused a flare of psoriasis, and this class of drug should be avoided in that instance.

Lack of adequate response to NSAIDs usually requires additional drug therapy. If the involvement is limited to one or two sites, local intra-articular steroid injections may relieve an isolated episode of severe synovitis, whereas enthesitis and tendinitis respond to injections into the tendon sheaths that may be performed under ultrasound imaging to assure delivery of the drug to the proper site.

Systemic steroid is not commonly administered because of its much lower efficacy in psoriatic arthritis compared to other autoimmune diseases, coupled with the risks of inciting a transition to pustular psoriasis, a rebound of the skin disease on withdrawal, and the well-known complications of steroid therapy. Similarly, parenteral or oral gold salts are not therapies of choice because of their limited efficacy in treating psoriatic arthritis.[57]

Moderate Joint Disease

Patients with moderate joint disease are optimally first treated by combining NSAID administration with sulfasalazine. Double blind trials have shown sulfasalazine is moderately effective in reducing clinical parameters of joint disease activity and laboratory indices of inflammation in approximately 30 percent to 40 percent of patients,[57] especially in those with spondylitis.[58] Sulfasalazine has no effect on skin disease. In those with more severe disease who cannot tolerate MTX, a trial of sulfasalazine may be warranted before administering the more potent DMARDs discussed below. A low incidence of untoward reactions to sulfasalazine have been noted, mainly hypersensitivity dermatitis or gastrointestinal intolerance.

Severe Psoriatic Arthritis

For severe joint involvement, enthesitis, and axial disease, NSAIDs are supplemented with a more potent anti-inflammatory agent with immunomodulatory properties, such as the first-line DMARD MTX, or if there is no objectively satisfactory response, to second-line DMARDs such as cyclosporine A class drugs or antimetabolites such as leflunomide either separately or in combination. TNF blockers are at the third level of therapy. These, and more newly developed second- and third-generation DMARDs, offer a variety of strategies to rationally downmodulate the immune response in difficult cases. As emphasized above, these guidelines summarized in Fig. 19-5 are an idealized flow diagram, but individual cases raise therapeutic challenges not encapsulated in the algorithm and these require individual solutions based on the knowledge of the patient, the disease, and the drugs.

The improved benefit of these new agents comes with a variety of new risks, and the risk-to-benefit ratio of each of these agents agent should be carefully weighed. Special concerns also exist about their use in children or during pregnancy. In addition to untoward responses unique to each agent there is an overarching potential for untoward suppression of the immune response with each of these agents and attention should be given to identifying patients that are persistently infected with pathogens, such as *Mycobacterium tuberculosis*, or HIV-1 that may contraindicate their use. Additional strategies of particular DMARD combinations for induction or rotational therapies for maintenance that reduce risk and gain benefit are currently being developed.

METHOTREXATE (See Chap. 228) MTX is currently the initial drug of choice for therapy of severe psoriatic arthritis in those with either mild to severe skin disease. Both parenteral and oral MTX are effective in psoriatic arthritis. The efficacy of parenteral MTX suggests that this route of administration may have some advantages for the induction phase of therapy especially in instances of particularly severe disease.[57] Maintenance MTX therapy may be administered by the oral route. The untoward effects of MTX are discussed in Chap. 228. Minimal immune impairment is sometimes encountered and the uncommon possibility of developing opportunistic infections such as *Pneumocystis carinii* should be kept in mind in the differential diagnosis of pneumonitis developing during MTX therapy.

Although in higher doses MTX is a DNA antimetabolite, MTX therapy in psoriatic arthritis and rheumatoid arthritis appears to act by increasing the release of adenosine, which engages adenosine receptors 2A and 2B, which in turn inhibit the release of pro-inflammatory cytokines and chemokines by macrophages.[59] MTX also enhances the production of anti-inflammatory cytokines, such as IL-10, by macrophages and appears to modulate the macrophages from a pro- to an anti-inflammatory differentiation state. Supporting the conclusion that the anti-inflammatory effect is not a consequence of the antifolate action of this compound is the recommendation that it be given together with folic acid.

The action of MTX on the inflammatory T cell infiltrate in the synovitis of psoriatic arthritis is consistent with the hypothesized mode of drug action.[7] The drug reduces the polyclonal infiltration of predominantly CD4 T cells but has little effect on the CD8 antigen–driven oligoclonal expansions over 12 to 18 months of therapy. The inability of MTX therapy to eliminate the expanded CD8 clones suggests that the MTX is suppressive rather than curative, and that these clones may be the basis of recrudescent disease that appears after cessation of the drug.

OTHER NONBIOLOGIC AGENTS (See Chap. 228)

Cyclosporine. Cyclosporine A is considered to be equivalent in efficacy to MTX; however, more serious untoward effects limit its use. Cyclosporine A improves both the psoriatic skin and joint disease in approximately 50 percent of patients. Improvement in skin disease occurs after 2 to 6 weeks of treatment, whereas the joint involvement takes up to 24 weeks to improve.[58,60] However, as with MTX and TNF inhibitors, within 4 weeks of discontinuing the drug exacerbations of both skin and joint disease were seen. Cyclosporine binds to cyclophilin and blocks the function of the serine-threonine phosphatase calcineurin. Consequently, the cytoplasmic component of the nuclear factor of activated T cells is not dephosphorylated and cannot enter the T-cell

nucleus, bind to the IL-2 gene promoter, and activate IL-2 synthesis. Cyclosporine inhibits T-cell activation and clonal expansion, acting at a different point in the pathogenesis of psoriatic arthritis than MTX and combinations of the two drugs may offer advantages. Untoward effects of cyclosporine A include renal toxicity, hypertension, and azotemia and the potential for the development of Epstein Barr virus–related B-cell lymphomas. Newer drugs of this class have improved safety profiles and appear to offer an improved benefit risk ratio, but extensive trials of their use have not been conducted in psoriatic arthritis.

DNA and RNA Antimetabolites. With the exception of leflunomide, a more recently introduced agent that inhibits de novo ribonucleotide synthesis, the place of DNA and RNA antimetabolites in the therapy of psoriatic arthritis has received less extensive recent analysis, compared to the immunobiologic agents, but antimetabolites appear to have a role in the therapy of this disease, especially in the maintenance phase of therapy. These agents have the potential to directly affect the lymphocyte populations that putatively drive the disease. As with the immunobiologics discussed in Immunobiologic Agents, there is a class risk of immunosuppression, but the emergence of autoimmunity has not been reported.

Leflunomide inhibits de novo ribonucleotide synthesis. The low levels of ribonucleotides trigger p53 to block entrance of lymphocytes into S phase and inhibit cytokine release. The therapeutic effect takes 2 to 3 months to be manifest and the drug persists for long periods, requiring chelation by cholestyramine for its elimination in the event of adverse responses. In a 24-week double-blind trial, 36.3 percent of patients with psoriatic arthritis that were treated with leflunomide achieved American College of Rheumatology 20 percent improvement criteria (ACR20) responses compared to 20.0 percent of placebo-treated controls.[61] Leflunomide is a moderately effective second-line DMARD for psoriatic arthritis. The spectrum of untoward effects and contraindications should be consulted.

Azathioprine, studied in a randomized trial, was comparable in efficacy to MTX on psoriatic arthritis, but had little effect on skin disease, limiting its potential use to those with disproportionally severe musculoskeletal disease.[57] Bone marrow suppression is the primary untoward effect. Mycophenolate mofetil has not been studied in a randomized trial, but appears efficacious in open label studies, with less potential for marrow suppression.[62] It has also been used to treat uveitis. A single report of the efficacy of 6-thioguanine in the treatment of psoriasis, associated with the depletion and induction of apoptosis in activated T lymphocytes, suggests that this compound could be beneficial in severe psoriatic arthritis as a complement to the mode of action of MTX and TNF blockers.[63]

IMMUNOBIOLOGIC AGENTS (See Chap. 235) Immunobiologic drugs offer new, incisive, but expensive approaches to interdicting some pathways in the pathogenesis of psoriatic arthritis (see Fig. 19-2). The first important advance in this area was inactivation of effector cytokines secreted by activated monocytes. Because of the important role of TNF-α as an effector of inflammation in psoriatic arthritis, the anti-TNF agents infliximab and etanercept are taking an important place in the therapy of severe destructive psoriatic arthritis, especially in individuals who do not respond to MTX.[64] Etanercept is a receptor fusion protein that binds circulating TNF-α, whereas infliximab is a chimeric monoclonal antibody that binds TNF-α both in circulating and receptor-bound form. Adalimumab is a fully humanized monoclonal antibody that similarly binds circulating and receptor-bound TNF-α.

Etanercept. Of 86 patients completing a double-blind trial randomized to etanercept given subcutaneously twice weekly at 48 weeks of therapy, 59 percent exhibited a sustained ACR20 improvement compared to 13 percent in the placebo group. Maximal clinical improvement occurred between 4 and 12 weeks. Radiographic progression was inhibited during treatment. At 24 weeks, 47 percent of treated patients achieved a Psoriasis Area and Severity Index (PASI)-50 compared to 18 percent in the placebo group, whereas only 23 percent of patients had a PASI-75 response.[65] Etanercept as a monotherapy at 50 mg twice weekly does not provide increased efficacy when compared to the standard dose of 25 mg twice weekly.[66]

Infliximab. Infliximab, administered intravenously at weeks 0, 2, 6, and 14 in a placebo-controlled double blind study, yielded a 65 percent ACR20 in the treated group and 10 percent in the placebo group when evaluated at week 16.[67] Forty-six percent and 29 percent, respectively, achieved ACR50 and ACR70 responses, with 0 percent responses in the placebo group. Clinical responses appear within the first weeks of therapy and were maximal by week 12. Sixty-eight percent of those with skin involvement achieved a PASI-75, versus 0 percent in the placebo group. Skin and musculoskeletal improvement persisted through week 50 of therapy. Infliximab appears to be the most potent of the three agents, perhaps because of its intravenous route of administration, and this suggests it would be the agent of choice in very severe and rapidly progressing psoriatic arthritis.

Adalimumab. Adalimumab administered subcutaneously biweekly in a placebo-controlled double blind study yielded a 57 percent ACR20 in the treated group and 15 percent in the placebo group when evaluated at week 24. Thirty-nine percent and 23 percent, respectively, achieved ACR50 and ACR70 responses, with 6 percent and 1 percent, respectively, responding in the placebo group.[68] Maximal responses were achieved by week 12. Fifty-nine percent of those with skin involvement achieved a PASI-75, versus 1 percent in the placebo group. Skin and musculoskeletal improvement persisted through week 50 of therapy.

Anti–TNF-α therapy results in reduction in lining layer thickness, vascularity, and infiltration with neutrophils and macrophages. It appears that TNF blockade therapy has an action similar to that of MTX on eliminating major components of the effector pathways of joint inflammation, without significantly acting directly on the lymphocyte populations underlying the autoimmune drive of psoriatic arthritis.[69] In view of the good responses of many patients to these agents, a perplexing feature of their pharmacology is that at least one-third of patients with severe disease do not have satisfactory responses. It is presumed that their disease does not use pathways involving TNF-α. Importantly, little or no added efficacy was seen in each of the studies when the TNF blocker was combined with MTX, perhaps because they interdict the same pathways of macrophage-mediated inflammation. There is cautious support for the combination of leflunomide or other antimetabolites with infliximab, reflecting the complementarity of mechanisms of action, but in some units a high rate of adverse events has led to frequent treatment discontinuation.[70] This combination therapy is considered justified for treatment of patients diag-

nosed early who are at risk for rapid progression and for patients who do not respond to monotherapy; it is suggested to add biologic agents to a previously established leflunomide monotherapy rather than starting both treatments simultaneously.[70] At this stage of knowledge, there is little information from rigorous clinical trials to guide the physician in when to stop TNF blockade therapy and the choice of a subsequent maintenance drug. MTX is commonly used in this situation, but a rationale could be made for using agents that target T cells.

Considering the central role of TNF-α in the effector arm of the adaptive and innate immune response, an anticipated class effect of blockade of this pathway is the potential to impair overall immune function. This is reflected by instances of activation of latent *M. tuberculosis* infection with therapy, the appearance of opportunistic infections, and the development of B-cell lymphoma. The risk of reactivation of latent *M. tuberculosis* infection is greater with infliximab than with the etanercept, possibly because infliximab and adalimumab reduced the proportion of tuberculosis-responsive $CD69^+$ CD4 cells by 70 percent and 49 percent, respectively, and suppressed antigen-induced interferon-γ production by 70 percent and 64 percent; in contrast, etanercept produced no significant effect.[71] An unanticipated untoward class effect of these agents is the development of certain autoimmune diseases during therapy, including lupus-like disorders, leukocytoclastic vasculitis, and Guillain-Barré or multiple sclerosis–like demyelinating diseases.[72] Combination therapy with leflunomide may increase the likelihood of the autoimmune diseases developing. The development of anti-nuclear and anti-DNA antibodies and other serologic evidence of autoimmunity, including anticardiolipin antibodies and antineutrophil cytoplasmic antibodies, commonly occurs during treatment. These are mainly of the immunoglobulin M (IgM) or IgA class and usually decline in titer or disappear after treatment is stopped. Most, but not all, of the autoimmune diseases are mild and usually remit on discontinuation of the biologic. The mechanism responsible for this autoimmune state induced by TNF blockade is unclear. The evolving guidelines for use of these agents should be consulted before therapy is considered.

Alefacept. Another group of more recently introduced immunobiologics block the induction or maintenance of T-cell activation in psoriatic arthritis. Alefacept is a LFA3-Ig fusion protein that specifically targets T cells by blocking the LFA3-CD2 interactions, that provide a component of signal 2 in lymphocyte activation. Alefacept also triggers apoptosis or killing of activated memory T cells expressing high levels of CD2 through binding to FcRIII IgG receptors on NK cells and macrophages. Alefacept in combination with MTX for the treatment of psoriatic arthritis gave an ACR20 response at week 24 in 54 percent of patients, compared with 23 percent in the placebo plus MTX control group. Fifty-three percent of patients receiving alefacept plus MTX had a 50 percent reduction in their PASI at week 14 compared with 17 percent of those receiving placebo plus MTX.[73]

Other intriguing biologics, such as anakinra, an IL-1 receptor antagonist (IL-1ra) or abatacept, a CTLA4-Ig reagent that blocks CD28 from receiving a costimulatory signal 2, have not had clinical trials in psoriatic arthritis. Efalizumab is a recombinant humanized monoclonal antibody against the CD11a that blocks the LFA-1/intercellular adhesion molecule does not appear to ameliorate the joint disease.

Therapies for Axial Disease

The management of axial disease in psoriatic arthritis is not well delineated. Intensive physiotherapy and adequate NSAID administration are the cornerstones of treatment. There is no evidence for an effect of sulfasalazine on axial disease. MTX is demonstrated to be effective in double-blind studies in ankylosing spondylitis,[74] and by extension of its beneficial effect on peripheral joints in psoriatic arthritis, is likely to be the DMARD of first choice in treating axial disease. In unresponsive patients, TNF blockade is the next step, but there are only limited data supporting an effect on axial disease in psoriatic arthritis.

Therapy in Human Immunodeficiency Virus Infection

In psoriatic arthritis associated with HIV infection, NSAIDs such as naproxen are the first line of therapy; however, in many patients this drug does not adequately control inflammation, especially the very disabling enthesitis. Etretinate therapy (see Chap. 229) may be particularly useful in this form of psoriatic arthritis because it lacks immunosuppressive effects.[75] MTX, although effective for HIV-associated psoriatic arthritis, has been associated with the abrupt development of opportunistic infection and death in individuals with advanced HIV infection.[48] Therefore, MTX and similar potentially immunosuppressive agents are to be used with very considerable caution. Exquisite attention should be directed to monitoring HIV-1 virion levels and overall immunologic competency during such therapy by closely following absolute numbers of CD4 and CD8 T cells. An increase in virion level or a notable decline in CD4 count not controlled by antiviral therapy is an indication to withhold immunosuppressive therapy. A report on the use of Etanercept in psoriatic arthritis associated with HIV infection noted excellent clinical response of the skin and joint manifestations, but the drug had to be discontinued because of the development of multiple infections.[76] These observations emphasize the need for considering the presence of HIV infection when instituting immunosuppressive therapy in an individual with recent onset severe psoriatic arthritis.

Surgery and Related Techniques

Reconstructive surgery for severely damaged joints is highly successful. Arthroscopic synovectomy or intra-articular injection of short-lived radioactive isotopes of elements, such as Ytterbium, is an experimental approach that has been effective in treating instances of severe chronic monoarticular synovitis. Because of the enhanced tendency to fibrosis associated with these therapies, anti-inflammatory and physical therapy measures aimed at improving range of motion are important adjuncts to these interventions. Joint replacement and forms of reconstructive therapy are appropriate in situations of advanced joint destruction.

CHAPTER 20

Reactive Arthritis

Andrew Keat

EPIDEMIOLOGY

Reactive arthritis appears to affect all populations world-wide though with varying prevalence and clinical associations. The epidemiology of these urethritis-associated and gastrointestinal forms of reactive arthritis is distinct. The former predominantly affects males and occurs sporadically, whereas the latter affects males and females equally and occurs either in outbreaks or sporadically. The possibility that reactive arthritis may also follow respiratory tract infections is unresolved.

Accurate measures of the incidence or prevalence of reactive arthritis are not available. There are several reasons for this, notably the wide variability in clinical practice of the application of this diagnosis, linked with variations in recognition and demonstration of precipitating infections. Moreover, many cases are mild and go unrecognized. It is clear that the prevalence of reactive arthritis correlates with the prevalence of HLA-B27 and with exposure to known initiating infections.[1,2] In Finland, the annual incidence of reactive arthritis after bowel or genitourinary infections was found to be approximately 30/100,000,[3] whereas German figures estimate a prevalence figure of 10/100,000.[4] A Norwegian study found the annual incidence of postenteric reactive arthritis to be 5/100,000 and of postchlamydial reactive arthritis to be 4.6/100,000,[5] whereas in the United States, the annual age-adjusted incidence has been reported to be 3.5/100,000.[6] It is more common in some circumpolar and North American populations,[7] and in some black African populations it has been linked with human immunodeficiency virus (HIV) infection.[8] Inevitably, some other cases identified only as seronegative oligoarthritis are probably reactive arthritis, so that the true incidence and prevalence are probably underestimated.

Reactive arthritis occurs at any age, but typically is a disorder of young adults aged between 20 and 40 years, being rare in young children and in older populations. Children appear to be less likely than adults to develop reactive arthritis even after apparently provocative enteric infections,[9,10] although reactive arthritis in children is well recognized.

In outbreaks of bacterial enteric infections caused by *Salmonella, Shigella,* and *Campylobacter* reactive arthritis has been reported in 1 percent to 4 percent.[11] In some outbreaks, the incidence of arthritis is higher[12] and in others no cases are detected in spite of involvement of apparently "arthritogenic" infections.[13] Some outbreaks of yersiniosis have been associated with a high prevalence of reactive arthritis whereas in others arthritis has not been recorded.[12,13] It is unclear to what extent this variability is attributable to bacterial, other environmental, and to host factors.

Among men with non-gonococcal genitourinary infections, reactive arthritis develops in approximately 1 percent to 3 percent;[14,15] no accurate prevalence or incidence data are available for women with genitourinary infections, though reactive arthritis is probably underrecognized in this group.

ETIOLOGY

Concept of Reactive Arthritis

The term *reactive arthritis* implies a clinically characteristic reaction to a precipitating infection. For practical purposes, the clinical entity is the same as Reiter syndrome. The term was introduced by Ahvonen and colleagues in 1974[16] to indicate the likely, if hypothetic, link between an initiating infection and the subsequent aseptic arthritis. The condition may best be defined by a modification of their description as "arthritis as-

REACTIVE ARTHRITIS AT A GLANCE

- Reactive arthritis is one of the spondyloarthropathy group of arthritides. Its defining feature is initiation by infection, usually in the genitourinary or gastrointestinal tract.
- Key clinical features are asymmetric arthritis at a few joints, most often the knee, ankle, or metatarsophalangeal joints, enthesitis typically at the Achilles tendon or plantar fascia attachments to the calcaneum and sacroiliitis.
- Psoriasiform lesions on the soles—keratoderma blenorrhagicum—or penis—circinate balanitis—occur in one-third of patients and inflammatory eye disease is present in a similar proportion. Urethritis may occur with or without urogenital infection.
- The presence of HLA-B27 predisposes to the development of reactive arthritis.
- *Salmonella*, *Campylobacter*, *Shigella*, *Yersinia*, and *Chlamydia* infections are particularly thought to trigger reactive arthritis, but other infections may also act as initiators.
- Most episodes of reactive arthritis resolve spontaneously within 12 months, with minimal sequelae, but up to one-half of those affected may develop a recurrence.

sociated with infection elsewhere in the body but without viable microorganisms in the joint." *Reiter syndrome* has been redefined more recently as "an episode of peripheral arthritis of more than 1 month's duration occurring in association with urethritis and/or cervicitis."[17] When only two of the three features of the classic Reiter syndrome triad are present, the term *incomplete Reiter syndrome* is sometimes used.[18] Both complete and incomplete Reiter syndrome should be considered to be inseparable from reactive arthritis.

Reactive arthritis has been subdivided into sexually acquired reactive arthritis (SARA)[19] and post-dysenteric arthritis or enteric reactive arthritis. *Chlamydia-induced arthritis* has been used to refer specifically to reactive arthritis thought to be triggered specifically by a chlamydial infection[20] and *post-streptococcal reactive arthritis* has been used to describe arthritis, with features resembling reactive arthritis, associated with streptococcal throat infection.[21]

The term *post-infective arthritis* is also used to refer to aseptic arthritis after a defined episode of infection, and includes some forms of meningococcal arthritis. Reactive arthritis is associated with characteristic clinical and genetic features and so is separated from post-infective arthritis on that basis. However, there is no clear separation between reactive and post-infective arthritis. Similarly, some conditions, notably Lyme arthritis, appear to share features with reactive and post-infective arthritis but, at least in some cases, are associated with viable microorganisms in the joint. Thus, such conditions should be regarded as primarily infective or low-grade septic arthritis. The term *microseptic arthritis* has been used.

In spite of the confusing plethora of terms, it is inescapable that reactive arthritis represents an overarching, if variable, condition with characteristic clinical and genetic features and established linkage with infection. Observations of familial clustering and shared clinical and genetic features justifies the inclusion of reactive arthritis within the spondyloarthritis family.

Initiating Infections

The understanding of reactive arthritis as a disease caused by certain bacterial infections is based on observations of associations, not on clear understanding of pathogenetic mechanisms. Studies of outbreaks have identified *Shigella, Campylobacter, Salmonella,* and *Yersinia* bacteria as being likely causes of reactive arthritis.[22–30] Small studies and anecdotal reports have also implicated a wide range of other bacteria and, occasionally, other microorganisms in the causation of reactive arthritis,[31] though their true role is not established. Chief among these are diarrhea-associated illnesses, including antibiotic associated colitis due to overgrowth of *Clostridium difficile,* though traveler's diarrhea, in which no specific microorganism is implicated, has also been linked with episodes of reactive arthritis.[32] Bacteria strongly linked to reactive arthritis share the property of persisting in macrophage endosomes. These include *Salmonella enteritidis, S. typhimurium,* and *S. heidelberg; Shigella flexneri* types 1b and 2a, and *S. dysenteriae* but not *S. sonnei; Yersinia enterocolitica* and *Y. pseudotuberculosis; Campylobacter fetus;* and *C. difficile*. Among the *Salmonella* and *Shigella* infections that result in Reiter syndrome there is a reported connection between the ability to induce Reiter syndrome and the presence of a distinctive plasmid.[33] Extensive studies of genital-tract infection have also indicated a likely similar role for *Chlamydia trachomatis* which can be isolated from the genital tract in 35 percent to 50 percent of cases,[34–37] as in uncomplicated non-gonococcal urethritis. Several studies have implicated other genitourinary pathogens, particularly *Neisseria gonorrhoeae*[38,39] and possibly mycoplasmas[40,41] in the causation of reactive arthritis and other inflammatory arthritides but the nature of the link remains uncertain.

Septic arthritis caused by microorganisms also associated with reactive arthritis, notably *Salmonella*, *Campylobacter,* and *Neisseria gonorrhoeae* must be distinguished from aseptic disease.

Reactive arthritis may occur linked to infective symptoms, but without identified pathogens. In some instances, evidence of infection may be absent because the symptoms of infection were mild or trivial so that the patient was not aware of them. Nevertheless, care should be taken to restrict the use of the term to episodes of arthritis conforming to a spondyloarthropathy temporally associated with a recognized initiating infectious event.

Human Immunodeficiency Virus Infection

Reactive arthritis and other forms of inflammatory arthritis may occur in HIV-infected individuals even in the presence of marked immunosuppression.[46,47] The prevalence of reactive arthritis appears to vary among different populations: in some black African populations, the high prevalence of HIV infection has been linked with an increased prevalence of reactive arthritis.[8] In North American and European populations, clinical features of the arthritis are typical of that found in HIV-negative individuals although psoriasis may be especially extensive and severe. Among HIV-infected black Africans, clinical characteristics may be atypical in that more joints tend to be affected and the course may be accelerated with rapid joint destruction.[48] Whether HIV infection actually contributes directly to the development of reactive or any form of aseptic arthritis remains uncertain; however, evidence that the incidence of arthritis is reduced by highly active antiretroviral therapy[49] is consistent with a direct effect of HIV on the development of arthritis. As in non–HIV-associated cases, it may be impossible to differentiate between reactive arthritis, psoriatic arthritis, and undifferentiated spondyloarthropathy.[50]

Genetic Factors

Although most patients do not give a family history of reactive arthritis or a related disease, genetic susceptibility to reactive arthritis conferred by HLA-B27 is well recognized. There is some correlation between the prevalence of HLA-B27 in a population and the prevalence of reactive arthritis and other spondyloarthropathies, though HLA-B27 is not essential for disease.

The prevalence of HLA-B27 and reactive arthritis varies around the world.[7,51] In healthy Caucasian populations, HLA-B27 is present in 7 percent to 9 percent; the gene being detected in 45 percent to 80 percent of those with reactive arthritis. Where the prevalence of HLA-B27 is low, as in some native populations of South America, Australia, and Southern Africa, the likelihood of reactive arthritis is also low. Conversely, groups with a high HLA-B27 prevalence, such as some Eskimo, Native American, and Melanesian (e.g., Papua New Guinean) populations, reactive arthritis, and other spondyloarthropathies are more common. Nonetheless, some HLA-B27 positive individuals do not develop arthritis even during a known trigger infection.[52]

Among the many HLA-B27 subgroups, not all have been detected among reactive arthritis patients. However, there is no clear linkage between

any individual B27 subgroup and reactive arthritis.

In addition to HLA-B27, other incompletely defined genes appear to be involved. In some families with HLA-B27, there is a strong familial aggregation of Reiter syndrome without ankylosing spondylitis, whereas in other families, the opposite is the case.[7] A similar divergence between Reiter syndrome and ankylosing spondylitis is evident among certain groups of American Indians and Inupiat Eskimos, in whom HLA-B27 is prevalent. Reiter syndrome/reactive arthritis, but not ankylosing spondylitis, is common among Navajo and Inupiat Indians, whereas the Haida and Pima have a high frequency of ankylosing spondylitis but not reactive arthritis.

HLA-B27 is associated with disease severity. Many patients, especially those with short-lived or mild disease, are HLA-B27 negative. HLA-B27 positivity is associated with more severe symptoms and joint damage, prolonged course, greater risk of chronicity, and the subsequent development of ankylosing spondylitis.[53]

HIV-infected Caucasians with reactive arthritis are usually HLA-B27 positive, whereas non-Caucasians tend to be HLA-B27 negative.[49,54]

TABLE 20-1
Characteristics of Spondyloarthropathy[a]

MUSCULOSKELETAL	GENETIC	EXTRA-ARTICULAR
Inflammatory oligoarthritis		Skin/mucosal psoriasis
Enthesitis		Genitourinary inflammation
Sacroiliitis	HLA-B27	Inflammatory bowel disease
Spondylitis		Inflammatory eye disease
Dactylitis		Carditis

[a]One or more musculoskeletal lesions often occurring in association with one or more characteristic extra-articular lesions, which may be subclinical, with negative tests for autoantibodies, including rheumatoid factor.

PATHOGENESIS

Although a number of microorganisms have been strongly linked with the cause of reactive arthritis and many others weakly associated, there are no adequate guiding principles to help to establish or refute a role for any specific microorganism as a causal agent. Criteria for inferring causality in reactive arthritis have been proposed[55] but further work is needed to clarify the situation. A temporal relationship between infection and arthritis may provide strong evidence of causality in some outbreaks but cannot be seen as such in sporadic cases. The isolation of *Chlamydia trachomatis* from joint samples in early studies[31] and the subsequent identification of chlamydial membrane proteins, genomic and plasmid DNA and RNA in synovium and synovial fluid from patients with reactive arthritis[56–60] strongly suggested that the microorganisms identified could be presumed to cause the arthritis. It is possible that intra-articular chlamydiae are viable.[61] Similarly, identification of membrane protein and lipopolysaccharide antigens from *Yersinia* and *Salmonella* bacteria in joint material supported the same conclusion.[62–64] Moreover, the presentation of bacterial antigens by antigen presenting cells within the joint[65] and the presence of sensitized T lymphocytes in the joint[66–68] have all been cited as supporting causal roles of specific bacteria in individual cases.[69,70] Suggestive as these pieces of evidence are, however, they leave the key issues unresolved. It seems likely that bacterial components in the circulation may enter inflamed joints non-specifically[71] and that many bacteria found within joints may be non-specific.[72,73]

Understanding of pathogenetic mechanisms in reactive arthritis is, in spite of the tantalizing prospects offered by HLA-B27 and specific bacteria, far from complete. Numerous studies have addressed the processing and presentation of bacterial antigens and the responses of CD8-positive lymphocytes, which processes appear to play critical roles in the pathogenesis of reactive arthritis and, perhaps, other spondyloarthropathies. The potential of various bacterial preparations to induce arthritis experimentally is well demonstrated in animal systems and more recent studies with HLA-B27 transgenic animals[74,75] have amplified, but not clarified, the case for a direct role for bacteria in arthritis in the context of HLA-B27.

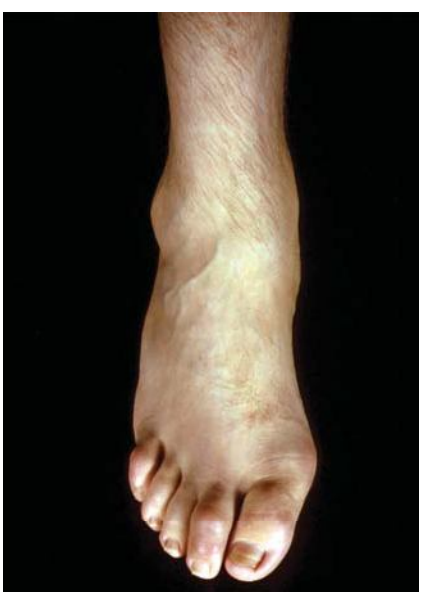
Currently no "front-runner" theory seems able to explain all the features of reactive arthritis. There is evidence, however, to implicate arthritogenic peptides, molecular mimicry between bacterial antigens and the HLA-B27 molecule, aberrant or misfolded forms of HLA-B27, as well as aspects of non-antigen-presenting functions of the HLA-B27 molecule, including altered intracellular bacterial killing and/or processing. The influence of non-HLA genes may also be important.

CLINICAL FINDINGS

History and Presenting Features

The characteristic features of reactive arthritis are those of spondyloarthropathy (Table 20-1) in general, temporally linked to a recognized precipitating infection. The interval between the onset of symptoms of infection and the onset of symptoms of arthritis may be up to 3 months but is typically less than 1 month. The condition usually evolves rapidly over 1 to 3 weeks, varying in severity from mild arthralgia to severely disabling polyarthritis.

Acute pain and swelling at a knee or metatarsophalangeal joint is the most common presentation. Dactylitis at a toe (sausage toe; Fig. 20-1) or heel pain due to enthesitis at the plantar fascia or Achilles tendon insertion (Fig. 20-2) is also a common presenting feature. Upper limb arthritis is rare and involvement of only one or a few joints contrasts with the picture of typical rheumatoid disease. A past history of eye or joint problems or a family history of spondyloarthropathy-related features, including inflammatory eye disease and ankylosing spondylitis, gives vital clues to the diagnosis. Reactive arthritis is a systemic



▲ **FIGURE 20-1** Dactylitis of second toe (sausage toe).

▲ **FIGURE 20-2** Achilles tendon bursitis.

disease, although the severity varies greatly. Malaise, fatigue, and low-grade fever or feverishness are common. Uncommonly, arthritis may be accompanied by high fever with a marked acute phase response suggestive of sepsis.

Symptoms of infection may be prominent, mild, or absent. Hence, men with urethritis may present to genitourinary medicine physicians being unaware of the significance of rheumatic symptoms and vice versa. In men with SARA, an urethral discharge, with or without dysuria, is usually present and most patients are able to give an accurate history of recent exposure to infection, if asked directly. However, genital tract infections in women are more often asymptomatic. Diarrhea and abdominal pain associated with an episode of arthritis are usually, but not always, mild. There may be symptomatic infection in family members, close contacts, or sexual contacts. Uncommonly, features of infection are highly atypical; gut infection, especially by *Yersinia*, may mimic appendicitis or salpingo-oophoritis. More commonly, symptoms are mild or absent, so that infection is overlooked.

Skin and Mucous Membrane Lesions

Psoriasiform skin and mucous membrane lesions occur in up to one-third of patients with SARA but in fewer of those with other forms of reactive arthritis. Circinate balanitis (Fig. 20-3) has been described in up to 36 percent of patients. It may accompany the acute episode or occur in isolation. The lesion is initially vesicular with little or no surrounding erythema. Irregular, moist, superficial ulcers form in the uncircumcised male and may coalesce to give a circinate distribution (see Fig. 20-3). These ulcers may occasionally become secondarily infected. In the circumcised male, the lesions evolve to form hard crusts and plaques. Circinate vulvitis has also been described.[83]

▲ **FIGURE 20-3** Circinate balanitis.

Examination of the soles of the feet may reveal keratoderma blenorrhagicum (Fig. 20-4), which is similar to palmoplantar pustulosis (see Chap. 21), in up to 15 percent of patients with SARA. The initial lesions are small vesicles or erythematous macules surrounded by an erythematous base, which may coalesce. The vesicle wall becomes progressively thickened, forming a small papule, nodule, or even a horny excrescence. The appearance of the lesions varies from a scaling plaque-like process that resembles pustular psoriasis to combinations of crusting, exudation, and erosion associated with erythema. Lesions on the soles may be markedly hyperkeratotic. Oral psoriasiform lesions (geographic tongue) occur uncommonly and painless mucosal ulcers may occur on the tongue, palate, buccal mucosa, and lips; they are usually transient and cause little or no morbidity. Histologically, keratoderma blennorrhagicum is indistinguishable from pustular psoriasis, being characterized by hyperkeratosis and parakeratosis, elongation and hypertrophy of the rete pegs, general epidermal hyperplasia, and extensive neutrophilic infiltration with formation of microabscesses and spongiform pustules (see Chap. 21). The histologic appearance of circinate balanitis is similar though the moist lesion in uncircumcised males is not keratinized. Mouth ulcers are similarly unkeratinized.

In the presence of HIV infection, keratoderma blennorrhagicum may be distributed over the entire body, also involving the digits, in a pattern that resembles that of pustular psoriasis and in the groin in the pattern of inverse psoriasis or sebopsoriasis. The keratoderma blennorrhagicum lesions may last for weeks to months, disappear, and then recur.[84] In patients with HIV infection, arthritis may begin as typical reactive arthritis but gradually transform into chronic psoriatic arthritis.

Typical psoriatic nail lesions may be seen and typical psoriatic plaques may occur elsewhere on the body.

Erythema nodosum may occur uncommonly after enteric infections, especially *Yersinia* infection, but is not associated with HLA-B27.

Joint and Enthesis Lesions

The musculoskeletal picture of reactive arthritis may be indistinguishable from psoriatic arthritis (see Chap. 19).

▲ **FIGURE 20-4** Keratoderma blennorrhagicum.

Monoarthritis or asymmetric oligoarthritis affecting knees, ankles, and subtalar and metatarsophalangeal joints are typical. The clinical picture contrasts with rheumatoid disease by predominantly affecting leg joints in an asymmetric fashion; however, small joint disease, especially at the metatarsophalangeal joints, may be erosive. In severe cases, extensive erosive damage produces severe, rheumatoid-like deformity, with marked subluxation and valgus deformity at the metatarsophalangeal joints. Other large joints, such as the hips and shoulders, may also be involved and persistent arthritis at the knee may be associated with huge effusions and the formation of a Baker's cyst. Rupture of a Baker's cyst may mimic deep vein thrombosis.

Pain in the buttock, often described as in the "hip," may be due to acute sacroiliitis. Sacroiliitis is difficult to diagnose acutely, as similar symptoms may be referred from non-inflammatory lesions in the lumbosacral spine. Radiographs are likely to be normal at this stage unless a previous episode of sacroiliitis has occurred and isotope bone scanning is often unhelpful. Magnetic resonance imaging (MRI) and computerized tomography scanning may, however, demonstrate early evidence of acute sacroiliitis. In reactive arthritis, this is often unilateral in contrast to the bilateral involvement in ankylosing spondylitis (see eFig. 20-4.1 in on-line edition).

Inflammation at entheses—sites of bony attachments of ligaments and tendons—is highly characteristic of all the spondyloarthropathies, including reactive arthritis.[6,85,86] Pain at the ankle region may be due to enthesitis at the Achilles tendon or plantar fascia attachments to the calcaneus. Achilles tendonitis may be associated with characteristic bursitis. Painful enthesopathy may also occur at costochondral junctions and at ischial tuberosities and iliac crests. Acute enthesopathic lesions may be well shown by MRI or by ultrasound scanning; plain radiographs demonstrate bony spurs, especially at the plantar fascia attachment, but these are late signs that often reflect previous disease rather than the current episode.

Genitourinary Features

Urogenital inflammation may occur either as a feature of initiating sexually transmitted infection or as a sterile reactive lesion. Thus, urethritis has been included in the triad classically recognized as Reiter syndrome irrespective of the presumed initiating event. Cystitis and prostatitis may be present and can sometimes lead to complications such as shrinking of the bladder. Furthermore, pelvic inflammatory disease, including salpingitis, may arise in women with reactive arthritis.[87,88] Inflammation of the urogenital tract has a tendency to relapse with or without apparent reinfection.

Gastrointestinal Involvement

Acute infective enteritis or colitis may, similar to urogenital infections, be the etiologic triggering event. It has become apparent, however, that, as in the urogenital system, the epithelium of the intestine may form part of the reactive disease itself. Ileocolonoscopic studies have demonstrated that in some patients with established reactive arthritis, irrespective of the presumed precipitating infection, macroscopic or microscopic inflammatory lesions in the small or large intestine, resembling ulcerative colitis or Crohn disease are present.[89,90] This is similar to findings in other spondyloarthropathies, especially ankylosing spondylitis, though the significance of these findings is unclear.

Ocular Lesions

One-third of patients with reactive arthritis develop unilateral or bilateral inflammatory eye lesions, which form a classic part of the clinical picture. Conjunctivitis with sterile discharge occurs in one-third of patients. It usually subsides spontaneously but may progress to episcleritis, keratitis, or even corneal ulceration. Acute anterior uveitis (iritis) occurs only in 4 percent to 5 percent of patients during an episode of reactive arthritis but is more usually asynchronous, a history of iritis supporting the rheumatic diagnosis.[91] Both conjunctivitis and iritis have a strong tendency to recur. Although iritis is more often associated with severe ocular pain, redness, lacrimation, photophobia, and visual impairment,[92] conjunctivitis and iritis are often indistinguishable without specialist assessment. Thus, the development of ocular pain and/or redness warrants urgent ophthalmologic examination to prevent permanent visual impairment.

Cardiac Lesions

Symptomatic heart disease is rare in reactive arthritis. Palpitations and pericardial type chest pain, occasionally with a pericardial rub, have been described.[93] However, electrocardiographic abnormalities are not uncommon early in disease with changes including first-, second-, and third-degree heart block, ST-segment and T- and Q-wave changes and significant dysrhythmias occurring in approximately 5 percent of patients.[94,95] These are usually without clinical sequelae.

As in other spondyloarthropathies, aortic root inflammation with or without aortic valve disease is an important, if uncommon, feature.[96,97] Symptomatic aortic valve disease, generally incompetence, occurs in 1 percent of patients and is an important cause of morbidity and mortality.

Other Systemic Manifestations

Numerous other lesions have been described anecdotally in patients with reactive arthritis or Reiter syndrome. These include glomerulonephritis and immunoglobulin A nephropathy, which seldom leads to permanently impaired renal function, peripheral neuropathy, pleurisy, pulmonary parenchymal inflammation, and amyloidosis.

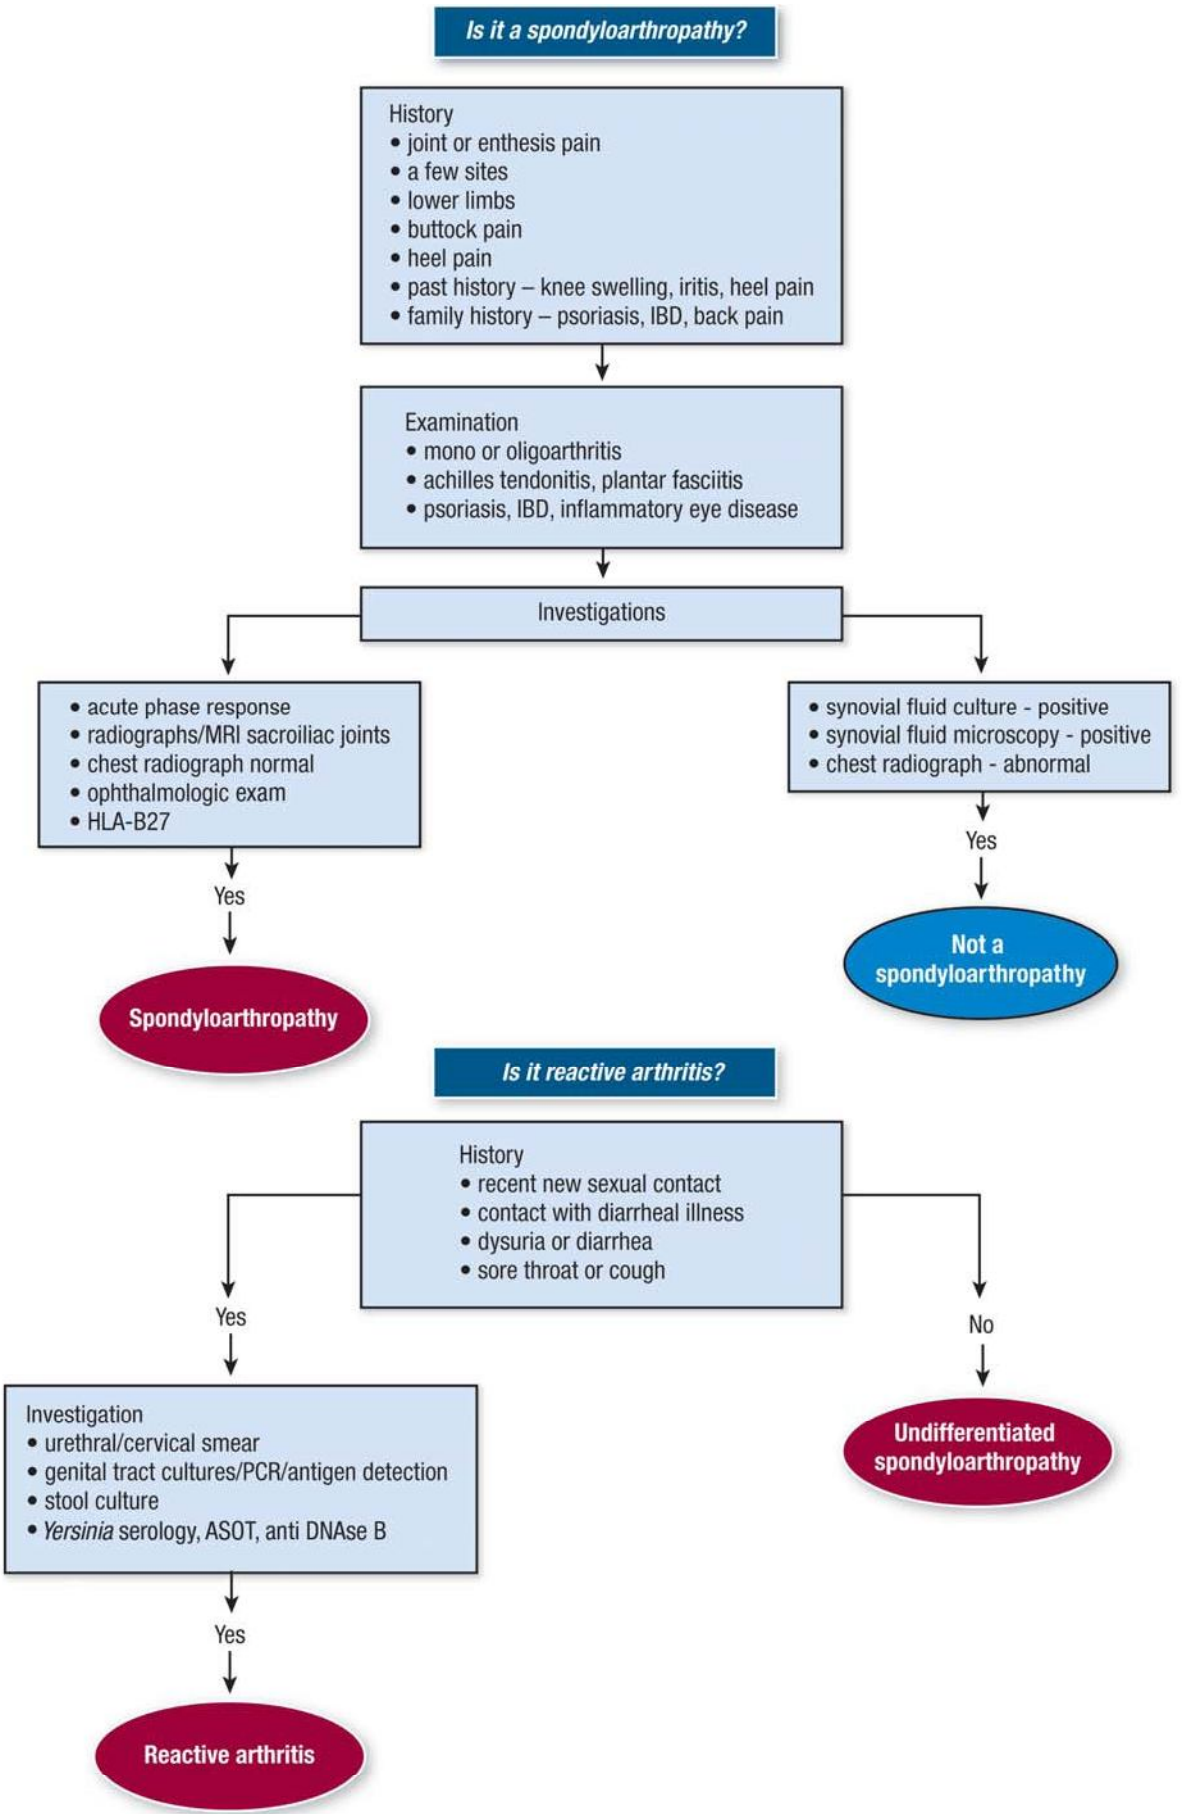
DIFFERENTIAL DIAGNOSIS

In many patients, the disease features are typical and the diagnosis is easy; however, in practice, the differential diagnosis is wide and misdiagnosis is common. Reactive arthritis has to be differentiated from other forms of inflammatory arthritis, including other spondyloarthropathies, rheumatoid arthritis, gout, sarcoidosis, and septic arthritides and from systemic vasculitides, which may present in their early stages in young adults with joint pain and fever, thus entering the differential diagnosis, albeit briefly. In addition, reactive arthritis must be differentiated from non-specific symptoms in patients who present with arthralgia and symptoms suggestive of infection, usually genitourinary but in whom a clear diagnosis of infection cannot be made. Inevitably, in some instances, the true diagnosis, especially rheumatoid arthritis, psoriatic arthritis, and ankylosing spondylitis, only becomes clear with clinical follow-up.

The diagnosis of reactive arthritis is reached in two stages: the recognition of a spondyloarthropathy and the establishment of a link with a "triggering" infection (Fig. 20-5).

Is It a Spondyloarthropathy?

There are no confirmatory tests for the diagnosis of spondyloarthropathy. Po-



▲ **FIGURE 20-5** Diagnostic algorithm "making the diagnosis." anti DNAse B = antideoxyribonuclease B; ASOT = antistreptolysin O titer; IBD = inflammatory bowel disease; MRI = magnetic resonance imaging; PCR = polymerase chain reaction.

tential diagnostic criteria have been put forward[98,99] and the characteristic clinical features of spondyloarthropathy, particularly lower limb mono- or oligoarthritis; enthesitis, especially at the heel, and buttock pain, often in a young adult, are readily recognized. A family history of spondyloarthropathy features, including inflammatory bowel disease and iritis, is suggestive. Presentation in the context of infection, whether in the presence of a known sporadic genitourinary or gut infection or during an outbreak of diarrhea, raises suspicion of the diagnosis, although gastrointestinal symptoms in cases of enteric reactive arthritis are often mild or even absent. Even isolated monoarthritis at a lower limb joint, such as a single swollen knee, should raise suspicion of a spondyloarthropathy.

Investigations serve to confirm the presence of inflammatory arthritis and demonstrate the presence or likely recent presence of an associated infection. Acute phase reactions, whether measured by C-reactive protein, erythrocyte sedimentation rate or plasma viscosity, are usually elevated. In patients with substantial systemic upset and fever, the C-reactive protein may be very high, suggesting sepsis, which is also a key differential diagnosis. With persistent, active disease, non-specific normochromic anemia and leukocytosis may also develop. Urinalysis should be carried out at diagnosis and should be repeated during the follow-up, as pyuria indicative of urethritis and proteinuria may indicate renal involvement. Tests for rheumatoid factor and other autoantibodies are usually negative.

An essential component of this initial diagnostic stage is the exclusion of alternative differential diagnoses. Septic arthritis attributable to both acute pyogenic organisms and to *Mycobacterium tuberculosis* needs to be excluded, especially in children. Hence, joint aspiration and occasionally synovial biopsy are important investigations. Blood cultures are also essential if sepsis is suspected. Arthroscopy and synovial biopsy may also be useful to exclude or confirm the diagnosis of pigmented villonodular synovitis, though otherwise findings are non-specific. Similarly, crystal synovitis occasionally presents with intense effusion at a knee or ankle in a young adult. This requires exclusion by examination of synovial fluid for crystals. Sarcoidosis and *Mycoplasma pneumoniae* infection should also be considered within the differential diagnosis and should necessitate chest x-ray with or without further investigations.

In those with eye symptoms, urgent assessment by an ophthalmologist is important as uveitis requires prompt and correct treatment if eyesight is to be protected. When cardiac abnormalities are detected clinically or rheumatic fever is suspected, electrocardiography and echocardiography may be helpful. In those with severe or prolonged episodes of reactive arthritis, however, conduction disturbances are common, though generally benign.

Is It Reactive Arthritis?

The diagnosis of reactive arthritis and its designation according to putative infectious cause are dependent on demonstrating a temporal relationship with a specific bacterial infection. A clear history of potentially infective symptoms, such as abdominal pain, diarrhea, dysuria, urethral or vaginal discharge, or possibly of other infective symptoms such as sore throat is important, though not essential. So too is a history of likely exposure to infection, including sexual intercourse with (a) new sexual partner(s) and the presence of other contacts with abdominal symptoms, including family members, who may also have eaten contaminated food. Sometimes the clue to a point source of bacterial food poisoning may come from public health services rather than the patient. The timing of contact with potential sources of infection should be carefully documented and contacts traced if appropriate. For some patients, evidence of a potentially initiating infection only emerges from a "blind" search in the absence of infective symptoms when other features raise this diagnostic possibility.

Once a probable trigger infection is identified, effort should be made to confirm the infective diagnosis and identify the putative causal microorganism. Specialist genitourinary examination may confirm the presence of urethritis or cervicitis; culture for appropriate pathogens can be taken along with immunodetection tests for *Chlamydia trachomatis.*

PROGNOSIS AND CLINICAL COURSE

Most episodes of reactive arthritis resolve within 3 to 5 months, with a mean episode duration of 19 weeks.[11,53] Sixty percent to 80 percent of patients are in remission at 12 months[101] and 75 percent to 100 percent have remitted by 2 years, those with enteric reactive arthritis faring slightly better than those with SARA.[11,53]

HLA-B27–positive individuals are more likely to develop sacroiliitis and subsequent ankylosing spondylitis,[53,102] and, in hospital-based studies, HLA-B27–positive individuals are likely to have longer episode duration, more extra-articular features, especially iritis, and erosive joint damage. Within spondyloarthropathies, male gender, a positive family history, the presence of chronic gut lesions detected endoscopically and hip involvement predict long episode duration.[102] Recurrent episodes and chronic disease are also linked to HLA-B27 positivity. A weighted risk analysis for severe prognosis in spondyloarthropathy has been proposed.[102] Each feature is scored and a total score is calculated. A poor outcome is predicted if hip arthritis is present or if more than three factors are present.

It appears that HLA-B27–negative individuals are largely, if not entirely, protected from developing sacroiliitis, destructive peripheral arthritis, iritis and subsequent ankylosing spondylitis. The identity of the triggering agent does not appear to influence the episode duration.

Back pain, whether inflammatory of non-specific, persists beyond the acute episode in up to 25 percent of patients.[103] Sacroiliitis, on plain radiography, has been reported in 14 percent to 49 percent of patients attending hospital. The issue as to whether reactive arthritis promotes the subsequent development of ankylosing spondylitis is unresolved but it is likely that the overall incidence of ankylosing spondylitis in individuals who have had reactive arthritis is significantly higher than the background prevalence among unselected HLA-B27–positive individuals.[104] The presence of chronic gut lesions on endoscopy is also a predictor of the development of chronic spondyloarthropathy, including ankylosing spondylitis; conversely, absence of such gut lesions or possession of HLA-Bw62 correlates positively with remission of arthritis without sequelae.[105]

Recurrence and Persistence

Between 30 percent and 50 percent of patients with SARA have a relapse; in contrast, relapse is less common in the enteric forms. Recurrences may be triggered by new infections but may also occur without evident provoking factors. Conversely, individuals with a past history of reactive arthritis may have a new infection by a bacterium known to trigger the disease without developing a recurrence. Iritis and psoriasiform rashes are particularly prone to recurrence independent of arthritis without recognizable triggers. Such recurrences tend to become less common with advancing age.

Persistence of arthralgia, fatigue, and pain resulting from joint damage is not uncommon for 2 or 3 years despite quiescence of the arthritis. Joints that have been affected by reactive arthritis may be prone to later osteoarthritis.

Work Disability

Work disability is difficult to analyze usefully because it has been addressed in rather disparate studies as social and unemployment support systems differ between countries. It seems likely that work disability is rare after outbreaks of enteric infection, but among hospital attenders some patients are unable to continue working, usually because of persistent disease, painful foot joint damage, or spondylitis. In North America and Canada, up to 16 percent of this latter group changes their work or becomes unemployable, and this figure may rise with late follow-up.[106,107] The presence of heel disease predicts poor outcome.

Mortality

Death is an extremely uncommon outcome of reactive arthritis. Anecdotally, occasional deaths have been attributed to carditis, cardiac valvular disease, amyloidosis, and complications of surgery. It is likely that mortality of patients with reactive arthritis does not differ from that of the healthy population.

TREATMENT

Skin and Mucosal Lesions

Skin and mucosal lesions are essentially psoriasis and should be managed accordingly (see Chap. 18). In mild cases, keratinolytic agents such as salicylic acid ointment or topical treatments, including vitamin D analogues and corticosteroids may be used; in more severe cases, methotrexate or retinoids are often beneficial.

Arthritis and Enthesitis

In most patients, episodes of reactive arthritis resolve spontaneously and treatment needs to recognize the likely natural course. It is also the case, however, that many patients are at a stage of life in which tolerance of even temporary disruption of occupational and recreational activities is low so that enthusiasm for restorative treatment is high. Thus, treatment decisions should seek to balance these conflicting facets of the condition. Treatment guidelines for SARA have been published.[108]

Making and explaining the diagnosis and its implications is the cornerstone of treatment. The role of infection also raises important issues that have to be anticipated and managed: Chief among these issues are the role, protection, and potential culpability of sexual partners and the public health and legal issues arising from the consumption of contaminated food.

Treatment of peripheral joint and enthesis lesions is exactly as for other inflammatory arthritides, with analgesics, nonsteroidal anti-inflammatory drugs, antitumor necrosis factor-α biologics, local steroid injections for individual lesions, physiotherapy and attention to footwear all playing important roles.

In nonsteroidal anti-inflammatory drug–resistant disease, with marked systemic features or prolonged active phase, systemic corticosteroids may be helpful. Steroids may be administered as a single intramuscular dose of depot methylprednisolone (80 to 120 mg), especially to "buy time" if a second-line drug is being introduced, or as a course of oral prednisolone (15 to 30 mg once daily), the dose being tapered according to response. Corticosteroid therapy should be used for the minimum possible period and accompanied by appropriate bone protective treatment.

In recurrent, chronic or erosive disease, second-line agents may be used as in rheumatoid arthritis. Of these, sulphasalazine is the best studied and shown to be well tolerated and probably effective for peripheral joint disease.[109,110] Treatment should be started at low dose, increasing to 2 to 3 g a day if tolerated by the patient, as in the treatment of rheumatoid arthritis. Gastrointestinal intolerance may limit dose escalation.

Other agents, including methotrexate, azathioprine, and leflunomide, may be effective though formal evidence for this in reactive arthritis is limited.[111,112]

Antitumor necrosis factor therapy has been used successfully on an anecdotal basis in a few patients with severe, chronic disease. The place of such biologic therapy in this condition is, however, far from established.

Treatment of arthritis in the context of HIV infection is as in HIV-negative patients but with the additional need for appropriate antiviral therapy. Local corticosteroid injections may also be used as in non-HIV cases. In long-standing cases, sulfasalazine may be beneficial.[113] Immunosuppressive agents should be used with great care, if at all, in individuals with HIV infection.[114]

Eye inflammation must be diagnosed and treated promptly if irreversible damage to eyesight is to be avoided. Treatment of iritis consists of corticosteroids in the form of eye drops, local injection or even systemically, and of mydriatics. The patient should be informed about the strong possibility of recurrence.

Antimicrobial Therapy

Appropriate antibiotic treatment of acute genitourinary infection, along with contact tracing and treatment of sexual partners is essential. Conversely, antibiotic treatment of bacterial diarrhea, other than in exceptional circumstances, is best avoided. It is unclear whether antibiotic treatment of acute sexually transmitted infections reduces the likelihood of reactive arthritis developing but there is some evidence that this may be so.[115] It is clear that many patients develop arthritis in spite of completing a course of antibiotics sufficient to clear their genitourinary infection. Short courses of antibiotics of 1 or 2 weeks do not appear to influence the course or duration of either SARA or enteric reactive arthritis.[116,117] Numerous studies have addressed the potential value of medium- to long-term (3 to 12 months) antimicrobial mtherapy in reactive arthritis but have been unable to demonstrate any convincing evidence of efficacy.

It is clear that medium- to long-term antibiotic treatment of patients with reactive arthritis is not justified by current evidence.[118]

CHAPTER 21

Pustular Eruptions of Palms and Soles

Ulrich Mrowietz

Pustular eruptions of the palms and soles include palmoplantar pustulosis (PPP), acrodermatitis continua (Hallopeau disease), and infantile acropustulosis (Table 21-1). The entities present with chronic and persistent eruptions of sterile, purulent vesicles.

PALMOPLANTAR PUSTULOSIS

PPP is a chronic pustular dermatosis localized on the palms and soles only. High resistance to treatment and a high recurrence rate are characteristic. Histologically, it is characterized by intraepidermal vesicles filled with neutrophils.

Previously, PPP was classified as a form of pustular psoriasis and many textbooks describe PPP in their respective chapter of psoriasis. Today, PPP is regarded as its own entity.

The involvement of palms and soles has a great impact on life quality and the ability to work.

Epidemiology

PPP has a worldwide distribution. It is a rare condition, but the exact incidence is not known.

Females show a higher prevalence than males, with a ratio of approximately 3:1. Onset of the disease occurs mostly between the ages of 20 and 60 years; rarely, the condition occurs after the sixth decade of life, and in 10 percent of the patients the onset is before the age of 20 years.

PALMOPLANTAR PUSTULOSIS AT A GLANCE

- Chronic inflammatory disorder with sterile pustule formation.
- Affects only palms and soles.
- Disabling in severe cases.
- High rate of recurrence.
- Often resistant to treatment.
- Can be part of SAPHO (synovitis, acne, pustulosis, hyperostosis, osteitis) syndrome.

Genetics

HLA typing of patients with PPP reveals no increased frequency of any of the known psoriasis-linked alloantigens.[1] In a direct comparison among chronic-plaque psoriasis, guttate psoriasis, and PPP, the three major candidate genes within the PSORS1 region (HLA-Cw*6, HCR*WWCC, and CDSN*5) showed a high association to guttate and chronic plaque psoriasis, not, however, to PPP.[2] Investigation of the apolipoprotein E alleles e2, e3, and e4 in chronic plaque and guttate psoriasis as well as in PPP in acitretin responders and nonresponders showed that the frequency of the e4 allele was significantly higher in the psoriasis groups but not in PPP patients as compared to healthy controls.[3] In chronic plaque psoriasis and psoriatic arthritis an association with tumor necrosis factor (TNF)-α–238 and –308 promotor polymorphisms have been found; however, the association has not been found in PPP.[4]

Studies from Japan provide evidence for phenotypic and genetic heterogeneity of PPP according to its association/provocation with tonsillitis. In patients in which PPP was not associated with tonsillitis, the phenotype frequency of the TNF-β2 allele of the TNF-β gene and of the allele B of the TNF-α gene (TNF-α pB) was significantly higher as compared to controls.[5]

These findings further substantiate the notion that PPP and psoriasis represent different entities.

Etiology

The cause of PPP is not known. An imbalance of the protease/antiprotease system in the skin consisting of decreased antileukoprotease (elafin/SKALP) activity in pustular psoriasis has been discussed as a possible mechanism of pustule formation.[6] Exacerbation of PPP has been observed after patch testing with metals and was accompanied by elevated leukotriene B4 levels in plasma and pustules.[7]

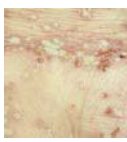
In a long-term survey from Japan, the incidence of PPP was found to be positively correlated to heavy smoking (more than 20 cigarettes per day), tonsillitis, and seasonal factors such as high humidity and high temperature.[8,9]

The most striking association in PPP is smoking. In two Swedish surveys, 95 percent of PPP patients were smokers at onset of disease and cessation of smoking was the most important measure to treat the disease.[10,11] There is evidence from immunohistochemical studies that nicotinic acetylcholine receptors are modulated in lesional skin from smoking PPP patients when compared to smokers and healthy controls suggesting an abnormal response to nicotine in PPP.[12]

Case reports have revealed multiple provocation factors of PPP including thyroid-diseases,[13] *Helicobacter pylori* infection,[14] and psychologic factors such as anxiety.[15]

TABLE 21-1
Pustular Eruptions of Palms and Soles

	Sterile Pustules on Palms and Soles	Age	Cutaneous Atrophy	Associated Disease	Histology
Palmoplantar pustulosis	Yes	Adults	Absent	Psoriasis, SAPHO (synovitis, acne, pustulosis, hyperostosis, osteitis) syndrome	Spongiform pustule, neutrophils, some eosinophils
Acrodermatitis continua (Hallopeau)	Yes	Adults	Present	Pustular psoriasis, Zumbusch type	Spongiform pustule, neutrophils
Infantile acropustulosis (see Chap. 106)	Yes	Infants	Absent	Absent	Subcorneal pustule, neutrophils, some eosinophils



Clinical Features

The primary lesions are pustules of nearly equal size measuring two to four mm in diameter. Crops of pustules usually arise within a few hours on the typical-appearing palmar and plantar skin (Fig. 21-1). Involvement usually is symmetric but unilateral location on palms and/or soles is seen. Single lesions then become surrounded by an erythematous ring. Sometimes, the pustules extend to the dorsa of the fingers, the feet, or over the volar wrists (see Fig. 21-1C). Episodes of new pustular eruptions occur at varying intervals and remain strictly confined to the sites of predilection.

As pustules become older, their yellow color changes to dark brown, so that in untreated PPP, the lesions show various shades of color (see Fig. 21-1C and D). Dried pustules are shed within approximately 8 to 10 days.

There are no symptoms other than itching or a burning sensation, which may precede new crops of lesions. However, in severe eruptions, pain and the inability to stand, walk, or do manual work may greatly reduce the quality of life. As remission begins, fewer pustules are produced, but the skin may remain erythematous and hyperkeratotic, resembling eczema. Remissions last for days, weeks, or months until pustulation again occurs.

Disease Associations

An association of PPP and osteoarthritis of the anterior chest wall was first described in Japan.[16] As reported by Swedish authors, involvement of the manubriosternal joint is present in 6 percent and of the sternoclavicular joints in 10 percent of patients.[17] Scintigraphic investigations showed sternocostoclavicular joint involvement to be present in 16 of 73 (22 percent) patients.[18] For this condition, the term *SAPHO* (synovitis, acne, pustulosis, hyperostosis, osteitis) has been established.[19] Clinical manifestations of SAPHO syndrome are similar whether they occur in relation to severe acne (mostly acne conglobata) or PPP (see Chap. 78). The primary lesion consists of a sterile abscess containing neutrophils. The site of predilection is the anterior chest wall. SAPHO syndrome can be associated with pseudoinfectious arthritis. Involvement of the sacroiliacal joints may be present.[20]

PPP is also seen in patients with chronic recurrent multifocal osteomyelitis as well as with noninfectious inflammatory bone lesions.

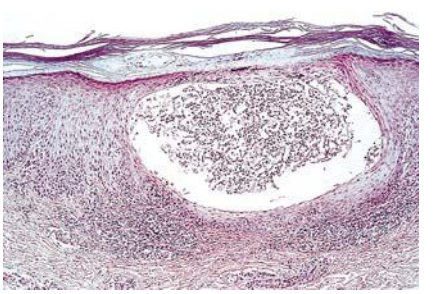
▲ **FIGURE 21-1** Palmoplantar pustulosis. **A** and **B.** Groups of pustules measuring 2 to 3 mm in diameter occur on erythematous skin on palms and soles. Both feet and both hands are normally affected symmetrically. **C** and **D.** Lesions may occasionally spread beyond the predilection sites, and pustules may appear on the wrists. Within several days after pustule formation, lesions dry, flatten, and acquire a brownish color. This may be followed by eczematous changes with scaling and fissuring.

Histopathology

Histologically, there is an intraepidermal cavity filled with polymorphonuclear leukocytes associated with spongiform changes within the surrounding epidermis (Fig. 21-2). Eosinophils and mast cells are present in increased numbers in PPP biopsies from lesional skin. Another hallmark is the inability to visualize the epidermal part of the eccrine duct in PPP specimens indicating an involvement of the acrosyringium.[21]

Laboratory Findings

The lesions of PPP are sterile; a moderately increased white blood cell count may occasionally be observed, but all other laboratory tests are usually normal. In patients with an infectious trigger, infection-associated laboratory parameters, such as C-reactive protein, may be increased. Increased levels of anti-gliadin antibodies may occasionally be found.



▲ **FIGURE 21-2** Histologically, there is a spongiform pustule and a moderate lymphohistiocytic infiltrate.

Box 21-1

Differential Diagnosis

Most Likely

- Dyshidrotic eczema with secondary bacterial infection
- Tinea of palms and soles with pustules

Consider

- Keratoderma blenorrhagicum in Reiter disease
- Involvement of palms and soles in generalized pustular psoriasis
- Infected scabies with pustulation
- Vesicopustular mycosis fungoides of palms and soles
- Pustular localized vasculitis

Diagnosis and Differential Diagnosis (Box 21-1)

PPP is a distinct entity. The course of the disease, together with the characteristic morphology, permits the proper diagnosis. The disease must be differentiated from "dyshidrotic" eczematous dermatitis (pompholyx), especially when pustules due to secondary infection are present (see Chap. 16). In that condition, the onset is also acute, but clear vesicles of various sizes are scattered on the palms, soles, and volar and interdigital aspects of the fingers. These may coalesce and secondarily become pustular because of secondary bacterial infection.

Pustular variants of tinea of the palms and soles or pustules developing in infected scabies may resemble PPP. Bacterial cultures or demonstration of hyphae or mites clearly separate these entities from PPP.

Rare clinical variants such as vesicopustular mycosis fungoides palmaris et plantaris,[22] pustular localized vasculitis,[23] or palmoplantar involvement of generalized pustular psoriasis may also resemble PPP.

Treatment

PPP is difficult to treat and all reported treatments have a high recurrence rate. The management of PPP is summarized in Box 21-2.

The first measure in the management of PPP is cessation of smoking. In patients with proven gluten intolerance, a gluten-free diet was found to have a beneficial effect on lesions in psoriasis and PPP.[24]

Among topical treatments only a few procedures have been identified as being of therapeutic benefit.[25] Unilateral involvement and/or PPP with a limited effect on daily living activities should be treated with topical agents. Due to the fact that skin penetration through palmar and plantar skin is highly restricted even in acute disease with focal skin barrier disruption only certain drugs can be used effectively. Potent and superpotent steroids are the drugs of choice and may be used under plastic film or hydrocolloid occlusion, particularly in the beginning of therapy.

Subsequent topical therapy with vitamin D_3-analogues such as calcipotriol/calcipotriene, tazarotene, or anthralin may prevent a quick relapse in some patients. However, every prolonged topical steroid use is usually needed to maintain a therapeutic effect, particularly when combined with these compounds on an every second- or third-day basis; this may also delay cutaneous side effects.

Psoralen and ultraviolet A light (PUVA) treatment has been used alone or in combination with systemic retinoids and found to be effective.

PUVA bath or PUVA with application of the photosensitizer in an ointment or gel formulation showed beneficial effects in case-controlled studies.[26]

In disabling PPP and in PPP with a high frequency of relapse systemic therapy is preferred. A systematic review found retinoids to be the only drugs with proven efficacy. However, as there is a female preponderance in PPP, the use of systemic retinoids is restricted at least in women with childbearing potential. Other systemic agents with efficacy are methotrexate (10 to 25 mg/week) and cyclosporine. It has been shown that cyclosporine is effective in a low-dose regimen (1 to 2 mg/kg/day) over a 1-year period.[27] Systemic steroids are of questionable value. Withdrawal is usually followed by a rebound. Efficacy of fumaric acid ester therapy in PPP has been decribed.[28]

There is debate as to whether TNF-α antagonists may be beneficial in PPP. Whereas in chronic plaque type psoriasis and generalized pustular psoriasis the anti-TNF α monoclonal antibody infliximab was found to be highly effective, this agent was found to be both of beneficial effect and to worsen PPP.[29,30] In the SAPHO syndrome, infliximab led to a complete remission of osteoarticular disease but PPP deteriorated during treatment.[31] Efalizumab, an anti-CD11a monoclonal antibody, seems to be beneficial in PPP, but experience is limited.

ACRODERMATITIS CONTINUA (HALLOPEAU)

Acrodermatitis continua is a rare, sterile, pustular eruption of the fingers or toes that slowly extends proximally. Continuous pustulation leads to nail destruction and atrophy of the distal phalanx.

In 1888, Crocker[32] described a relapsing bullous and pustular eruption on hands and feet; this was further delineated by Hallopeau.[33] Acrodermatitis continua is now classified as a form of acropustular psoriasis.

Clinical Features

Acrodermatitis continua most often begins at the tips of one or two fingers (Fig.

Box 21-2

Treatments for Palmoplantar Pustulosis and Acrodermatitis Continua

	TOPICAL		PHYSICAL		SYSTEMIC	
First line	Potent and superpotent steroids Calcipotriol	bid, plastic film occlusion bid	Bath-psoralen and ultraviolet light	4/wk	Acitretin	0.5 mg/kg/bw/day

21-3), less often on the toes. The nail folds are affected very early, and trauma is thought to play an initiating role. The first signs consist of small pustules, which, on bursting, leave an erythematous, shiny area in which new pustules develop. These then tend to coalesce, forming polycyclic lakes of pus. As the disease extends proximally, the affected area shows either glossy erythema or a crusted, keratotic, and fissured surface with newly formed pustules underneath (see Fig. 21-3). Pustulation of the nail bed and the nail matrix almost always occurs and quite often leads to loss of the nail plate or severe onychodystrophy (see Fig. 21-3). Acrodermatitis continua of long duration may show complete destruction of the nail matrix and thus lead to anonychia. The skin becomes shiny and severely atrophic, and there is atrophic thinning of the distal part of the phalanx.

▲ **FIGURE 21-3** **A.** Acrodermatitis continua demonstrating acral pustule formation and subungual lakes of pus with destruction of the nail plate. **B.** Repeated eruptions lead to nail loss and severe atrophy. Note pustulation within the atrophic epidermis of the distal phalanges.

The disease may remain confined to the original site, sometimes up to several years, but more often it spreads proximally to cover the hand, dorsum of forearm, or foot. In such instances more than one extremity is involved. Acrodermatitis continua may be associated with generalized pustular psoriasis of the Zumbusch type (see Chap. 18).

Histopathology

The main histopathologic feature of acrodermatitis continua is a subcorneal cavity filled with neutrophils. Epidermal cell necrosis and spongiosis does not occur, but the roof and shoulder zones adjacent to the pustule show aggregated leukocytes between the epidermal cells, forming spongiform pustules. There is a moderate lymphohistiocytic infiltrate in the upper dermis, together with focal edema.

Lesions of long duration show severe atrophy of the papillary dermis and thinning of the epidermis.

Laboratory Findings

Systemic abnormalities are absent, and laboratory tests are usually within normal ranges. The pustules are sterile. In advanced cases, x-ray may reveal atrophy of the distal phalanx and arthropathy of the interphalangeal joints.

Diagnosis and Differential Diagnosis

Acrodermatitis continua at an early stage must be differentiated from acute paronychia caused by bacteria or fungi. Cultures and smears help rule out infectious causes. The distal localization and the tendency of the pustules to become confluent, forming denuded, erythematous, or crusted lesions, distinguishes acrodermatitis continua from PPP or pustular dyshidrotic eczema. Atrophy and loss of nails do not occur in these conditions. Contact dermatitis with secondary infection and pustulation has less clearly defined margins, runs a different clinical course, and lacks the persistence typical for acrodermatitis continua.

Treatment

As in pustular psoriasis, no specific drug is able to induce lasting remissions. Potent or superpotent topical steroids, preferentially under occlusion, are useful in blocking pustulation. Caution is advised in cases already showing atrophy. PUVA suppresses the eruption of new pustules and can be employed for long periods as maintenance treatment (see Chap. 239).

Treatment with a combination of systemic acitretin and local calcipotriol/calcipotriene was successful in one patient in a left-right comparison.[34] In recalcitrant patients, dapsone may be tried.[35] Recently, topical treatment with tacrolimus 0.1 percent ointment alone or in sequential combination with calcipotriol was found successful.[36,37] In more severe cases, TNF-α antagonists infliximab, etanercept, and adalimumab, the latter two in combination with acitretin, have been successfully used.[38–40]

In principle, regimens used for treatment of PPP may also be used for therapy of acrodermatitis continua (see Box 21-2). The therapeutic result lasts as long as the drugs are given, and relapses occur after withdrawal.

Course and Prognosis

Acrodermatitis continua shows a chronic course with a tendency of the lesions to spread proximally. Spontaneous improvement is rare, and episodes of acute pustulation occur without apparent cause. The development of pustules at other sites, or even the eruption of generalized pustular psoriasis, supports the idea that acrodermatitis continua is a variant of psoriasis.

INFANTILE ACROPUSTULOSIS

Infantile acropustulosis is discussed in Chap. 106.

CHAPTER 22

Seborrheic Dermatitis

Gerd Plewig
Thomas Jansen

Seborrheic dermatitis is a common chronic papulosquamous dermatosis that is usually easily recognized. It affects infants and adults and is often associated with increased sebum production (seborrhea) of the scalp and the sebaceous follicle–rich areas of the face and trunk. The affected skin is pink, edematous, and covered with yellow-brown scales and crusts. The disease varies from mild to severe, including psoriasiform or pityriasiform patterns and erythroderma.[1] Seborrheic dermatitis is one of the most common skin manifestations in patients with human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS).[2] Consequently, it is included in the spectrum of premonitory lesions and should be carefully evaluated in high-risk patients.

EPIDEMIOLOGY

Seborrheic dermatitis has two age peaks, one in infancy within the first 3 months of life and the second around the fourth to the seventh decades of life. No data are available on the exact incidence of seborrheic dermatitis in infants, but the disorder is common. The disease in adults is believed to be more common than psoriasis, for example, affecting at least 3 percent to 5 percent of the population in the United States.[3] Men are affected more often than women in all age groups. There does not appear to be any racial predilection. Seborrheic dermatitis is found in up to 85 percent of patients with HIV infection and AIDS.[2]

ETIOLOGY AND PATHOGENESIS

Although many theories abound, the cause of seborrheic dermatitis remains unknown.

SEBORRHEA

Seborrhea is associated with oily-looking skin (seborrhea oleosa), although an increased sebum production cannot always be detected in these patients.[4] Even if seborrhea does provide a predisposition, seborrheic dermatitis is not a disease of the sebaceous glands. The high incidence of seborrheic dermatitis in newborns parallels the size and activity of the sebaceous glands at this age. It has been shown that newborns have large sebaceous glands with high sebum secretion rates similar to adults.[5] In childhood, sebum production and seborrheic dermatitis are closely connected. In adulthood, however, they are not, as the sebaceous gland activity peaks in early puberty and decades later seborrheic dermatitis may occur.

The sites of predilection—face, ears, scalp, and upper part of the trunk—are particularly rich in sebaceous follicles. Two diseases are prevalent in these regions: seborrheic dermatitis and acne. In patients with seborrheic dermatitis, the sebaceous glands are often particularly large on cross-sectional histologic specimens. In one study, skin surface lipids were not elevated but the lipid composition was characterized by an increased proportion of cholesterol, triglycerides, and paraffin, and a decrease in squalene, free fatty acids, and wax esters.[6] However, mild abnormalities in the skin surface lipids could well result from the ineffective keratinization, which is often demonstrable histopathologically. Seborrheic dermatitis seems to be more frequent in patients with parkinsonism and other neurologic disorders, in whom sebum secretion is increased. Similarly, after reduction of sebum production induced by levodopa and by promestriene, seborrheic dermatitis may improve.

The synonym *eczéma flannelaire* stems from the idea that a retention of skin surface lipids by clothing and rubbing of rough textiles on the skin (flannel), or synthetic underwear promotes or aggravates seborrheic dermatitis.

MICROBIAL EFFECTS

Unna and Sabouraud, who were among the first to describe the disease, favored an etiology involving bacteria, yeasts, or both. This hypothesis has remained unsupported, although bacteria and yeasts can be isolated in great quantities from affected skin sites.

In infancy, *Candida albicans* is often found in dermatitic skin lesions and in stool specimens. Although intracutaneous tests with candidin, positive agglutinating antibodies in serum, and positive lymphocyte-transformation tests in affected infants revealed sensitization to *C. albicans,* this yeast cannot be convincingly linked to the pathogenesis.

Aerobic bacteria were recovered from the scalp of patients with seborrheic dermatitis (140,000 bacteria/cm^2 vs. 280,000 in unaffected individuals and 250,000 in persons with dandruff). In contrast, *Staphylococcus aureus* was rarely seen in unaffected persons or those with dandruff. *Staphylococcus* was recovered in approximately 20 percent of patients with seborrheic dermatitis, accounting for an average of approximately 32 percent of the total skin flora.[7]

Propionibacterium acnes counts were low in patients with seborrheic dermatitis (7550 bacteria/cm^2 in those without dandruff). The small quantities of *P. acnes* in patients with seborrheic dermatitis may explain the low yield of free fatty acids from their skin surfaces.

The lipophilic yeast *Malassezia furfur* (also known as *Pityrosporum*) is abundant in normal skin (504,000 organisms/cm^2 vs. 922,000 in individuals with dandruff and 665,000 in patients with seborrheic dermatitis).[7] Some authors claim strong evidence in favor of a pathogenic role for these microbes, whereas others do not share this view. Their argument is that *M. furfur* is not the causative organism, but is merely present in large numbers. In patients with pityriasis versicolor[8] and *Malassezia* folliculitis,[9] seborrheic dermatitis has been found in a higher percent-

SEBORRHEIC DERMATITIS AT A GLANCE

- Infantile and adult forms exist.
- Characterized by erythema and greasy scaling.
- Lesions favor scalp, ears, face, chest, and intertriginous areas.
- Generalized and even erythrodermic forms may occur.
- Etiology unknown but may be related to increased sebum secretion, abnormal sebum composition, certain drugs, or *Malassezia* yeasts.
- May be a cutaneous marker of human immunodeficiency virus infection and acquired immunodeficiency syndrome, especially when severe, atypical, and therapy resistant.

age than expected. Clearing of seborrheic dermatitis by selenium sulfide and continued suppression of *M. furfur* with topical amphotericin B caused a relapse of the disease on inflamed scalp skin.[10] In seborrheic dermatitis, both normal and high levels of serum antibodies against *M. furfur* have been demonstrated. A cell-mediated immune response to *M. furfur* has been found in normal individuals using *Malassezia* extracts in lymphocyte-transformation studies.[11] Overgrowth of *M. furfur* may lead to inflammation, either through introduction of yeast-derived metabolic products into the epidermis or as a result of the presence of yeast cells on the skin surface. The mechanism of production of inflammation would likely then be through Langerhans cell and T lymphocyte activation by *Malassezia* or its by-products. When *M. furfur* comes into contact with serum, it can activate complement via the direct and alternative pathways and this may play some part in the introduction of inflammation.[12] A possible role for this yeast in the pathogenesis of seborrheic dermatitis is supported by the fact that seborrheic dermatitis–like lesions have been shown to be reproducible in animal models by inoculation of *M. furfur*.[13]

MISCELLANEOUS

Drugs

Several drugs have been reported to produce seborrheic dermatitis–like lesions, including arsenic, gold, methyldopa, cimetidine, and neuroleptics.

Neurotransmitter Abnormalities

Seborrheic dermatitis is often associated with a variety of neurologic abnormalities, pointing to a possible influence of the nervous system. These neurologic conditions include postencephalitic parkinsonism, epilepsy, supraorbital injury, facial paralysis, unilateral injury to the trigeminal ganglion, poliomyelitis, syringomyelia, and quadriplegia. Emotional stress seems to aggravate the disease; a high rate of seborrhea is reported among combat troops in times of war.

Physical Factors

It has been suggested that cutaneous blood flow and skin temperature may be responsible for the distribution of seborrheic dermatitis.[14] Seasonal variations in temperature and humidity are related to the course of the disease. Low fall and winter temperatures and low humidity in centrally heated rooms are known to worsen the condition. Seborrheic dermatitis of the face was observed in 8 percent of 347 patients receiving psoralen and ultraviolet A light therapy for psoriasis and occurred within a few days to 2 weeks after the beginning of treatment;[15] the patients had no previous history of facial psoriasis or seborrheic dermatitis. Lesions were avoided by masking the face during irradiation.

Aberrant Epidermal Proliferation

Epidermal proliferation is increased in seborrheic dermatitis, similar to psoriasis, explaining why cytostatic therapeutic modalities may improve the condition.[16]

Nutritional Disorders

Zinc deficiency in patients with acrodermatitis enteropathica and acrodermatitis enteropathica-like conditions may be accompanied by dermatitis mimicking seborrheic dermatitis of the face. Seborrheic dermatitis is, however, not associated with zinc deficiency nor does it respond to supplementary zinc therapy.

Seborrheic dermatitis in infancy may have a different pathogenesis. Biotin deficiency, whether secondary to holocarboxylase or biotinidase deficiency, and abnormal metabolism of essential fatty acids have been proposed as possible mechanisms.[17] However, biotin has been subsequently shown to have no more than placebo effect when studied in a double-blind manner.[18] Although one study suggested the possible role of food allergy in seborrheic dermatitis of infancy,[19] this has not been confirmed.

Genetic Factors

Recently, a condition considered to be seborrheic dermatitis with a gene defect in a zinc finger protein has been described.[20]

IMMUNODEFICIENCY AND SEBORRHEIC DERMATITIS

The development of seborrheic dermatitis either de novo or as a flare of preexisting disease also may serve as a clue to the presence of HIV infection and AIDS. The first report of this association in 1984 was followed by observations from all parts of the world.[2]

The increased incidence and severity of seborrheic dermatitis in HIV seropositive individuals has led to speculation that unchecked growth of *Malassezia* in immunosuppressed patients is responsible. However, a study that compared quantitative *Malassezia* cultures in AIDS patients with and without seborrheic dermatitis did not demonstrate increased yeast colonization in patients with seborrheic dermatitis.[21]

PSORIASIS AND SEBORRHEIC DERMATITIS

In patients with a psoriatic predisposition, particularly adults, seborrheic dermatitis is said to evolve into psoriasis. The term *sebopsoriasis* is sometimes used for these overlapping conditions. It should be used with caution because psoriasis, especially of the scalp, is clinically and histopathologically almost indistinguishable from seborrheic dermatitis.

CLINICAL FINDINGS

In all patients with seborrheic dermatitis there is a so-called *seborrheic stage*, which is often combined with a gray-white or yellow-red skin discoloration, prominent follicular openings, and mild to severe pityriasiform scales. Several forms can be distinguished (Table 22-1).

SEBORRHEIC DERMATITIS IN INFANTS

The disease occurs in infants predominantly within the first months of life as an inflammatory disease mainly affecting the hairy scalp and intertriginous folds with greasy-looking scales and crusts (Fig. 22-1). Other regions such as the center of the face, chest, and neck may also be affected. Scalp involvement

is fairly characteristic. The frontal and parietal scalp regions are covered with an oily-looking, thick, often fissured crust (*crusta lactea*, *milk crust*, or *cradle cap*). Hair loss does not occur and inflammation is sparse. In the course of the disease, the redness increases and the scaled areas form clearly outlined erythematous patches topped by a greasy scale. Extension beyond the frontal hairline occurs. The retroauricular folds, the pinna of the ear, and the neck may also be involved. Otitis externa is often a complicating factor. Semiocclusive clothing and diapers favor moisture, maceration, and intertriginous dermatitis, particularly in the folds of the neck, axillae, anogenital area, and groin. Opportunistic infection with *C. albicans*, *S. aureus*, and other bacteria occurs. The clinical aspect reminds one of psoriasis, hence the expressions *psoriasoid* or *napkin psoriasis.*

Prognosis and Clinical Course

The disease is usually protracted over weeks to months. Exacerbation and, rarely, generalized exfoliating dermatitis may occur. The prognosis is good. There is no indication that infants with seborrheic dermatitis are more likely to suffer from the adult form of the disease.

Differential Diagnosis (See Box 22-1)

The most useful distinguishing feature between atopic dermatitis and seborrheic dermatitis is the increased number of lesions on the forearms and shins in the former and in the axillae in the latter. The development of skin lesions solely in the diaper area favors a diagnosis of infantile seborrheic dermatitis. Radioallergosorbent assay test screening to egg white and milk antibodies or other geographically or ethnically relevant allergens (e.g., soybean), and, to a lesser extent, total immunoglobulin E levels, may be useful in diagnosing atopic dermatitis at an early stage and distinguishing it from infantile seborrheic dermatitis. Absent to mild pruritus is considered a significant feature of infantile seborrheic dermatitis. Some authors believe that infantile seborrheic dermatitis is a clinical variant of atopic dermatitis rather than a separate entity.[22]

Box 22-1

ERYTHRODERMA DESQUAMATIVUM (LEINER DISEASE)

Erythroderma desquamativum is a complication of seborrheic dermatitis in infants (dermatitis seborrhoides infantum) and was described in 1908 by Leiner.[23] There is usually a sudden confluence of lesions, leading to a universal scaling redness of the skin (erythroderma). The young patients are severely ill with anemia, diarrhea, and vomiting. Secondary bacterial infection is common. The prognosis is very good unless proper intensive care and skin care are not provided. The disease is both a familial and a nonfamilial form. The former is noted for having a functional deficiency of C5 complement, resulting in defective opsonization. These patients respond to antibiotics and infusions of fresh frozen plasma or whole blood. The true nature of this disease remains obscure.

SEBORRHEIC DERMATITIS IN ADULTS

The clinical picture and course of seborrheic dermatitis in adults differs from that of infants.

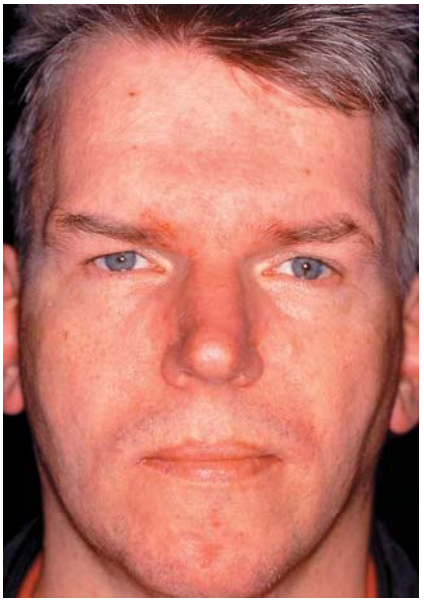
Seborrheic eczematid is the mildest form of the disease (eczematid = eczema-like, dermatitis-like). It is associated with seborrhea, scaling, mild redness, and often pruritus of the scalp, eyebrows, nasolabial folds, and retroauricular area, as well as over the sternum and the shoulder blades. Asymptomatic fluffy, white dandruff of the scalp represents the mild end of the spectrum of seborrheic dermatitis and has been referred to as *pityriasis sicca*. Nasolabial erythema, more common in young women than men, may be part of this disease spectrum.

Patchy seborrheic dermatitis is the classic, well-known disease with chronic recurrent lesions. Lesions have a predilection for scalp, temples, inner parts of the eyebrows and glabella with nasolabial folds (Figs. 22-2 and 22-3), retroauricular folds and external ear canal (Fig. 22-4) and V-shaped areas of the chest and back (Fig. 22-5). Less frequently, intertriginous areas, such as the side of the neck, axillae, submammary region, umbilicus, and genitocrural folds, are involved.

Clinical Findings

Skin lesions are characterized by a yellow color, mild to severe erythema, mild inflammatory infiltrate, and oily, thick scales and crusts. This has occasionally been referred to as *pityriasis steatoides*. Patients report pruritus, particularly on the scalp and in the ear canal. The lesions start with follicular and perifollicular redness and mounds; they spread until they form clearly outlined, round to circinate (petaloid) patches (Greek *petalon,* a thin plate or leaf). The pityriasiform type of seborrheic dermatitis is seen on the trunk and mimics the

▲ **FIGURE 22-2** Seborrheic dermatitis with involvement of nasolabial folds, cheeks, eyebrows, and nose.



▲ **FIGURE 22-3** Seborrheic dermatitis of the forehead and centrofacial region.

lesions of pityriasis rosea, producing oval scaly lesions whose long axes tend to parallel the ribs. In some individuals, only one or two sites are involved. Chronic dermatitis of the ear canal may be the sole manifestation of seborrheic dermatitis, often mistaken for fungal infections. Another possible manifestation is blepharitis with honey-colored crusts along the rim of the eyelid and casts of horny cell debris around the eyelashes. In men, a more follicular type of seborrheic dermatitis may extend over large parts of the back, flanks, and abdomen.

Prognosis and Clinical Course

Usually, the disease lasts for years to decades with periods of improvement in warmer seasons and periods of exacerbation in the colder months. Widespread lesions may occur as a result of improper topical treatment or sun exposure. The extreme variant of the disease is generalized exfoliative erythroderma (seborrheic erythroderma). Onychodystrophy, electrolyte imbalance, and thermal dysregulation are additional features sometimes found in these patients.

▲ **FIGURE 22-4** Seborrheic dermatitis of the earlobe and ear.

▲ **FIGURE 22-5** Seborrheic dermatitis of the upper back.

PITYRIASIS AMIANTACEA

Pityriasis amiantacea (synonyms: tinea amiantacea, asbestos scalp, porrigo amiantacea, tinea asbestina, keratosis follicularis amiantacea) is the name given to a disease of the scalp in which heavy scales extend onto the hairs and separate and bind together their proximal portions. See Box 22-2 for site-specific differential diagnosis of seborrheic dermatitis.

Pityriasis amiantacea is a reaction of the scalp, often without evident cause, that may occur at any age. It may be observed as a complication or sequel of streptococcal infection, seborrheic dermatitis, atopic dermatitis, lichen simplex, and it also occurs in psoriasis, of which it may be the first clinical manifestation.[24]

The process may be circumscribed or diffuse. It is only slightly inflammatory with dry, micaceous scales, or markedly inflammatory with admixture of a crust (Fig. 22-6). Removal of the scales reveals normal or erythematous edematous epidermis. The process is not followed by atrophy, scarring, or alopecia. If scarring alopecia occurs, it may be related to secondary infection. A common form complicates chronic or recurrent fissuring behind one or both ears, mostly in young girls. The sticky scales extend several centimeters into the neighboring scalp. Another form extends from patches of lichen simplex and is seen mainly in middle-aged women.

▲ **FIGURE 22-6** Pityriasis amiantacea. Masses of sticky silvery scales adhere to the scalp and are attached in layers to the shafts of the hairs that they surround.

SEBORRHEIC DERMATITIS IN HUMAN IMMUNODEFICIENCY VIRUS–INFECTED INDIVIDUALS

The expression of seborrheic dermatitis differs in several aspects from its classic form seen in HIV seronegative individuals: The distribution is extensive, severity is marked (Fig. 22-7), and treatment often difficult. Even the histopathologic changes differ somewhat from those seen in commonly encountered seborrheic dermatitis (Table 22-2).

HISTOPATHOLOGY

The histopathologic picture varies according to the stage of the disease: acute, subacute, or chronic.[25,26] In acute and subacute seborrheic dermatitis,

▲ **FIGURE 22-7** Widespread unusual distribution pattern of seborrheic dermatitis in a patient with acquired immunodeficiency syndrome (AIDS). **A.** Moist patches on the centrofacial region and hairy scalp. **B.** Moist lesions on the chest. In patients with AIDS, the disease responds poorly to conventional therapy.

there is a sparse superficial perivascular infiltrate of lymphocytes and histiocytes, slight to moderate spongiosis, slight psoriasiform hyperplasia, follicular plugging by orthokeratosis and parakeratosis, and scale-crusts containing neutrophils at the tips of the follicular ostia (see Table 22-2). In chronic seborrheic dermatitis, there are markedly dilated capillaries and venules in the superficial plexus, in addition to the above-mentioned features.

Clinically and histopathologically the lesions of chronic seborrheic dermatitis are psoriasiform and often difficult to distinguish from those of psoriasis.[25] Abortive forms of psoriasis share many features with seborrheic dermatitis. There are lesions that resemble psoriasis and may persist over many years before they finally turn into overt psoriasis. The most important diagnostic signs of seborrheic dermatitis are mounds of scale-crust–containing neutrophils at the tips of the dilated horn-filled follicular infundibula. Acrosyringia and acroinfundibula may be plugged by corneocyte casts.

The most consistent findings in pityriasis amiantacea are spongiosis, parakeratosis, migration of lymphocytes into the epidermis, and a variable degree of acanthosis.[27] The essential features responsible for the asbestosis-like scaling are diffuse hyperkeratosis and parakeratosis together with follicular keratosis in which each hair is surrounded by a sheath of corneocytes and debris.

Cytologic abnormalities of superficial horny cells (corneocytes) including ortho- and parakeratotic (nucleated) cells, horny cells in different stages of nuclear decomposition (halo cells), and masses of leukocytes can be evaluated by exfoliative cytology. Seborrheic dermatitis and psoriasis, however, present similar findings compared with other conditions of the dermatitis-eczema group.[28] The histopathology of AIDS-associated seborrheic dermatitis is more severe and differs in some respects from the classical form (see Table 22-2).

TREATMENT

General Considerations

In general, therapy is directed toward loosening and removal of scales and crusts, inhibition of yeast colonization, control of secondary infection, and reduction of erythema and itching. Adult patients should be informed about the chronic nature of the disease and understand that therapy works by controlling the disease rather than by curing it. The prognosis of infantile seborrheic dermatitis is excellent because the condition is benign and self-limited.

Infants

SCALP Treatment consists of the following measures: removal of crusts with 3 percent salicylic acid in olive oil or a water-soluble base; warm olive oil compresses; application of low-potency glucocorticosteroids (e.g., 1 percent hydrocortisone) in a cream or lotion for a few days; topical antifungal agents such as imidazoles (in a shampoo); mild baby shampoos; proper skin care with emollients, creams, and soft pastes.

INTERTRIGINOUS AREAS Treatment measures include drying lotions, such as 0.2 percent to 0.5 percent clioquinol in zinc lotion or zinc oil. In cases of candidiasis, nystatin or amphotericin B lotion or cream can be applied followed by soft and stiff pastes. In cases of oozing der-

TABLE 22-2
Histopathologic Differences Between Acquired Immunodeficiency Syndrome–Associated Seborrheic Dermatitis and Classic Seborrheic Dermatitis

Classic Seborrheic Dermatitis	Acquired Immunodeficiency Syndrome–Associated Seborrheic Dermatitis

matitis, application of 0.1 percent to 0.25 percent gentian violet where still available in combination with cotton or muslin diapers is often helpful. Imidazole preparations (e.g., 2 percent ketoconazole in soft pastes, creams, or lotions) may also be effective.

DIET Milk-free and high-protein, low-fat diets have not been shown to be of value, nor has the efficacy of oral or intramuscular biotin, vitamin B complex, or essential fatty acids been established.

Adults

Because the disease runs an unpredictably long course, careful and mild treatment regimens are recommended. Anti-inflammatory agents and, when indicated, antimicrobial or antifungal agents have to be used.

SCALP Frequent shampooing with shampoos containing 1.0 percent to 2.5 percent selenium sulfide, imidazoles (e.g., 2 percent ketoconazole), zinc pyrithione, benzoyl peroxide, salicylic acid, coal or juniper tar where still available, or detergents is recommended. Crusts or scales can be removed by overnight application of glucocorticosteroids or salicylic acid in water-soluble bases or, when necessary, under occlusive dressings. Tinctures, alcoholic solutions, hair tonics, and similar products usually aggravate the inflammatory state and should be avoided.

In pityriasis amiantacea, scales should be removed by the use of cade oil ointment or a topical tar/salicylic ointment. Either preparation should be washed out of the scalp after 4 to 6 hours with a suitable shampoo (e.g., tar or imidazole shampoo). Potent topical corticosteroid scalp creams or liquids may be beneficial in some cases, preferably under plastic occlusion in the initial phase. If topical treatment does not work, systemic glucocorticosteroids (e.g., 0.5 mg prednisolone/kg body weight/day for approximately 1 week) in combination with topical treatment (steroid under occlusion, followed by open application) should be considered. Concomitant antimicrobial treatment (e.g., macrolides, sulfonamides) is reserved for stubborn cases, especially if bacterial co-infection of the scalp is proven or suspected. Of course, the underlying condition must be treated. Treatment remains difficult, and relapses occur frequently.

FACE AND TRUNK Patients should avoid greasy ointments and reduce or omit the use of soaps. Alcoholic solutions or pre- or aftershave lotions should not be recommended. Low-potency glucocorticosteroids (1 percent hydrocortisone is usually sufficient) are helpful early in the course of the disease. Uncontrolled long-term applications lead to side effects such as steroid dermatitis, steroid rebound phenomenon, steroid rosacea, and perioral dermatitis.

SEBORRHEIC OTITIS EXTERNA Seborrheic otitis externa can be best treated with a low-potency glucocorticosteroid cream or ointment. Many otic preparations (solutions) that contain neomycin and other antibiotics, often in combination, are strong sensitizers and should be avoided. Once dermatitis is under control, the glucocorticosteroid should be discontinued and a solution containing aluminum acetate should be applied once or twice daily to maintain control. This acts as a drying agent and reduces the microbial flora. Basic ointments or plain petroleum jelly, gently applied into the ear canal (without cotton tips), are often helpful to maintain satisfaction of the patient. Topical pimecrolimus is effective.

SEBORRHEIC BLEPHARITIS Special consideration is given to the treatment of seborrheic blepharitis. The use of hot compresses with gentle débridement with a cotton-tipped applicator and baby shampoo one or more times daily is recommended. Stubborn cases may require the use of a topical antibiotic such as sodium sulfacetamide ophthalmic ointment. The use of ocular preparations containing glucocorticosteroids should be deferred to an ophthalmologist. If *Demodex folliculorum* mites occur in large numbers, a trial with antiparasitic drugs such as crotamiton, permethrin, or benzyl benzoate is worthwhile.

Antifungals

Good results are achieved with topical application of antifungal agents, especially imidazoles. Clinical studies have reported response rates ranging from 63 percent[29] up to 90 percent[30] after 4 weeks. In these trials, imidazoles such as itraconazole, miconazole, fluconazole, econazole, bifonazole, climbazole, ciclopirox, and ciclopiroxolamine were studied. The imidazole compound that has been mostly used is ketoconazole. In several clinical studies, 2 percent ketoconazole cream has been found as effective as glucocorticosteroid creams, and this often results in more prolonged remissions.[29,31] Comparative studies of topical antifungal agents, however, are lacking. Personal experience, though based on open uncontrolled studies only, favors 2 percent ketoconazole cream. Other antifungal agents may also be effective. In a limited trial, 1 percent butenafine cream, a benzylamine derivative, demonstrated efficacy in the topical treatment of seborrheic dermatitis.

Oral antifungal agents such as ketoconazole, itraconazole, and terbinafine are also effective, but because of potential side effects and pharmacoeconomic considerations, should probably be limited to severe or refractory cases. Antifungal agents have a wide spectrum of effects, including anti-inflammatory properties and inhibition of cell wall lipid synthesis. This efficacy is not proof of a causal relationship between *M. furfur* and seborrheic dermatitis.

Metronidazole

Topical metronidazole is a worthwhile alternative in the treatment repertoire of seborrheic dermatitis. It has been used successfully in patients with rosacea. Extemporaneous formulations (1 percent to 2 percent in a cream base) or commercial products (0.75 percent gel, cream, or lotion; 1 percent cream) are used once or twice daily. Recently, a significant benefit of using 1 percent metronidazole gel over placebo in the treatment of seborrheic dermatitis was demonstrated.[32] Conversely, 0.75 percent metronidazole gel was shown to have similar efficacy than placebo in the treatment of seborrheic dermatitis.[33]

Lithium

Other topical agents that are effective in the treatment of seborrheic dermatitis are lithium succinate[34] and lithium gluconate,[35] which possess antifungal properties.

Calcineurin Inhibitors

Topical tacrolimus[36] and pimecrolimus[37] may be superior alternatives to corticosteroids as they both have anti-inflammatory properties but do not have long-term side effects. Tacrolimus also exhibits antifungal properties.

Vitamin D_3 Analogues

Vitamin D_3 analogues (calcipotriol cream or lotion, calcitriol ointment, or tacalcitol

ointment) are also recommended and useful in selected patients.[38] Their anti-inflammatory and antifungal properties may be responsible for their efficacy in seborrheic dermatitis.

Isotretinoin

Oral isotretinoin (13-*cis*-retinoic acid) is a useful, although not officially approved, drug for this indication. Low doses (0.05 to 0.10 mg/kg body weight daily) given for several months clear stubborn seborrheic dermatitis in many cases. In women of child-bearing age, all precautions must be met (see Chap. 229).

Phototherapy

Narrow-band ultraviolet B phototherapy appears to be an effective and safe treatment option for patients with severe and refractory seborrheic dermatitis.[39] Psoralen and ultraviolet A light therapy has been used successfully in the erythrodermic form of the disease.[40]

CHAPTER 23

Exfoliative Dermatitis

Jane Margaret Grant-Kels
Megan L. Bernstein
Marti J. Rothe

EPIDEMIOLOGY

The incidence of exfoliative dermatitis (ED) has varied widely in studies from 0.9 to 71.0 per 100,000 outpatients.[1–4] Males are affected more commonly than females with a 2:1 to 4:1 male-to-female ratio. The average age of disease onset varies from 41 to 61, with the majority of studies excluding children.

Preceding skin disease plays a role in more than one-half of the cases of ED. Psoriasis is the leading underlying skin disease identified in almost one-fourth of the cases. Recently, ED was reported in 87 of 160 cases of severe psoriasis.[5]

ETIOLOGY AND PATHOGENESIS

ED can be caused by a wide range of cutaneous and systemic diseases (Table 23-1). Data from 18 published studies on ED were compiled to assess etiology.[1,2,4,6–20] Pre-existing skin disease plays a role in approximately 52 percent (range, 27 percent to 68 percent) of ED cases. ED is most commonly caused by psoriasis (23 percent), spongiotic dermatitis (20 percent), drug hypersensitivity reactions (15 percent), and cutaneous T-cell lymphoma (CTCL) or Sézary syndrome (5 percent). In approximately 20 percent of ED cases (range, 7 percent to 33 percent), no underlying etiology is identified and these cases are classified as idiopathic. Less common causes of ED in adults include immunobullous disease; connective tissue disease; infections, including scabies and dermatophytes; pityriasis rubra pilaris (PRP) (4 percent of dermatoses); and underlying malignancy. In neonates and infants, the differential diagnosis includes dermatoses (such as psoriasis, atopic dermatitis, and seborrheic dermatitis), drugs, and infection (particularly staphylococcal scalded-skin syndrome). In addition, several congenital disorders including the ichthyoses, both bullous and non-bullous congenital ichthyosiform erythroderma, Netherton syndrome, and immunodeficiencies should be considered (Box 23-1).

Drugs are implicated in a significant percentage (mean, 15 percent; range, 4 percent to 39 percent) of ED cases, and the list is constantly expanding. Table 23-2 is a listing of drugs reported to cause ED. However, many of these drugs are reported in single case notes. The most commonly implicated drugs include calcium channel blockers, antiepileptics, antibiotics (penicillin family, sulfonamides, vancomycin), allopurinol, gold, lithium, quinidine, cimetidine, and dapsone.

EXFOLIATIVE DERMATITIS AT A GLANCE

- Exfoliative dermatitis (ED) is diffuse erythema and scaling of the skin involving more than 90 percent of the total body skin surface area.
- Common underlying etiologies are psoriasis, atopic dermatitis and other spongiotic dermatoses, drug hypersensitivity reactions, and cutaneous T-cell lymphoma.
- The cause of ED is unknown in approximately 20 percent of cases (idiopathic ED).
- Diagnostic workup includes a complete history, physical examination, dermatohistopathology, and other laboratory work up determined by clinical clues.
- Systemic complications include fluid and electrolyte imbalance, thermoregulatory disturbance, fever, tachycardia and high-output failure, hypoalbuminemia, and peripheral edema.
- Treatment addresses the underlying etiology, symptomatic relief, and potential systemic complications.

TABLE 23-1
Diseases Associated with Exfoliative Dermatitis

DERMATOSES
- Spongiotic dermatitis
  - Atopic dermatitis[a]
  - Seborrheic dermatitis[2]
  - Contact dermatitis
  - Stasis dermatitis
- Bullous
  - Pemphigus foliaceus
  - Paraneoplastic pemphigus
  - Bullous pemphigoid
  - Hailey-Hailey[73]
- Papulosquamous
  - Psoriasis[a]
  - Pityriasis rubra pilaris[a]
  - Impetigo herpetiformis[74]
- Photosensitive
  - Chronic actinic dermatitis
  - Actinic reticuloid [75]
- Adverse drug[a]
- Other
  - Pseudolymphoma[76]
  - Erythema gyratum repens[77]
  - Perforating folliculitis[78]
  - Radiation recall dermatitis[79]
  - Senile erythroderma with hyperIgE[80]

SYSTEMIC
- Dermatomyositis[81–84]
- Subacute cutaneous lupus[85,86]
- Acute graft-versus-host disease[87,a]
- Postoperative transfusion induced[88]
- Thyrotoxicosis[89]
- Sarcoidosis[90–92]
- Hypercalcitonemia [93]
- Idiopathic hypereosinophilic syndrome[94]

INFECTIONS
- Bacterial
  - Tuberculosis[95]
  - Congenital syphilis[96]
- Viral
  - Hepatitis C[97]
  - Human immunodeficiency virus
  - Human herpesvirus 6[98]
- Fungal
  - Dermatophyte[14,18]
  - Histoplasmosis[99–101]
  - Congenital cutaneous candidiasis[102]
- Parasite
  - Norwegian scabies
  - Toxoplasmosis[103]
  - Leishmaniasis[104]
- Toxin-mediated infections
  - Staphylococcal scalded-skin syndrome[a]
  - Toxic shock syndrome

MALIGNANCY
- Solid tumors
  - Lung[14,17,18,105]
  - Prostate[14,18,106]
  - Thyroid[14]
  - Liver[14,107]
  - Gallbladder[108]
  - Melanoma[18,109]
  - Breast[18]
  - Ovary[18]
  - Fallopian tube[110]
  - Esophagus[111]
  - Stomach[17,112]
  - Rectum[18]
  - Buschke-Loewenstein tumor[113]
- Lymphoproliferative
  - Cutaneous T-cell lymphoma[a]
  - Sézary syndrome
  - Papuloerythroderma of Ofuji
  - Hodgkin lymphoma[11,14,15,114]
  - B-cell lymphoma[115]
  - (Cutaneous) anaplastic large cell lymphoma[116,117]
  - Angioimmunoblastic T-cell lymphoma[118]
  - Castleman disease[119]
  - Acute myeloid leukemia M6[120]
  - Acute myelomonocytic leukemia[121]
  - Adult T-cell leukemia[122]
  - Chronic lymphocytic leukemia[11]
  - Chronic eosinophilic leukemia[123]
  - Myelodysplasia[124]
  - Multiple myeloma[23]
  - Reticulum cell sarcoma[6]
  - Angioimmunoblastic lymphadenopathy[125]
  - Cutaneous lymphoid hyperplasia
  - Hypereosinophilic syndrome[126,127]
  - Mastocytosis (type II-IV)[128,129]
  - Histiocytosis[130]
  - Rosai-Dorfman disease

CONGENITAL
- Immunodeficiency
  - Common variable hypogammaglobulinemia[131]
  - Wiskott-Aldrich syndrome
  - Severe combined immunodeficiency
  - Omenn syndrome
  - Leiner disease
  - Hyperimmunoglobulin-E (hyperIgE) syndrome[132]
  - Secretory IgA deficiency
- Metabolic
  - Maple syrup urine disease
  - Neutral lipid storage disease
  - Essential fatty acid deficiency
  - Holocarboxylase synthetase deficiency[133]
- Ichthyosis
  - Bullous congential ichthyosiform erythroderma
  - Non-bullous congenital ichthyosiform erythroderma
  - Netherton syndrome
  - Conradi-Hünermann syndrome[134]
  - Epidermolytic hyperkeratosis
  - Keratitis, ichthyosis, and deafness[135]
  - Lamellar ichthyosis
  - Lethal congenital erythroderma[136]
  - Sjögren-Larsson syndrome

[a]Most common diseases.

ED can result from an exacerbation of previously localized disease in more than one-half of patients.[9] Possible triggers for psoriatic ED include:

- Discontinuation of potent topical or oral corticosteroids, methotrexate, or biologics (efalizumab)[21]
- Medications, such as lithium, terbinafine, and antimalarials
- Topical irritants including tars
- Systemic illness
- Infection including human immunodeficiency virus
- Phototherapy burns
- Pregnancy
- Emotional stress

It is critical to consider other possible etiologies, even in patients with pre-existing dermatoses or with evidence of an underlying dermatosis on skin examination. In one case series, malignancy-related ED was identified in seven patients, five of whom had a pre-existing dermatosis.[9]

Some patients with chronic idiopathic ED have been reported to develop CTCL. This has led to the concern that patients with chronic idiopathic ED may be at increased risk for progression to mycosis fungoides or Sézary syndrome.[18,22] Some theories propose that the chronic T-cell stimulation in chronic ED (atopic ED) may promote the development of CTCL.[23–27] A monoclonal expansion of $CD4^+CD7^-CD26^-$ lymphocytes was recently noted in elderly patients with chronic or relapsing ED without progression to hematologic malignancy, CTCL, or Sézary syndrome. Therefore, the term *monoclonal T-cell dyscrasia of undetermined significance*, a T-cell equivalent to monoclonal gammopathy of undetermined significance, was pro-

Box 23-1

Differential Diagnosis

Most Likely

- Spongiotic dermatitis (20%–24%) (atopic, 9%; contact dermatitis, 6%; seborrheic dermatitis, 4%; chronic actinic dermatitis, 3%)
- Psoriasis (23%)
- Drug hypersensitivity reaction (15%)
- Cutaneous T-cell lymphoma (5%)
- Idiopathic (approximately 20%)

Consider

- Contact dermatitis
- Immunobullous disease (superficial pemphigus, bullous pemphigoid, paraneoplastic pemphigus)
- Infection (scabies, dermatophytosis)
- Toxin-mediated (toxic shock syndrome, staphylococcal scalded-skin syndrome)
- Chronic actinic dermatitis
- Pityriasis rubra pilaris
- Collagen vascular disease
- Paraneoplastic (solid tumors and hematologic)
- Primary immunodeficiency
- Congenital ichthyoses

Always Rule Out

- Cutaneous T-cell lymphoma
- Drug-induced hypersensitivity syndrome
- Paraneoplastic

TABLE 23-2
Drugs Implicated in Exfoliative Dermatitis

Antibiotics
- Aztreonam
- Cefoxitin[137,138]
- Doxycycline[125]
- Gentamicin[71]
- Isoniazid[2,11,15]
- Minocycline
- Neomycin
- Penicillin[6,11,14,15]
- Ribostamycin[139]
- Rifampin
- Streptomycin[2,14]
- Sulfasalazine[36]
- Sulfonamides[11,14]
- Teicoplanin[140]
- Thiacetazone[2]
- Tobramycin[141]
- Trimethoprim[1]
- Vancomycin[142,143]

Antivirals
- Dideoxyinosine[144]
- Indinavir[145]
- Interferon α[146]
- Zidovudine[147]

Anti-lepromatous
- Clofazimine[148]
- Dapsone[149–154]

Anti-epileptics
- Carbamazepine[8,17,155,156]
- Lamotrigine[157]
- Phenytoin[11,17,37,158]
- Phenobarbital[159]

Anti-inflammatory
- Aspirin
- Celecoxib[160]
- Diflunisal[161]
- Metamizole[162]
- Phenylbutazone[2]
- Piroxicam[163]

Cardiac drugs
- Amiodarone
- Captopril[164]
- Diltiazem[165,166]
- Isosorbide dinitrate[11]
- Mexiletine
- Nifedipine[167]
- Practolol[1]
- Quinidine[6,17]

Chemotherapy
- Carboplatin[168]
- Cisplatin[169]
- Doxorubicin[170]
- Fluorouracil
- Imatinib[171,172]
- Mitomycin C[173]
- Pentostatin[174]
- Vinca alkaloids[175]

Diabetic
- Sulfonylureas
- Chlorpropamide[176]

Psychiatric
- Barbiturates
- Bupropion[177]
- Chlorpromazine[1]
- Etumine[8]
- Lithium[178]
- Phenothiazines

Other
- Allopurinol[1,8,11,17]
- Antimalarials[6,11,14,45,179]
- Arsenicals
- Bacille Calmette-Guérin immunization[180]
- Bromodeoxyuridine[181]
- Cimetidine[182]
- Clodronate[183]
- Codeine[14,184]
- Ephedrine[185]
- Epoprostenol[186]
- Erythropoietin[187,188]
- Ethylenediamine[189]
- Fluindione[190]
- Gold[1,6,14,17]
- *Hypericum* (St. John's wort)[191]
- Interleukin 2[192]
- Iodine[14]
- Leflunomide[193]
- Mercurials[14,15]
- Nystatin [194]
- Omeprazole[195,196]
- Phenolphthalein[14]
- Propolis[197]
- Pseudoephedrine[72]
- Ranitidine
- Retinoids[198]
- *Rhus* (lacquer)[199,200]
- Roxatidine acetate hydrochloride[201]
- Terbinafine[202]
- Terbutaline[11]
- Tetrachloroethylene[14]
- Thalidomide[203–205]
- Thiazide[11]
- Timolol eye drops[206]
- Tramadol
- Tumor necrosis factor-α[192]

posed to indicate a possible pre-malignant or pre–Sézary-like condition.[23] On the other hand, chronic idiopathic ED may also represent primary chronic, undiagnosed CTCL.

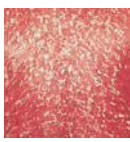
The pathogenesis of ED is related to the pathogenesis of the underlying disorders which are covered in their respective chapters. The mechanisms by which an underlying disease manifests as ED, a pre-existing dermatosis explodes into ED, or the de novo development of idiopathic ED are not well understood.

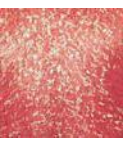
Recent research on the immunopathogenesis of toxin-mediated infection demonstrates staphylococcal pathogenicity islands encoding superantigens (see Chap. 178). These islands carry the genes for the toxins of toxic shock syndrome and staphylococcal scalded-skin syndrome.[28] It has been theorized that possibly *Staphylococcus aureus* colonization or another antigen, such as toxic shock syndrome toxin-1, may play a role in the pathogenesis of ED.[29,30] Patients with ED were noted to have *S. aureus* colonization in the nares in 83 percent, and in the skin and nares in 17 percent[30]; however, only one in six patients was *S. aureus* enterotoxin positive.[30]

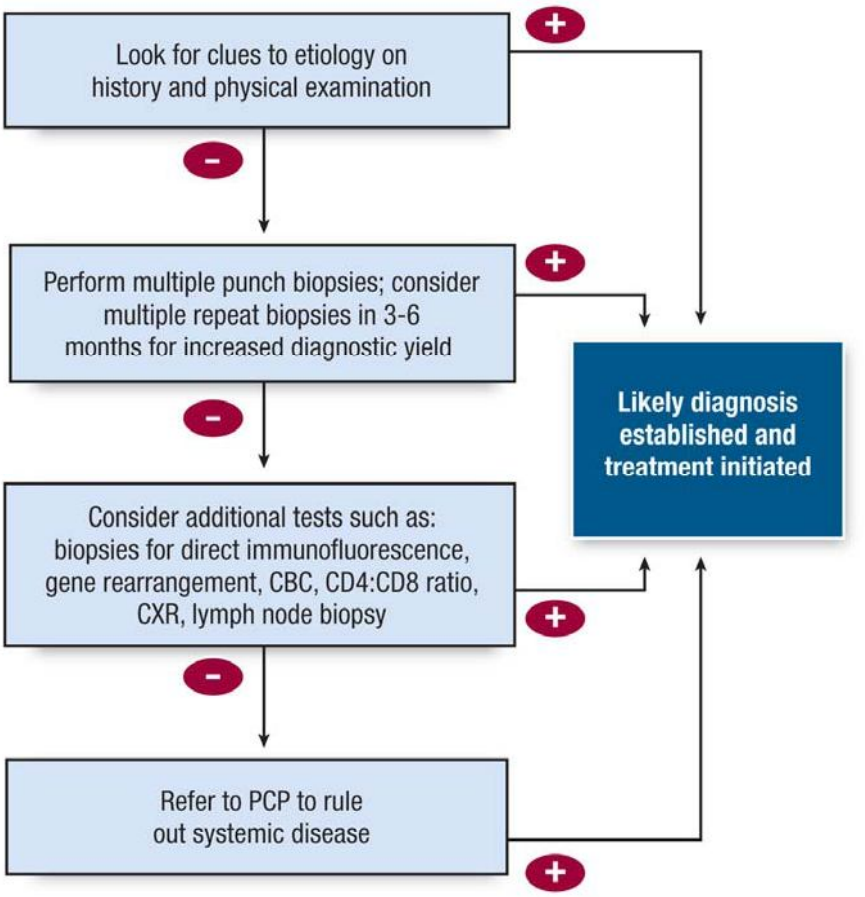
Cytokine profiles in dermal infiltrates may be different depending on the underlying cause of ED. Benign ED demonstrates a T helper 1 cytokine profile; in contrast, Sézary syndrome shows a T helper 2 cytokine profile pointing to a different pathophysiologic mechanism.[31]

Elevations in immunoglobulin E (IgE) are noted in many types of ED and, again, the mechanism may be different in different types of ED. For example, it has been theorized that elevations in IgE in psoriatic ED may point to a change from a T helper 1 cytokine profile in psoriasis to a T helper 2 cytokine in psoriatic ED.[32] This secondary mechanism is different than the primary overproduction of IgE in atopic dermatitis. HyperIgE syndrome is an immune deficiency that has been associated with ED, and has high IgE production due to selective insufficient interferon-γ secretion.[33] The mechanisms related to this elevation of IgE may be related to the underlying disease process or to the manifestation of the disease as ED.

ED secondary to atopic dermatitis, psoriasis, and CTCL is associated with increased circulating levels of adhesion molecules: intercellular adhesion molecule 1, vascular cell adhesion molecule 1, and E-selectin. In contrast, there are no differences in expression of adhesion molecules (vascular cell adhesion molecule 1, intercellular adhesion molecule 1, P-selection, E-selectin) on endothelial cells in different types of ED. Similarities in adhesion molecule profile in different types of ED may reflect similarities in end-stage immunologic pathways, which in turn result in the similar clinical examination observed in patients with diverse etiologies of ED.[34]







▲ **FIGURE 23-1** Approach to the patient with exfoliative dermatitis. CBC = complete blood cell count; CXR = chest x-ray; PCP = primary care physician.

Mitotic rate, and thus number of germ cells, is increased in the skin of ED. The significant scaling of ED skin reflects decreased transit time through the epidermis. This scaling also leads to loss of protein, amino acids, and nucleic acids. Protein loss may increase by 25 percent to 30 percent via scaling in psoriatic ED, and 10 percent to 15 percent in nonpsoriatic ED.[35] Additionally, protein-losing enteropathy may contribute to hypoalbuminemia.

CLINICAL FINDINGS

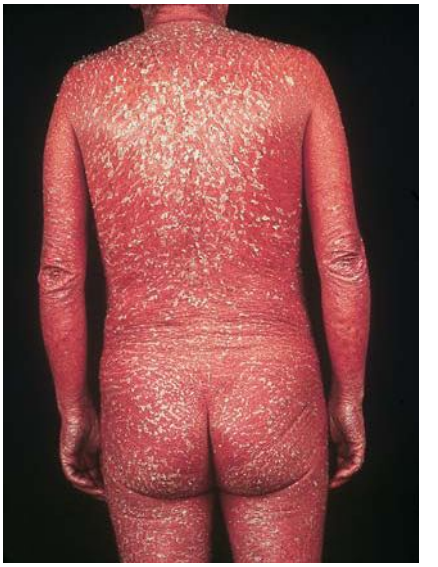
Fig. 23-1 is an algorithm showing the approach to a patient with ED.

History

Obtaining a detailed history of a patient who presents with ED is critical to the determination of the etiology. The history can uncover possible precipitating causes including relevant past medical history (history of dermatoses, systemic medical conditions), family history, and medication use. Patients with history of psoriasis and atopic dermatitis should be queried specifically regarding use of topical and systemic corticosteroids, methotrexate, and other systemic medications; topical irritants; systemic illness; infection; phototherapy burns; pregnancy; and emotional stress. Thermoregulatory disturbance, malaise, fatigue, and pruritus are commonly reported by ED patients; these symptoms are not specific to any etiology.

Time of onset is important to assess possible etiologies of ED. Onset of ED due to drug reactions is classically rapid, and resolution is also faster than other causes of ED. One exception is ED in association with drug hypersensitivity reactions due to anticonvulsants, antibiotics, and allopurinol. This reaction develops in 2 to 5 weeks after medication is started and may remain ongoing after discontinuation of the medication. Associated signs of a possible drug etiology include fever, lymphadenopathy, organomegaly, edema, leukocytosis with eosinophilia, and liver and renal dysfunction.[36,37]

History of transplant should raise suspicion of CTCL, as it has been found that there is a higher frequency of ED secondary to CTCL in post-transplant patients.[38]



▲ **FIGURE 23-2** Exfoliative dermatitis in psoriasis. There is universal erythema, thickening of the skin, and heavy scaling. The patient had fatigue, malaise, and was shivering.

Cutaneous Lesions

ED, by definition, is generalized erythema and scaling of the skin involving more than 90 percent of the patient's skin surface (Fig. 23-2). The initial presentation is erythematous patches that progress to generalized red erythema with a shiny appearance. Fine white or yellow scaling begins a few days after onset of erythema, classically arising in the flexures. Plate-like scaling may occur acutely and on the palms and soles. The scaling progresses further with the skin appearing dull red.

Areolar sparing has been noted in some cases of CTCL, drug reactions, eczema, psoriasis, photosensitivity, and PRP.[39] Typically, there is not mucosal involvement.

With chronicity, edema and lichenification lead to skin induration. Ectropion and epiphora may develop secondary to chronic periorbital involvement (Fig. 23-3). Palmoplantar keratoderma (Fig. 23-4) has been noted in up to 80 percent of patients with chronic ED.[18]

Chronic ED also manifests with scaling of the scalp and, in some cases, diffuse effluvium. Nail changes may include onycholysis, subungual hyperkeratosis, splinter hemorrhages, paronychia, Beau's lines, and, occasionally, onychomadesis.[2] Shore-line nails with alternating bands of nail plate discontinuity represent drug-induced ED reflecting the periods of time the drug was used[40] (see Chap. 87).

▲ **FIGURE 23-3** Blepharitis, epiphora, and ectropion in exfoliative dermatitis of atopic dermatitis.

Eruptive seborrheic keratoses may arise in patients with ED.[41–43] The keratoses often resolve spontaneously as the ED subsides.

Specific Features of Underlying Diseases

Features of underlying diseases may aid in diagnosis and are listed in Table 23-3 (see eFigs. 23-4.1–4.4 in on-line edition).

Related Physical Findings

Related physical findings due to ED of any etiology may include the following:

- Thermoregulatory disturbances can result in hyperthermia or less commonly hypothermia; however, most patients complain of feeling chilly.
- Tachycardia due to increased blood flow to the skin and fluid loss due to disrupted epidermal barrier.
- High-output cardiac failure has been infrequently reported secondary to the high flow state in ED.[44]
- Peripheral pedal or pretibial edema may occur in up to 54 percent of patients.[15,22] Rarely, facial edema has been reported in drug-induced ED.
- Generalized lymphadenopathy occurs in more than one-third of patients.[2,11,15] The clinician must distinguish between dermatopathic lymphadenopathy and lymphoma. If lymphadenopathy is prominent, a lymph node biopsy may be required.
- Hepatomegaly may occur in about one-third of patients[2,11,15] and is more commonly seen in drug-induced ED.
- Splenomegaly has also been rarely reported[11] and is most commonly associated with lymphoma.

Laboratory Tests

Laboratory tests are most often nonspecific. The most common laboratory abnormalities include anemia, leukocytosis, lymphocytosis, eosinophilia, increased IgE, and an elevated erythrocyte sedimentation rate. Fluid loss may lead to electrolyte abnormalities and abnormal renal function (elevated creatinine level). Elevated IgE levels have been noted in patients with ED unrelated to atopic dermatitis,[8,11,18] including in 81.3 percent of psoriatic ED patients.[32] Eosinophilia is non-diagnostic and has been found in 20 percent of ED patients.[17] However, when highly elevated eosinophil counts are noted, the possibility of associated Hodgkin disease must be investigated. Decreased serum albumin can also be noted in ED.[2,8,15,45]

▲ **FIGURE 23-4** Exfoliative dermatitis in pityriasis rubra pilaris. Note keratoderma with an orange hue and thickening of the thumb nails.

Sézary cell count may be used for differentiation of Sézary syndrome from other benign causes of ED. Greater than 20 percent circulating Sézary cells is diagnostic for Sézary syndrome, whereas less than 10 percent is non-specific.[17,22] Sézary cells may be found in numbers less than 10 percent in several benign dermatoses, including psoriasis, atopic dermatitis, discoid lupus, lichen planus, and "parapsoriasis."[46] In addition, quantitative real-time polymerase chain reaction assay for five genes may be used for molecular diagnosis of Sézary syndrome[47] (see Chap. 146). Immunophenotyping of skin lymphocytes may be a useful adjunct study in differentiation of Sézary syndrome from actinic reticuloid. In patients with underlying actinic reticuloid,[48] there is a $CD8^+$ lymphocyte predominance, in contrast to Sézary patients with clonal CD4+ predominance. More specifically, $CD28^+/CD5^+/NKa^-/CD4^+$ T cells with reduction of CD3, CD4, CD7, CD2, and/or T-cell receptor α/β supports the diagnosis of Sézary syndrome in ED patients.[49]

Histopathology

Clinical evaluation in conjunction with multiple skin punch biopsies over time are required. The histopathology differs depending on the underlying diagnosis. However, there are often many nonspecific features seen in ED, including hyperkeratosis, parakeratosis, acanthosis, and a chronic inflammatory infiltrate, that may mask features of the underlying etiology. In addition, the histologic features of the underlying diagnosis may be more subtle than usually seen in that disease entity when unassociated with ED.[50] One-third of biopsy specimens of erythroderma fail to reveal the underlying diagnosis.[50] An accurate diagnosis was made 50% of the time when dermatopathologists blinded to clinical information reviewed biopsies of erythroderma.[51] Therefore, multiple punch biopsies obtained simultaneously and repeated over time are recommended to maximize the possibility of histopathologic diagnosis. In addition to standard hematoxylin and eosin–stained sections evaluated with routine microscopy, various special stains, immunoperoxidase studies, gene rearrangement studies, and direct immunofluorescence may be helpful in determining the underlying cause.

The histologic clues of underlying disease are found in the on-line version of this book.

TABLE 23-3
Specific Features of Underlying Disease Process

Underlying Disease Process	Clinical Clues	
Idiopathic erythroderma ("red man syndrome")	Elderly men Chronic and relapsing course Dermatopathic lymphadenopathy	Pruritus Palmoplantar keratoderma
Psoriasis (see Chap. 18)	History of localized disease[10] Personal or family history of psoriasis Classic psoriasiform plaques on elbows, knees, sacrum, etc. Well-circumscribed plaques at margins of erythroderma	Large lamellar scales Psoriatic nail changes: pits, oil drop sign, onycholysis, subungual hyperkeratosis Collarettes of scale suggestive of ruptured pustules of pustular psoriasis Psoriatic arthritis
Atopic dermatitis (see Chap. 14)	History of localized disease,[10] most often moderate to severe Personal or family history of atopy (atopic dermatitis, asthma, rhinoconjunctivitis) Marked pruritus	Classic atopic lesions in antecubital and popliteal fossae Lichenification and prurigo nodularis Excoriations Focal skin atrophy from years of use of potent topical steroids
Spongiotic dermatitis of other etiologies, such as contact dermatitis (see Chap. 13) or stasis dermatitis (see Chap. 17)	Distribution of original skin lesions History of contactant History of pre-existing venous disease	
Drug reaction (see Chap. 40)	Recent start of new drug, or use of frequently implicated drug Rapid onset of rash and progression to exfoliative dermatitis	Lymphadenopathy Organomegaly Fever
Cutaneous T-cell lymphoma (see Chap. 146)	Severe debilitating pruritus Fissured, painful keratoderma Hepatosplenomegaly	Lymphadenopathy Alopecia Leonine facies
Immunobullous disease		
Pemphigus foliaceus and fogo selvagem (see Chap. 52)	Flaccid blisters Collarettes of scale at sites of previous blisters Superficial erosions and crusts	
Bullous pemphigoid (see Chap. 54)	Tense blisters (early lesions) Deep erosions and superficial ulcers Urticarial plaques	Pruritus Elderly patient
Paraneoplastic pemphigus (see Chap. 53)	Mucosal erosions and crusting prominent Rash resembles erythema multiforme Failure to thrive (i.e., cachexia)	
Paraneoplastic ED	Failure to thrive (i.e., cachexia)	
Pityriasis rubra pilaris (see Chap. 24)	Initial lesion: Seborrheic dermatitis-like eruption of the scalp Worsening post-sun exposure Generalized salmon-colored slightly infiltrated erythema	Islands of sparing Palmoplantar keratoderma, often orange Follicular pink papules of elbows, wrists, dorsal fingers or in skin spared from ED
Chronic actinic dermatitis (see Chap. 91)	Photo-accentuation	
Acute graft-versus-host disease (see Chap. 28)	History of bone marrow transplantation or blood transfusion	Initial lesion: palmar erythema Progression to toxic epidermal necrolysis
Dermatomyositis (see Chap. 157)	Gottron papules Heliotrope sign Poikiloderma	Periungual telangiectasia Muscle weakness
Sarcoidosis (see Chap. 153)	Apple jelly papules, plaques, and/or nodules	
Norwegian scabies (see Chap. 208)	Down syndrome or nursing home patient Burrows	Massively thickened nails Keratoderma

ED = exfoliative dermatitis.

Special Tests

Laboratory testing is driven by the patient's medical history and clinical presentation. In addition to multiple skin biopsies, lymph node biopsies may be indicated if the lymph node enlargement is prominent and the clinical scenario suggests the possibility of lymphoma rather than dermatopathic lymphadenopathy. If the condition is thought to be paraneoplastic, radiologic workup should be undertaken. CD4:CD8 ratios and immunophenotyping of skin and blood should be considered if a lymphoproliferative disease is considered a possible cause of the ED.

COMPLICATIONS

Systemic complications of ED include fluid and electrolyte imbalances, thermoregulatory disturbance, infection, high-output cardiac failure,[44] cardiogenic shock,[52] acute respiratory distress syndrome,[53] decompensation of chronic liver disease,[54] and gynecomastia.[55]

Fluid and electrolytes are lost from leaky capillaries, which leads to fluid and electrolyte imbalances. Protein loss increases in ED via scaling by 10 percent to 15 percent in nonpsoriatic ED and up to 25 percent to 30 percent in psoriatic ED.[35] This significant protein loss leads to a negative nitrogen balance and may cause edema, muscle wasting, and hypoalbuminemia.

High-output cardiac failure may occur due to increased blood flow to the skin, and is of particular concern in patients with cardiac conditions and the elderly.[44] This shunting of blood, in conjunction with increased transepithelial water loss secondary to vasodilatation, leads to temperature dysregulation. The capillaries cannot respond appropriately to temperature changes via vasoconstriction and vasodilation.[56] The basal metabolic rate is also increased, which also elevates the skin temperature.[57]

Increased susceptibility to bacterial colonization occurs due to inflammation, fissuring, and excoriation of the skin. Sepsis may occur occasionally. Patients with CTCL and human immunodeficiency virus–positive ED are at increased risk for staphylococcal sepsis.[29,53,58]

PROGNOSIS AND CLINICAL COURSE

The clinical course and prognosis of ED vary depending on the underlying etiology. Drug-induced ED improves with discontinuation of the offending drug.[1] An important exception to this is with severe systemic hypersensitivity reactions in which the ED may persist for weeks after discontinuation of the drug, and is seen in association with liver and renal dysfunction. Psoriatic and atopic ED typically improves in weeks to months; however, chronic and persistent cases occur. Recurrence of psoriatic ED occurs in 15 percent of patients after initial resolution.[45]

Malignancy-related ED (including CTCL) is most often chronic and refractory. Positive prognostic factors for mycosis fungoides and Sézary syndrome–related ED include age younger than 65 years, symptom duration of greater than 10 years before diagnosis, absence of evidence of lymphoma involving a lymph node, and the absence of circulating Sézary cells in mycosis fungoides.[59] Mean survival ranges from 1.5 to 10.2 years based on these prognostic indicators.[59] Complete remission occurs in one-third of idiopathic ED patients and partial remission occurs in one-half of patients.[18,22] Patients with chronic idiopathic ED are at increased risk of evolution to the diagnosis of CTCL.[8,11,18,22] The proposed monoclonal T-cell dyscrasia of undetermined significance is intended to indicate this possible pre-malignant or pre–Sézary-like condition.[24]

The mortality rate for ED has varied from 3.75 percent to 64.00 percent in six series over 51 years.[4,8,11,14,16,20] Early series of ED reported high mortality rates due to severe drug reactions, lymphoproliferative malignancy, pemphigus foliaceus, and idiopathic ED.[6] These deaths were due to complications such as sepsis, pneumonia, and cardiac failure.[6,14,20] More recent studies have shown lower mortality rates with most deaths occurring in patients with malignancy-associated ED,[1,11,17] usually due to underlying disease progression, treatment complications, or sepsis.[11] A recent study demonstrated a death rate of 3.75 percent (3 of 80 patients) in a 30-month follow-up with deaths due to pneumonia in patients with pemphigus foliaceus and Sézary syndrome.[16] High-output cardiac failure has also been reported as a cause of death.[8]

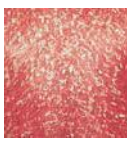
TREATMENT

Initial treatment of ED of any etiology involves fluid and electrolyte replacement. Although most patients can be managed on an outpatient basis, patients with significant fluid and electrolyte imbalance or cardiovascular or respiratory compromise require inpatient management. Possible offending drugs should be discontinued, including drugs such as lithium and antimalarials that may trigger a flare in patients with underlying psoriasis. Folate supplementation and a diet of 130 percent of normal dietary requirements for protein aids in replacing nutrient losses.[35,60]

The treatment of ED is summarized in Box 23-2. The environment should be warm and humid for patient comfort and skin moisture, as well as preventing hypothermia. Gentle local skin care, including oatmeal baths and wet dressings to weeping or crusted lesions, bland emollients, and low-potency topical steroids should be started. High-potency topical steroids[61] and topical immunomodulators, such as tacrolimus,[62] should be avoided as systemic absorption may occur due to the increased skin permeability and large surface area involved. In addition, topical irritants, such as anthralin and tar, should be avoided. Symptomatic treatment includes sedating antihistamines for pruritus, and diuretics for leg edema refractory to leg elevation. Systemic antibiotics are required for patients with evidence of localized and systemic secondary infection. Patients without evidence of secondary infection may also benefit from systemic antibiotic therapy as bacterial colonization may exacerbate ED.

ED refractory to local therapy may require systemic dermatologic therapy with therapy tailored to the underlying etiology, if known. Systemic corticosteroids should be avoided in patients with possible underlying psoriasis. Psoriatic ED may be responsive to methotrexate, cyclosporine, acitretin, mycophenolate mofetil, and biologics. Intravenous infliximab of 5 to 10 mg/kg has been prescribed with complete remission of psoriatic ED.[63,64] Lower doses of infliximab (2.7 to 4.4 mg/kg) have been used in combination with methotrexate with good clinical response.[65]

Etanercept has been used as a steroid-sparing agent with relief of pruritus in Sézary syndrome in two patients.[66] However, etanercept should be used with caution in these patients because of risk of further immunosuppresion. CTCL may be treated with topical corticosteroids, psoralen plus ultraviolet A, total skin electron beam irradiation, systemic chemotherapy including CHOP-like regimens (*c*yclophosphamide, *h*ydroxydaun*o*mycin, vincristine, and *p*rednisone), interferon-α, extracorporeal photochemotherapy, and biologics such as monoclonal antibodies (alemtuzumab),[67] bexarotene (selective retinoic X receptor retinoid),[68,69] and denileukin diftitox.



Box 23-2

Therapy

	TOPICAL	SYSTEMIC	DOSAGE
First line	Oatmeal baths Wet dressings Bland emollients Low-potency corticosteroids	Sedating antihistamines Systemic antibiotics if secondary infection Diuretics for peripheral edema Fluid and electrolyte replacement	
Second line (once etiology established)		Corticosteroids for drug hypersensitivity reactions, immunobullous disease, atopic dermatitis. Cyclosporine for psoriasis, atopic dermatitis Methotrexate for psoriasis, atopic dermatitis, pityriasis rubra pilaris Acitretin (Soriatane) for psoriasis, pityriasis rubra pilaris Mycophenolate mofetil for psoriasis, atopic dermatitis, immunobullous disease Infliximab for psoriasis	1–2 mg/kg/day with taper 4–5 mg/kg/day 5–25 mg qwk depending on renal function and response to treatment 25–50 mg qd 1–3 g qd 5–10 mg/kg

Systemic corticosteroids are useful for drug hypersensitivity reactions. Cyclosporine, methotrexate, azathioprine, mycophenolate mofetil, and systemic corticosteroids may be helpful for spongiotic (eczematous) dermatitis. PRP usually responds to systemic retinoids or methotrexate. Papuloerythroderma of Ofuji has been treated with topical and systemic corticosteroids, cyclosporine, interferon, etretinate, and most recently with a combination of retinoid plus psoralen and ultraviolet A light.[70]

Empiric therapy with systemic agents including methotrexate, cyclosporine, acitretin, mycophenolate mofetil, and systemic corticosteroids have been used when the underlying cause of ED is not known. It should be emphasized that a strong suspicion for psoriatic ED precludes systemic corticosteroid use due to risk for a rebound flare. Immunosuppressive drugs should not be used until CTCL has been ruled out with the most current laboratory testing.

PREVENTION

Prevention of ED may be aided by avoidance of medications that have previously caused ED. Careful records of allergies should be maintained by the patient. This should include potentially cross-reactive medications, including topical agents (examples: ED occurring secondary to systemic gentamicin use in a patient with known contact allergy to neomycin,[71] ED secondary to pseudoephedrine use in a patient with a contact allergy to phenylephrine).[72] Avoidance of systemic steroids by clinicians in patients with psoriasis aids in prevention of rebound flares.

CHAPTER 24

Pityriasis Rubra Pilaris

Daniela Bruch-Gerharz
Thomas Ruzicka

EPIDEMIOLOGY

Pityriasis rubra pilaris is a rare chronic disorder with an estimated incidence ranging from 1 in 5000 to 1 in 50,000 dermatology patients. The age distribution is bimodal with peak incidences in the first and fifth decades of life. The disease occurs in all races and affects the sexes equally.[1]

ETIOLOGY AND PATHOGENESIS

Although an underlying dysfunction in vitamin A metabolism has been suggested as a cause, the etiology and pathogenesis of pityriasis rubra pilaris are poorly understood. The role of vitamin A deficiency remains uncertain, because attempts to produce keratotic lesions by vitamin A deprivation have been unsuccessful. Moreover, a deficiency of retinol-binding protein as an underlying pathogenic mechanism resulting in inadequate transport of vitamin A to the skin has yet to be ascertained. Larregue et al. reported that a previous upper respiratory tract episode appeared to trigger the onset of the disease.[2] A report of an acute exanthematous form of juvenile pityriasis rubra pilaris that followed an upper respiratory tract infection and initially resembled Kawasaki disease supports the hypothe-

PITYRIASIS RUBRA PILARIS AT A GLANCE

- A papulosquamous disorder of unknown etiology that often progresses to erythroderma and a disabling keratoderma.
- The disease is subclassified into six types, including both hereditary and acquired forms.
- Typically, pityriasis rubra pilaris includes follicular hyperkeratosis and a reddish orange, scaling dermatitis with islands of normal skin.
- Confusion with psoriasis is the major problem in diagnosis.
- Histopathologic examination reveals hyperkeratosis, alternating vertical and horizontal parakeratosis, and a mild superficial perivascular lymphocytic infiltrate.
- No single therapy is effective; most effective are retinoids, psoralen plus ultraviolet A phototherapy, and methotrexate.

sis of a superantigen-mediated process.[3] Finally, genetic factors with an autosomal dominant pattern of inheritance have been believed to play a critical role in the induction of pityriasis rubra pilaris. Nevertheless, affected relatives are not observed in the classical acute-onset disease and are found infrequently with other variants.

CLINICAL FINDINGS

Cutaneous Lesions

Pityriasis rubra pilaris is generally believed to comprise more than a single entity, and a classification scheme based on clinical characteristics and course has been proposed by Griffiths[1] (Table 24-1).

Type I (classic adult) is the most common subtype, accounting for more than 50 percent of all cases. Characteristically, patients show an eruption of follicular hyperkeratotic papules that spread in a cephalocaudal direction (Fig. 24-1). As the disease further evolves, a reddish orange, scaling dermatitis appears that often progresses to a generalized erythroderma over a period of 2 to 3 months (Fig. 24-2). A diagnostic hallmark of pityriasis rubra pilaris is sharply demarcated islands of unaffected skin ("nappes claires") in a random distribution (see Fig. 24-2B). Many patients develop a waxy, diffuse, yellowish keratoderma of the palms and soles (Fig. 24-3). Peripheral edema is common. Nail changes are not uncommon and include distal yellow-brown discoloration, nail plate thickening, splinter hemorrhages, and subungual hyperkeratosis. Eventually, the mucous membranes may be affected with a diffuse whitish appearance of the buccal mucosa as well as lacy white plaques and erosions. Hair and teeth are normal.

Type II is an atypical variant with onset in adulthood. Areas of follicular hyperkeratosis as well as ichthyosiform scaling, especially on the legs, dominate the clinical picture. This variant lacks the typical cephalocaudal progression observed in type I, and there is less tendency for patients to become erythrodermic. Sparseness of the scalp hair is occasionally seen.

Type III (classic juvenile) typically begins in year 1 or 2 of life and shows all the morphologic features of type I (Fig. 24-4).

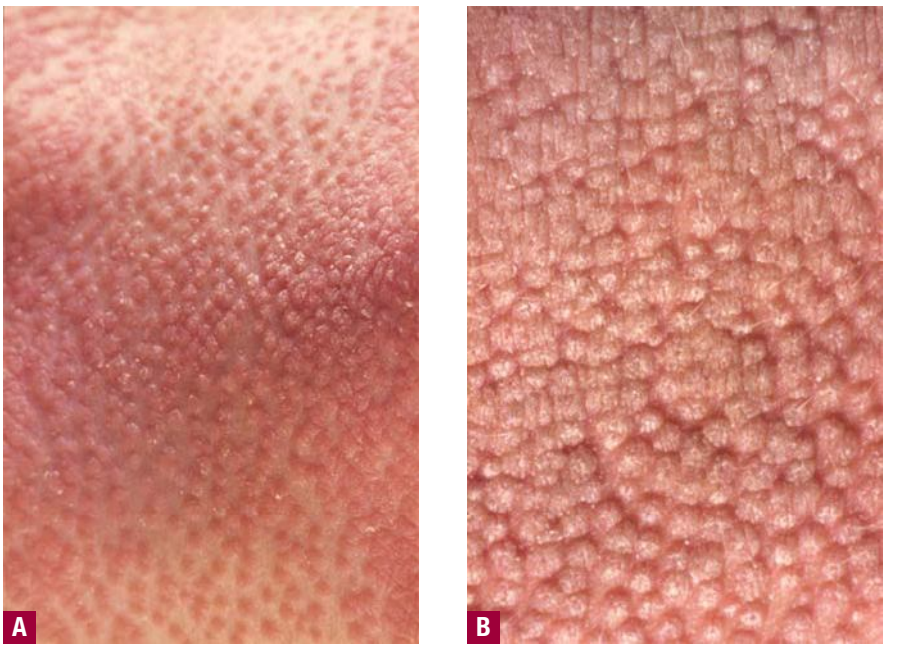
Type IV (circumscribed juvenile) affects approximately 25 percent of patients. This type usually presents several years after birth and is characterized by well-demarcated hyperkeratotic erythematous plaques on the elbows and knees, resembling localized psoriasis. According to Griffiths,[1] these lesions do not progress to the widespread types I and III. Yet, some cases show marked palmoplantar keratoderma.

Type V is an atypical variant of juvenile pityriasis rubra pilaris that usually presents in the first few years of life and has a more chronic course. This type is distinguished by follicular hyperkeratosis with only minimal erythema and a scleroderma-like appearance of the hands and feet. Most cases of familial pityriasis rubra pilaris belong to this type, which may even represent a different clinical entity sharing features with several poorly defined ichthyotic disorders such as follicular ichthyosis and the erythrokeratodermas.

TABLE 24-1
Classification Scheme for Pityriasis Rubra Pilaris (Types I–VI According to Griffiths[1] and Gonzáles-López[4])

Type	Description	%	Clinical Characteristics	Distribution	Course
I	Classic adult	> 50	Erythroderma with islands of normal skin ("nappes claires"), follicular hyperkeratosis, waxy diffuse palmoplantar keratoderma	Generalized, beginning on the head and neck, then spreading caudally	Often resolves within an average of 3 y
II	Atypical adult	5	Combination of follicular hyperkeratosis and ichthyosiform lesions on the legs, sparse scalp hair	Generalized	Long duration (> 20 y)
III	Classic juvenile	10	Similar to type I but appears in year 1 or 2 of life	Generalized	Often resolves within an average of 1–2 y
IV	Circumscribed juvenile	25	Prepubertal children; well-demarcated scaly, erythematous plaques on the elbows and knees, resembling localized psoriasis	Localized	Uncertain, some cases clear in the late teens
V	Atypical juvenile	5	Begins in first few years, accounts for most familial cases; follicular hyperkeratosis, scleroderma-like appearance of the hands and feet	Generalized	Chronic course, improves with retinoids but relapses when they are stopped
VI	Human immunodeficiency virus infection associated	NA	Similar to type I with variable beginning; associated with acne conglobata, hidradenitis suppurativa, and lichen spinulosus	Generalized	May respond to antiretroviral triple therapy

NA = data not available.



▲ **FIGURE 24-1** Acuminate follicular papules of pityriasis rubra pilaris. Close-ups of discrete (**A**) and confluent (**B**) lesions.

Some reports have described a type VI variant associated with human immunodeficiency virus (HIV) infection.[4] The clinical features of this variant are similar to those of type I but with increased severity and additional manifestations of acne conglobata, hidradenitis suppurativa, and lichen spinulosus.

Related Findings

There have been rare cases of a pityriasis rubra pilaris–like eruption, clinically and histologically, in patients with dermatomyositis, often associated with internal neoplasia. Concomitant rheumatologic disorders, mainly inflammatory polyarthritis, have also been reported. In addition, numerous other non-cutaneous diseases have been considered to be related to pityriasis rubra pilaris, which in all cases probably occurred fortuitously.

PATHOLOGY

Pathologic findings in pityriasis rubra pilaris vary according to the duration of the disease. The findings are most likely to be diagnostic in the acute phase, when hyperkeratosis, acanthosis with broad short rete ridges, and alternating orthokeratosis and parakeratosis oriented in both horizontal and vertical directions can be observed (see Pityriasis Rubra Pilaris At a Glance). Usually, there is a sparse superficial, perivascular lymphocytic infiltrate in the underlying dermis. Keratinous plugs of the follicular infundibula as well as perifollicular areas of parakeratosis may also be present. A prominent granular layer and dilated, but not tortuous, capillaries are features that help to distinguish pityriasis rubra pilaris from psoriasis, the most important differential diagnosis.

▲ **FIGURE 24-2** Generalized pityriasis rubra pilaris. Reddish orange, scaling dermatitis (**A**) with islands of normal skin ("nappes claires") (**B**).

DIFFERENTIAL DIAGNOSIS

See Box 24-1.

COMPLICATIONS

Systemic symptoms are uncommon except when generalized erythroderma occurs, and then they are comparable to those seen in exfoliative dermatitis. Occasionally, a mild ectropion may develop when the face becomes uniformly erythematous. Although they are rare, moderate to severe pruritus or burning sensations may occur.

PROGNOSIS AND CLINICAL COURSE

The classic adult disease (type I) usually remits completely within an average of 3 years (see Table 24-1). Recurrences are recognized in up to 20 percent of patients, however, sometimes after long periods of subclinical disease. In the classic juvenile variant (type III), spontaneous clearing is commonly observed in 1 to 2 years. The atypical variants (type II and IV), however, have a less favorable prognosis for remission, although some cases of type IV improve in the late teens. There is little or no tendency for type V to resolve spontaneously; improvement with administration of systemic retinoids has been described, but relapses occurred when treatment was withdrawn. Clinical manifestations in the HIV infection–associated type VI are severe and occasionally fatal, with death occurring due to complications of cutaneous sepsis.

TREATMENT

Patients with pityriasis rubra pilaris are often unresponsive to multiple therapies, both topical and systemic.[5] Because of the relative rarity of the disease and its variable course, the chances for

▲ **FIGURE 24-3** Keratoderma in pityriasis rubra pilaris. Palmar (**A**) and plantar (**B**) erythema and waxy hyperkeratosis are frequent manifestations. Sometimes, there is an orange-yellow tint.

clinical trials to assess treatment options are limited. Previous treatment strategies, which relied on megadoses of oral vitamin A or the anabolic steroid stanozolol, proved to be largely ineffective.

Currently, oral retinoids are the first line of therapy in patients with pityriasis rubra pilaris. Isotretinoin has been reported to be of value, although a comprehensive review suggests that acitretin may be more effective in clearing lesions. Accordingly, most patients are treated first with acitretin today. Therapy with methotrexate, using the guidelines established for psoriasis has shown variable rates of success. Some cases respond well to photochemotherapy (psoralen with ultraviolet A phototherapy), some may flare, and others require combination treatment with retinoids or methotrexate. In patients with severe symptoms, effective amelioration of the disease may require extracorporeal photopheresis. Immunosuppressive agents are of inconsistent benefit. Thus, controversy persists about the role of cyclosporine in the treatment of pityriasis rubra pilaris. Although most studies show lack of efficacy, several cases of adult-type pityriasis rubra pilaris showed significant clearance in 2 to 4 weeks with this therapy. Some patients are helped by azathioprine, but this effect is also inconsistent. The use of glucocorticosteroids in the management of pityriasis rubra pilaris has been studied, but there is no evidence to suggest a beneficial effect. Whether phototherapy can be effective is controversial. Ultraviolet B irradiation, which is efficiently used for psoriasis, has not been helpful or has even worsened pityriasis rubra pilaris.[6] Ultraviolet A1 phototherapy may be a satisfactory alternative.

When conventional treatment strategies fail, new therapeutic approaches may include the use of immunomodulatory drugs. Fumaric acid esters were reported as successful in inducing remission in a patient with juvenile pityriasis rubra pilaris unresponsive to the usual treatment options.[7] Moreover, there is some evidence indicating that blockade of tumor necrosis factor-α, which is beneficial in psoriasis and psoriatic arthritis, is effective in the adult-onset type I of pityriasis rubra pilaris.[8]

Topical treatment with keratolytics (when possible, under an occlusive plastic dressing) has proved a valuable mode of adjuvant therapy in pityriasis rubra pilaris. For symptomatic relief, emollients and antihistamines provide significant benefit. Topical therapy with calcipotriol showed encouraging results. Its disadvantage is that total body treatment for the erythrodermic patient can be toxic. Success has been reported with topical aminonicotinamide 1 percent, although it is not commonly used.[5]

Pityriasis rubra pilaris associated with HIV infection has responded to triple antiretroviral therapy.[4]

Current therapeutic options for pityriasis rubra pilaris used in adults and children (including drug doses) are listed in Box 24-2.

▲ **FIGURE 24-4** Juvenile pityriasis rubra pilaris: **A.** Confluence of lesions leads to extensive erythroderma. **B.** Characteristic scattered islands of unaffected skin are evident. So is the plantar hyperkeratosis.

Box 24-1

Differential Diagnosis of Pityriasis Rubra Pilaris

Most Likely

- Localized
  - Psoriasis
  - Follicular ichthyosis
- Generalized
  - Psoriasis
  - Erythrokeratodermia variabilis

Consider

- Localized
  - Follicular eczema
  - Lichen ruber acuminatus
  - Keratosis pilaris
- Generalized
  - Pityriasis lichenoides chronica
  - Nonbullous ichthyosiform erythroderma

Always Rule Out

- Generalized (therapy-resistant cases)
  - Human immunodeficiency virus infection
  - Cutaneous T-cell lymphoma

PREVENTION

Pityriasis rubra pilaris is a rare but socially and psychologically disabling condition, occurring in children and adults of both sexes. Suicide remains a risk in patients with generalized disease. Knowledge of the clinical pattern and cutaneous findings, therefore, is crucial to permit early therapeutic intervention and may allow prevention of protracted illness and serious complications in this clinically challenging condition.

Box 24-2

Treatments for Pityriasis Rubra Pilaris

FIRST LINE

- Topical
  - Emollients (water in oil emulsion)
  - Keratolytics (salicylic acid, urea)
  - Vitamin D_3 (calcipotriol)
- Physical
  - Photochemotherapy (topical or systemic psoralen plus ultraviolet A)
  - Extracorporeal photopheresis
- Systemic
  - Retinoids (0.5 to 0.75 mg/kg acitretin per day)
  - Methotrexate (10 to 25 mg weekly, intramuscularly or orally, in divided doses, once a week)
  - Triple antiretroviral therapy (for human immunodeficiency virus–associated variant)

SECOND LINE

- Topical
  - Glucocorticoids (medium to high potency)
  - Vitamin A analogues (tazarotene)
- Physical
  - Ultraviolet A1 phototherapy
  - Narrowband ultraviolet B phototherapy
  - Ultraviolet B phototherapy
- Systemic
  - Azathioprine (100 to 150 mg/day)
  - Cyclosporine A (5 mg/kg/day)
  - Fumaric acid esters[7]
  - Tumor necrosis factor-α antagonists[8]

CHAPTER 25

Parapsoriasis and Pityriasis Lichenoides

Gary S. Wood
Chung-Hong Hu
Andrea L. Garrett

PARAPSORIASIS

Historical Aspects

As shown in Table 25-1, the currently accepted classification of parapsoriasis includes large and small-plaque forms of parapsoriasis en plaques (often referred to simply as *parapsoriasis*) as well as acute and chronic forms of pityriasis lichenoides [known today as *pityriasis lichenoides et varioliformis acuta* (PLEVA) and *pityriasis lichenoides chronica* (PLC), respectively].[1] Pityriasis lichenoides was first described in 1894 by Neisser[7] and Jadassohn.[8] In 1899 Juliusberg delineated the chronic form and named it PLC.[9] Mucha redescribed the acute form in 1916 and distinguished it from the chronic form.[10] Habermann named the acute variant PLEVA in 1925.[11] Mucha-Habermann disease is synonymous with PLEVA. Some authors regard lymphomatoid papulosis as a variant of pityriasis lichenoides, whereas others consider it to be a separate disease.[1,12–14] Lymphomatoid papulosis is discussed in Chap. 146 as part of the spectrum of $CD30^+$ cutaneous lymphoproliferative disorders.

TABLE 25-1
Classification of Parapsoriasis

1. Parapsoriasis en plaques
   - A. Large-plaque parapsoriasis
     Variants: poikilodermatous, retiform
   - B. Small-plaque parapsoriasis
     Variant: digitate dermatosis
2. Pityriasis lichenoides
   - A. Pityriasis lichenoides chronica (Juliusberg)
   - B. Pityriasis lichenoides et varioliformis acuta (Mucha-Habermann)

Epidemiology

Large-plaque parapsoriasis (LPP) and small-plaque parapsoriasis (SPP) are, in general, diseases of middle-aged and older people, with a peak incidence in the fifth decade. Occasionally, lesions arise in childhood and may be associated with pityriasis lichenoides. SPP shows a definite male predominance of approximately 3:1. LPP is probably more common in males, but the difference is not as striking as in SPP. Both occur in all racial groups and geographic regions.

Etiology and Pathogenesis

It is likely that a complete understanding of the pathogenesis of parapsoriasis will develop with our understanding of the pathogenesis of both chronic dermatitis and mycosis fungoides (MF), because parapsoriasis appears to bridge these disorders. The T cells that mediate most inflammatory skin diseases belong to the skin-associated lymphoid tissue (SALT).[15] These T cells express the cutaneous lymphocyte-associated antigen and traffic between the skin and the T-cell domains of peripheral lymph nodes via the lymphatics and bloodstream. MF (see Chap. 146) has been shown to be a neoplasm of SALT T cells. Sensitive polymerase chain reaction (PCR)–based tumor clonality assays have underscored the SALT nature of MF tumor clones by showing that they can continue to traffic after neoplastic transformation[16] and can even participate in delayed-type hypersensitivity reactions to contact allergens.[17] This implies that rather than being a skin lymphoma per se, MF is actually a SALT lymphoma; that is, a malignancy of a T-cell circuit rather than of one particular tissue. Trafficking of MF tumor cells has been detected even in patients with very early stage disease whose lesions were consistent clinicopathologically with LPP.[16,18] Therefore, it can be said that at least in some cases LPP is a monoclonal proliferation of SALT T cells that have the capacity to traffic between the skin and extracutaneous sites.

This view is also supported by the presence of structural and numerical chromosomal abnormalities in the peripheral blood mononuclear cells of pa-

PARAPSORIASIS AT A GLANCE

- Also known as *parapsoriasis en plaques.*
- Parapsoriasis occurs worldwide and affects mainly adults.
- Large-plaque parapsoriasis (LPP) and small-plaque parapsoriasis (SPP) are recognized.
- Large and small "plaque" lesions actually present as flat patches rather than infiltrated plaques.
- Lesions are chronic and favor non–sun-exposed skin; LPP may be poikilodermatous.
- Pathology consists of superficial, mostly $CD4^+$ T-cell infiltrate; dominant clonality is more common in LPP than in SPP.
- LPP appears to exist on a continuum with patch-stage mycosis fungoides (MF) and progresses to overt MF at a rate of approximately 10 percent per decade.
- SPP has minimal risk of progression to overt MF in the experience of most experts.
- Treatment options include topical corticosteroids; ultraviolet B irradiation, and psoralen and ultraviolet A irradiation; and topical cytotoxic drugs.

tients with LPP.[19] In this context, LPP can be regarded as the clinically benign end of the MF disease spectrum, which eventuates in transformed large cell lymphoma at its malignant extreme. To say that these diseases belong to the same disease spectrum is not to say that they are biologically equivalent disorders. To lump them all together simply as "MF" would be to ignore their distinctive clinicopathologic features, which are likely due to genetic and/or epigenetic differences, such as the *p53* gene somatic mutations observed in some cases of large cell transformation of MF.[20–22] It is likely that several such differences separate these clinicopathologically defined disorders in a stepwise fashion analogous to the sequential acquisition of somatic mutations that occurs in the colon cancer disease spectrum as colonic epithelial cells progress through normal, hyperplastic, in situ carcinoma, invasive carcinoma, and metastatic carcinoma stages.[23,24]

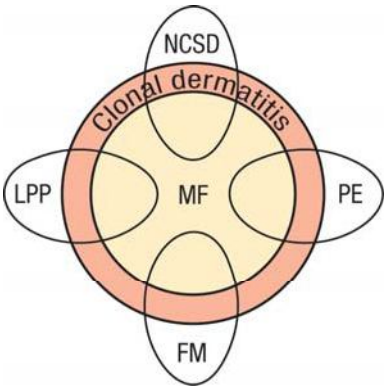
A unifying feature of the parapsoriasis group of diseases is that all of them appear to be cutaneous T-cell lymphoproliferative disorders: LPP,[16,25–33] SPP,[26,33,34] pityriasis lichenoides,[33,35–37] and lymphomatoid papulosis[26,38–40] have all been shown to be monoclonal disorders in many cases.[5] These relationships suggest that progression from LPP through the various stages of the MF disease spectrum is accompanied by an increasing gradient of dominant T-cell clonal density resulting from mutations that confer increasing growth autonomy to the neoplastic T-cell clone.[41] Interestingly, analysis of peripheral blood has demonstrated that clonal T cells are often detectable in patients with LPP/early MF[31,33] or SPP,[33,42] which again supports the systemic SALT nature of these "primary" skin disorders.

Dominant clonality as seen in the parapsoriasis disease group, follicular mucinosis, pagetoid reticulosis, and certain other disorders does not equate to clinical malignancy. In fact, most patients with these diseases experience a benign clinical course, and in some cases the disease resolves completely. In addition, other types of chronic cutaneous T-cell infiltrates sometimes exhibit dominant clonality, including primary (idiopathic) erythroderma and non-specific chronic spongiotic dermatitis. This has given rise to the concept of clonal dermatitis,[18,28] originally described in the context of clonal non-specific chronic spongiotic dermatitis but later expanded to include other nonlymphomatous cutaneous T-cell infiltrates that harbor occult monoclonal T-cell populations. Several cases of clonal dermatitis, some of which have progressed to MF, have been identified.[18,28,32] We suspect that for each disease with a potential for progression to MF, the principal risk may reside in the subset showing clonal dermatitis, because this is the subset in which dysregulation has begun to occur.

The postulated relationships among MF, clonal dermatitis, and selected types of chronic dermatitis are depicted in Fig. 25-1. Each of the entities shown is postulated to be at risk for MF through a clonal dermatitis intermediate. In this model, MF becomes the final common pathway for the clonal evolution of neoplastic T cells emerging from the polyclonal SALT T-cell populations present in each of the various precursor diseases.

Clinical Findings

CUTANEOUS LESIONS LPP lesions are either oval or irregularly shaped patches



▲ **FIGURE 25-1** The relationship of clonal dermatitis to mycosis fungoides (MF) and various types of chronic dermatitis. The proportions of each entity that represent clonal dermatitis and mycosis fungoides vary with each disease and are not drawn to scale. FM = follicular mucinosis; LPP = large-plaque parapsoriasis; NCSD = nonspecific chronic spongiotic dermatitis; PE = primary erythroderma.

or very thin plaques that are asymptomatic or mildly pruritic. They are usually well marginated but may also blend imperceptibly into the surrounding skin. The size is variable, but typically most lesions are larger than 5 cm, often measuring more than 10 cm in diameter. Lesions are stable in size and may increase in number gradually. They are found mainly on the "bathing trunk" and flexural areas (Fig. 25-2). Extremities and the upper trunk, especially the breasts in women, also may be involved. They are light red-brown or salmon pink, and their surface is covered with small and scanty scales. Lesions may appear finely wrinkled—"cigarette paper" wrinkling. Such lesions exhibit varying degrees of epidermal atrophy. Telangiectasia and mottled pigmentation also are observed when the atrophy becomes prominent (Fig. 25-3). This triad of atrophy, mottled pigmentation, and telangiectasia defines the term *poikiloderma* or *poikiloderma atrophicans vasculare*, which also may be seen in other conditions (Box 25-1).

▲ **FIGURE 25-2** Large-plaque parapsoriasis. Irregularly shaped patches of variable size on the arm of a 16-year-old girl.

▲ **FIGURE 25-3** Large-plaque parapsoriasis. Poikilodermatous variant.

Retiform parapsoriasis refers to a rare variant of LPP that presents as an extensive eruption of scaly macules and papules in a net-like or zebra-stripe pattern that eventually becomes poikilodermatous (Fig. 25-4).

SPP characteristically occurs as round or oval discrete patches or very thin plaques, mainly on the trunk (Fig. 25-5). The lesions measure less than 5 cm in diameter; they are asymptomatic and covered with fine, moderately adherent scales. The general health of the patient is unaffected. A distinctive variant with lesions of a finger shape, known as *digitate dermatosis*,[3] has yellowish or fawn-colored lesions (Fig. 25-6). It follows lines of cleavage of the skin and gives the appearance of a hug that left fingerprints on the trunk. The long axis of these lesions often measures greater than 5 cm. Chronic superficial dermatitis is a synonym for SPP.[43] Digitate lesions with a yellow hue were referred to in the past as *xanthoerythrodermia perstans*.[1]

Laboratory Tests

HISTOPATHOLOGY In early LPP lesions, the epidermis is mildly acanthotic and slightly hyperkeratotic with spotty parakeratosis. The dermal lymphocytic infiltrate tends to be perivascular and scattered (Fig. 25-7). In the more advanced lesions one observes an interface infiltrate with definite epidermotropism. These invading lymphocytes may be scattered singly or in groups, sometimes associated with mild spongiosis. In addition, the poikilodermatous lesions show atrophic epidermis, dilated blood vessels, and melanophages (Fig. 25-8). Immunohistologic studies have revealed similar features in LPP and early MF, including a predominance of $CD4^+$ T-cell subsets, frequent CD7 antigen deficiency, and widespread epidermal expression of class II HLA (HLA-DR).[25–27,44–47]

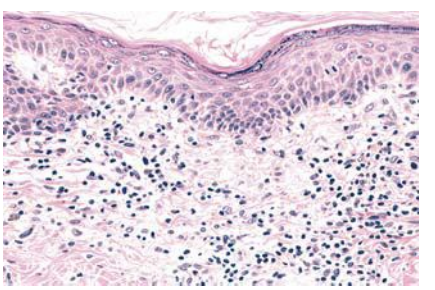
▲ **FIGURE 25-5** Small-plaque parapsoriasis. Small, discrete patches less than 5 cm in diameter.

▲ **FIGURE 25-6** Small-plaque parapsoriasis. Digitate dermatosis variant. Typical "fingerprint" patches on the flank. Note that their length often exceeds 5 cm.

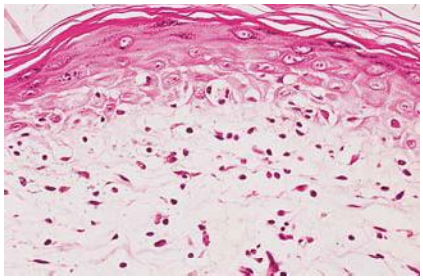
SPP exhibits mild spongiotic dermatitis with focal areas of hyperkeratosis, parakeratosis, scale crust, and exocytosis. In the dermis, there is a mild superficial perivascular lymphohistiocytic infiltrate and dermal edema (Fig. 25-9). There is no progression of the histologic features with time. Immunohistologic studies reveal a predominantly $CD4^+$ T-cell infiltrate with non-specific features resembling those seen in various types of dermatitides.[45]

Diagnosis and Differential Diagnosis

LPP is distinguished from SPP by the larger size, asymmetric distribution, and irregular shape of its lesions, which are



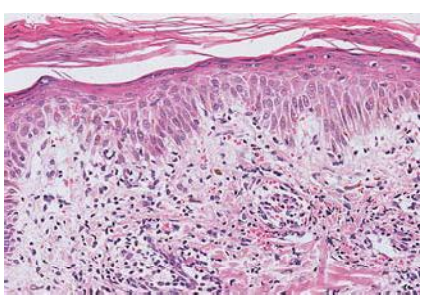
▲ **FIGURE 25-7** Large-plaque parapsoriasis. Mildly hyperkeratotic and focally parakeratotic epidermis with moderately dense superficial perivascular infiltrate. Lymphoid cells are mostly small, cytologically normal lymphocytes, and there is focal single-cell epidermotropism. (Used with permission from Helmut Kerl, M.D.)



▲ **FIGURE 25-8** Large-plaque parapsoriasis. Atrophic variant. Sparse superficial lymphoid infiltrate with mild epidermotropism and epidermal atrophy.

less discrete and often poikilodermatous. LPP may be clinically and histopathologically indistinguishable from the patch stage of MF. Both LPP and SPP are readily distinguished from more advanced infiltrated plaques of MF because parapsoriasis lesions are, by definition, not thicker than patches or at most very thin plaques. This is so because the English equivalent of the French term *plaques* is *patches*, that is, lesions that are essentially flat and devoid of induration or palpable infiltration.[48] Failure to appreciate this important distinction has led to considerable confusion and misuse of the terms *large-plaque* and *small-plaque parapsoriasis* by some individuals. These designations more appropriately might be thought of as *large-patch* and *small-patch parapsoriasis*.

The degree to which LPP is differentiated from early MF depends primarily on the histopathologic criteria used to diagnose the latter disorder. Unfortunately, there are no universally accepted minimal criteria for the diagnosis of MF; however, one set proposed by the International Society for Cutaneous Lymphoma is presented in Table 25-2.[49] This algorithm is based on a holistic integration of clinical, histopathologic, immunopathologic, and clonality data. It differs significantly from many prior approaches because it does not rely solely on histopathologic features.[50] Assuming that histopathologic examination does not disclose features diagnostic of some other dermatosis, these criteria allow lesions to be classified as either patch-stage MF or not. For the practical purposes of clinical management, patients presenting clinically with patch lesions whose features result in a score of 4 points or more are considered to have unequivocal MF. Obviously, the more liberal the criteria, the more cases could be considered to be MF. However, there will always be some cases that fail to meet any specific set of criteria, and the designation *LPP* is a useful term to apply to them because it guides treatment and follow-up and conveys an understanding that the risk of dying from lymphoma is small.



▲ **FIGURE 25-9** Small-plaque parapsoriasis. Superficial perivascular lymphoid infiltrate, mild spongiosis, parakeratosis, and focal scale crust.

TABLE 25-2
Algorithm for the Diagnosis of Patch-Stage Mycosis Fungoides (Four Points Are Required)

PARAMETER	2 POINTS	1 POINT
Clinical:	Any two	Any one
Persistent, progressive patches and plaques ±		
Non–sun-exposed distribution		
Variation in size and shape		
Poikiloderma		
Histopathologic:	Both	Either
Superficial dermal T-cell infiltrate ±		
Epidermotropism		
Nuclear atypia		
Immunopathologic:	Not applicable	Any one
CD2, CD3, or CD5 < 50%		
CD7 < 10%		
Epidermal-dermal discordance		
Molecular biologic:	Not applicable	Present
Dominant T-cell clonality		

Note: Epidermotropism implies the lack of significant spongiosis (intraepidermal lymphoid cells associated with spongiosis is termed *exocytosis* rather than *epidermotropism*). Discordance refers to differential antigen expression between the epidermis and dermis, as opposed to the biopsy specimen as a whole.
From Pimpinelli N et al: Defining early mycosis fungoides. *J Am Acad Dermatol* **53**:1053, 2005, with permission.

The clinical and/or histopathologic differential diagnosis of LPP also includes those collagen vascular diseases and genodermatoses exhibiting poikilodermatous features, lichenoid drug eruptions, secondary syphilis, chronic radiodermatitis, and occasionally several other diseases tabulated in Box 25-2. These generally can be distinguished by their associated clinical findings. Histopathologic differentiation among these diseases is covered largely in the discussion of pseudo-MF in Chap. 147.

SPP, when it presents with its distinctive digitate dermatosis lesions parallel to skin lines in a truncal distribution, stands out from other types of parapsoriasis. Individual SPP lesions may show some superficial resemblance to PLC. SPP is distinguished from psoriasis by the absence of the Auspitz sign (see Chap. 18), micaceous scale, nail pits, and typical psoriatic lesions involving the scalp, elbows, and knees. Histologically, its mild spongiotic dermatitis and absence of other characteristic features distinguish it from PLC, psoriasis, and several of the other entities listed in Box 25-2. Clinical features are also important, such as the herald patch of pityriasis rosea and the papulovesicular coin-shaped patches favoring the lower extremities in nummular dermatitis.

Sometimes patients with MF may exhibit small patches of disease at presentation; however, these lesions typically have histopathologic features at least consistent with MF and generally are associated with larger, more classic lesions of MF elsewhere on the skin. They also may show poikilodermatous features not seen in SPP. Furthermore, the presence of well-developed, moderate to thick small plaques, as seen in some MF patients, is incompatible with the diagnosis of SPP because the latter disorder includes only lesions that are no more than patches or very thin plaques. It is also important to recognize that partially treated or early relapsing lesions of MF may show only non-specific features that should not be taken as evidence of a pathogenetic link to SPP or any other dermatosis.

Complications

LPP can be associated with other forms of parapsoriasis and overt cutaneous

Box 25-2

Differential Diagnosis of Large-Plaque Parapsoriasis (LPP) and Small-Plaque Parapsoriasis (SPP)

Most Likely

- LPP
  - Tinea corporis
  - Plaque-type psoriasis
  - Contact dermatitis
  - Subacute cutaneous lupus erythematosus
- SPP
  - Nummular dermatitis
  - Pityriasis rosea
  - Plaque and guttate psoriasis
  - Pigmented purpuric dermatoses
  - Pityriasis lichenoides chronica

Consider

- LPP
  - Xerotic dermatitis
  - Atopic dermatitis
  - Dermatomyositis
  - Drug eruption
  - Erythema dyschromicum perstans
  - Pigmented purpuric dermatoses
  - Early inflammatory morphea
  - Atrophoderma of Pasini-Pierini
  - Erythema annulare centrifugum
  - Pityriasis rubra pilaris
  - Genodermatoses with poikiloderma
  - Chronic radiodermatitis
- SPP
  - Tinea versicolor
  - Seborrheic dermatitis
  - Drug eruption

Always Rule Out

- LPP
  - Mycosis fungoides
- SPP
  - Mycosis fungoides
  - Secondary syphilis

lymphomas as detailed elsewhere in this chapter. Both LPP and SPP occasionally can develop areas of impetiginization secondary to excoriation.

Prognosis and Clinical Course

Both LPP and SPP may persist for years to decades with little change in appearance clinically or histopathologically. Approximately 10 to 30 percent of cases of LPP progress to overt MF.[1,51] In this context, LPP represents the clinically benign end of the MF disease spectrum, with transformation to large cell lymphoma at the opposite extreme. The rare retiform variant is said to progress to overt MF in virtually all cases.[1]

In contrast to LPP with its malignant potential, SPP is a clinically benign disorder in the experience of most experts. Patients with this disease as defined in this chapter rarely, if ever, develop overt MF.[15,43,52] Despite this fact and what most observers consider to be its nonspecific histopathologic features, some authors favor lumping SPP within the MF disease spectrum as a very early, nonprogressive variant.[53] This issue has been debated at length.[36,54,55]

Box 25-3

Treatment of Large-Plaque Parapsoriasis and Small-Plaque Parapsoriasis

FIRST LINE

- Emollients
- Topical corticosteroids
- Topical tar products
- Sunbathing
- Broadband ultraviolet B phototherapy
- Narrowband ultraviolet B phototherapy

SECOND LINE

(Mainly for large-plaque parapsoriasis cases considered to be early mycosis fungoides)

- Topical bexarotene
- Topical imiquimod
- Psoralen and ultraviolet A phototherapy
- Topical mechlorethamine
- Topical carmustine (BCNU)

Treatment

Patients with SPP should be reassured and may forego treatment. The disease may be treated with emollients, topical tar preparations, topical corticosteroids, and/or broadband or narrowband ultraviolet B (UVB) phototherapy (Box 25-3).[56] Response to therapy is variable. Patients should initially be examined every 3 to 6 months and subsequently every year to ensure that the character of the process is stable.

LPP requires more aggressive therapy: high-potency topical corticosteroids with phototherapy such as broadband UVB, narrowband UVB, or psoralen and ultraviolet A (PUVA). The goal of treatment is to suppress the disorder to prevent possible progression to overt MF. Other methods of treatment, such as topical nitrogen mustard, have been used, particularly for the poikilodermatous type. The patient should be examined carefully every 3 months initially and every 6 months to 1 year subsequently for evidence of progression. Repeated multiple biopsies of suspicious lesions should be performed. Cases that satisfy the clinicopathologic criteria for early MF can be treated with broadband UVB, narrowband UVB, PUVA, topical nitrogen mustard, topical bexarotene gel, topical imiquimod, or topical carmustine (BCNU).[57] Electron-beam radiation therapy generally is reserved for more advanced, infiltrated lesions of MF.

Prevention

Because LPP and SPP are uncommon diseases that appear to affect patients randomly, there are no known preventive measures.

PITYRIASIS LICHENOIDES

Epidemiology

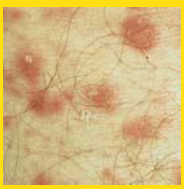
Pityriasis lichenoides affects all racial and ethnic groups in all geographic regions. It is more common in children and young adults but can affect all ages. There is a male predominace of 1.5:1 to 3:1.[58,59] PLC is three to six times more common than PLEVA.

Etiology and Pathogenesis

The etiology of pityriasis lichenoides is unknown. Some cases have been associated with infectious agents such as *Toxoplasma gondii*,[60,61] Epstein-Barr virus,[62,63] cytomegalovirus,[62] parvovirus B19,[62,64,65] and human immunodeficiency virus.[66,67] At least one case was linked repeatedly with estrogen-progesterone therapy and another with chemotherapy drugs.[68] It is uncertain whether these agents are actively involved in disease pathogenesis or merely coincidental bystanders; however, several cases associated with toxoplasmosis have cleared fairly quickly in response to specific therapy.[61]

Immunohistologic studies have shown a reduction in $CD1a^+$ antigen–presenting dendritic (Langerhans) cells within the central epidermis of pityriasis lichenoides lesions.[69] Keratinocytes and endothelial cells are $HLA\text{-}DR^+$, which suggests activation by T-cell cytokines.[69] $CD8^+$ T cells predominate in PLEVA, whereas either $CD8^+$ or $CD4^+$ T cells predominate in PLC.[69–71] Many of these T cells express memory proteins (CD45RO) and cytolytic proteins (TIA-1 and granzyme B).[64,72] Dominant T-cell clonality has been demonstrated in about half of PLEVA cases and a minority of PLC cases.[35–37,73] In aggregate, these findings raise the possibility that pityriasis lichenoides is a variably clonal cytolytic memory T-cell lymphoproliferative response to one or more foreign antigens. Deposition of immunoglobulin M, C3, and fibrin in and around blood vessels and along the dermoepi-

PITYRIASIS LICHENOIDES AT A GLANCE



- Pityriasis lichenoides et varioliformis acuta (PLEVA) and pityriasis lichenoides chronica (PLC) represent two ends of a disease spectrum; both entities and intermediate forms can coexist.
- All forms are characterized by spontaneously resolving, temporally overlapping crops of papules.
- PLEVA papules last for weeks and may develop crusts, vesicles, pustules, or ulcers.
- PLC papules persist for months and develop scales.
- All forms contain interface, cytolytic T-cell infiltrates with variable epidermal destruction.
- In PLEVA, $CD8^+$ cells predominate.
- In PLC, $CD8^+$ or $CD4^+$ cells predominate.
- Dominant T-cell clonality can be detected in all forms, more often in PLEVA than in PLC.
- Treatment depends on severity and ranges from topical steroids, systemic antibiotics, ultraviolet irradiation, and psoralen and ultraviolet A to systemic immunosuppressants.

dermal junction in early acute lesions suggests a possible concomitant humoral immune response, although this could be a secondary phenomenon.

The relationship of pityriasis lichenoides to lymphomatoid papulosis remains controversial[14,50,69] (see also Chaps. 146 and 147). Common features include dominant T-cell clonality and spontaneous resolution of papular, predominantly lymphoid lesions. Furthermore, individual lesions with the clinicopathologic characteristics of either pityriasis lichenoides or lymphomatoid papulosis can co-exist in the same patient, either concurrently or serially. It remains to be determined whether this can be explained as an artifact of sampling lymphomatoid papulosis lesions at various stages of their evolution. The presence of large $CD30^+$ atypical lymphoid cells is the hallmark of lymphomatoid papulosis (at least types A and C).[74] Furthermore, these cells are typically $CD4^+$ and often lack one or more mature T-cell antigens such as CD2, CD3, and CD5. These features serve to distinguish lymphomatoid papulosis from pityriasis lichenoides. Although occasional $CD30^+$ cells can be seen in a wide variety of dermatoses, the presence of any appreciable number should favor lymphomatoid papulosis over pityriasis lichenoides as a matter of definition. It may be that the "PLC-PLEVA" and "lymphomatoid papulosis–$CD30^+$ anaplastic large cell lymphoma" disease spectra are intersecting rather than overlapping entities; that is, although pityriasis lichenoides is a distinct cutaneous T-cell disorder, it is possible that it may sometimes serve as fertile soil for the development of the $CD30^+$ T-cell clone characteristic of lymphomatoid papulosis.

Clinical Findings

CUTANEOUS LESIONS PLC and PLEVA exist on a clinicopathologic continuum.[1,50] Therefore, individual patients may exhibit a mixture of acute and chronic lesions sequentially or concurrently. In addition, lesions representing clinical or histopathologic intergrades between the extremes may also occur at any time.

Lesions are often asymptomatic but can be pruritic or burning, especially in the more acute cases. PLC typically presents as recurrent crops of erythematous scaly papules that spontaneously regress over several weeks to months (Fig. 25-10). PLEVA manifests as recurrent crops of erythematous papules that develop crusts, vesicles, pustules, or erosions before spontaneously regressing within a matter of weeks (Fig. 25-11). The more severe ulcerative variant is known as *pityriasis lichenoides with ulceronecrosis and hyperthermia (PLUH)* or *febrile ulceronecrotic Mucha-Habermann disease*. It presents as purpuric papulonodules with central ulcers up to a few centimeters in diameter (Fig. 25-12). Some have proposed that this severe variant is actually an overt T-cell lymphoma.[75] Pityriasis lichenoides lesions tend to concentrate on the trunk and proximal extremities,

▲ **FIGURE 25-10** Pityriasis lichenoides chronica. Polymorphous appearance ranging from early erythematous papules to scaling brown-red lesions and tan-brown involuting, flat papules and macules.

▲ **FIGURE 25-11** Pityriasis lichenoides et varioliformis acuta. **A.** Adolescent with multiple erythematous papules and crusted lesions in various stages of evolution. **B.** Larger papulovesicular and hemorrhagic, crusted lesions in an adult. Note varioliform scars adjacent to active lesions on posterior thigh and leg. **C.** Pustules, crusts, and necrotic-centered papules with erythematous, indurated base.

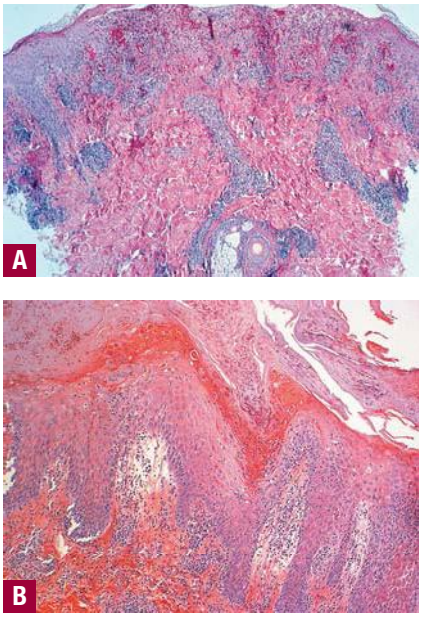
▲ **FIGURE 25-12** Pityriasis lichenoides, ulceronecrotic, hyperacute variant. Large necrotic eschar with halo erythema developing in febrile patient with antecedent pityriasis lichenoides et varioliformis acuta.

but any region of the skin and even mucous membranes can be involved. Rare regional or segmental lesion distributions have been described.[76,77] Although there are usually numerous co-existent lesions, occasionally only a small number of lesions will be present at any one time. All forms of pityriasis lichenoides can result in post-inflammatory hypopigmentation or hyperpigmentation. Chronic lesions can resolve with post-inflammatory hypopigmentation, sometimes presenting as idiopathic guttate hypomelanosis. Chronic lesions rarely lead to scars. In contrast, acute lesions result in deeper dermal injury and consequently often resolve leaving varioliform (smallpox-like) scars. The presence of lesions in various stages of evolution imparts a polymorphous appearance that is characteristic of pityriasis lichenoides.

Laboratory Tests

Miscellaneous non-specific abnormalities in blood test results occur but are of little practical value. Leukocytosis and a decreased CD4/CD8 ratio can occur.

HISTOPATHOLOGY As with the morphology of the clinical lesions, pityriasis lichenoides can exhibit a range of histopathologic features encompassing acute, chronic, and intermediate lesional variants (Figs. 25-13 and 25-14). All cases of pityriasis lichenoides contain an interface dermatitis that is denser and more wedge shaped in the acute lesions. The infiltrate is composed mainly of lymphocytes with a variable admixture of neutrophils and histiocytes. There is exocytosis, parakeratosis, and extravasation of erythrocytes. Epidermal damage ranges from intercellular and extracellular edema in less severe cases to extensive keratinocyte necrosis, vesicles, pustules, and ulcers. The acute variants can exhibit lymphocytic vasculitis with fibrinoid degeneration of blood vessel walls.



▲ **FIGURE 25-13** Pityriasis lichenoides et varioliformis acuta. **A.** Ulcerated papule with epidermal necrosis, hemorrhage, and superficial and deep perivascular lymphocytic infiltrate. Hematoxylin and eosin (H&E) stain. **B.** Parakeratosis and crust with marked spongiosis and epidermal necrosis. Lymphocyte exocytosis and basal hydropic changes. H&E stain.

Occasional CD30$^+$ lymphoid cells and occasional atypical lymphoid cells may be seen as a non-specific finding in many cutaneous lymphoid infiltrates. The presence of an appreciable numbers of these cells is not consistent with classic pityriasis lichenoides of any type and should raise concern for the lymphomatoid papulosis–CD30$^+$ anaplastic large cell lymphoma disease spectrum.[74] Other immunohistologic features and the clonality of pityriasis lichenoides are discussed in Etiology and Pathogenesis.

Differential Diagnosis

The differential diagnosis of pityriasis lichenoides includes many papular eruptions (Box 25-4). Those that develop crusts, vesicles, pustules, or ulcers are grouped with PLEVA, whereas those that form predominantly scaly papules are grouped with PLC. Most of them can be excluded based on history and typical clinicopathologic features. A few, such as secondary syphilis and viral-associated lesions, also can be excluded based on serologic tests. Among the most challenging diseases to distinguish from pityriasis lichenoides are lymphomatoid papulosis and macular or papular variants of MF.[78] As detailed earlier, the presence of large atypical lymphoid cells (often CD30$^+$) differentiates lymphomatoid papulosis from pityriasis lichenoides.[74] Macular or papular variants of MF are rare. They exhibit classic features of MF, including small atypical epidermotropic lymphoid cells with convoluted nuclei and a band-like superficial dermal lymphoid infiltrate.[78]

Complications

Secondary infection is the most common complication of pityriasis lichenoides. PLEVA may be associated with low-grade fever, malaise, headache, and arthralgia. Patients with PLUH can develop high fever, malaise, myalgia, arthralgia, and gastrointestinal and central nervous system symptoms. Occasionally, debilitated patients may die. PLC has been associated uncommonly with LPP in children.[79] Despite

  - Lymphomatoid papulosis
  - Mycosis fungoides (papular variant)
  - Secondary syphilis

their sometimes dominant T-cell clonal nature, PLC and PLEVA are considered clinically benign disorders without significant linkage to lymphomas or other malignancies.

Prognosis and Clinical Course

Pityriasis lichenoides has a variable clinical course characterized by recurrent crops of lesions that spontaneously resolve. The disorder may resolve spontaneously within a few months or, less commonly, persist for years. PLEVA usually has a shorter duration than PLC.

Box 25-5

Treatment of Pityriasis Lichenoides et Varioliformis Acuta and Pityriasis Lichenoides Chronica

FIRST LINE

- Topical corticosteroids
- Antibiotics (erythromycin 500 mg PO 2–4× daily[80]; tetracycline 500 mg PO 2–4× daily,[81] minocycline 100 mg PO twice daily)
- Phototherapy (sunbathing, ultraviolet B,[82] ultraviolet A + ultraviolet B,[83] narrowband ultraviolet B[84])

SECOND LINE

- Topical tacrolimus[85,86]
- Prednisone (60/40/20 mg PO taper, 5 days each)[87]
- Methotrexate (10–25 mg PO weekly)[88,89]
- Phototherapy (ultraviolet AI, psoralen plus ultraviolet A)
- Cyclosporin (2.5–4 mg/kg/day total dose divided into twice-daily PO doses; use the minimum)[66]
- Retinoids (e.g., acitretin 25–50 mg PO daily)[90]

Although the conclusion was not confirmed by subsequent investigation, one report suggested that the duration of pityriasis lichenoides in children correlated better with its clinical distribution than with the relative abundance of acute and chronic lesions, which often co-existed.[59] From longest to shortest duration, the distribution of lesions ranged from peripheral (distal extremities) to central (trunk) to diffuse.

Treatment

The mainstay of traditional therapy has been a combination of topical corticosteroids and phototherapy (Box 25-5). Systemic antibiotics in the tetracycline and erythromycin families are used primarily for their anti-inflammatory rather than antibiotic effects. Cases with minimal disease activity may not require any treatment. The more acute the clinical course and the more severe the individual lesions, the more systemic therapy is indicated. Methotrexate is often effective in relatively low doses. Calcineurin inhibitors and retinoids may also be beneficial. Severe cases of PLEVA and PLUH often require systemic corticosteroids or similar drugs to gain control of systemic symptoms. Topical and systemic antibiotics may be needed to treat secondary infections complicating ulcerated skin lesions. These agents are often selected initially to cover Gram-positive pathogens, but subsequent use should be guided by culture results.

Prevention

There are no known preventive measures.

CHAPTER 26

Lichen Planus

Mark R. Pittelkow
Mazen S. Daoud

Lichen planus (Greek *leichen*, "tree moss"; Latin *planus*, "flat") is a unique, common inflammatory disorder that affects the skin, mucous membranes, nails, and hair. The appearance of lichen planus and lichen planus–like or lichenoid dermatoses has been likened to the scurfy, finely furrowed, dry excrescences of the symbiotic vegetation known as *lichen*. Although this morphologic comparison may be antiquated, lichen planus is a distinctive entity with prototypic "lichenoid" papules that show distinctive color and morphology, develop in typical locations, and manifest characteristic patterns of evolution. Microscopic features, similar to the gross morphology, are distinctive although the microscopic pattern of inflammation and skin response is shared by several dermatoses. The term *lichenoid reaction* is the histologic description used to capsulize the pathologic characteristics of skin diseases resembling lichen planus.

The four Ps—purple, polygonal, pruritic, papule—is the mnemonic device often used to recall the constellation of symptoms and skin findings that characterize lichen planus.

HISTORICAL ASPECTS

EPIDEMIOLOGY

The exact incidence and prevalence of lichen planus are unknown, but the overall prevalence is believed to be somewhat less than 1 percent of the general population. Estimates between 0.14 percent and 0.80 percent have been reported worldwide and approximately 0.44 percent in the United States. No racial predilection has been observed.[2]

At least two-thirds of cases occur between the ages of 30 and 60 years of age. No sexual predilection is evident. Females are usually affected in their fifties and sixties, whereas males develop lichen planus at a somewhat earlier age. The disease is less common in the very young and the elderly. The development of lichen planus may be affected by seasonal or environmental factors.[2]

Fewer than 100 cases of familial lichen planus have been reported. The familial form tends to be more protracted and severe and presents in erosive, linear, or ulcerative patterns or with atypical features affecting young adults and children.[3] Some believe that the familial form represents a separate, unique dermatosis. Different HLA haplotypes were reported in familial lichen planus, including HLA-B7, -Aw19, -B18, and -Cw8. In non-familial lichen planus, HLA-A3, -A5, -A28, -B8, -B16, and -Bw35 are more common.[4] HLA-B8 is more common in patients with oral lichen planus as a sole manifestation, and HLA-Bw35 is more strongly associated with cutaneous lichen planus.

ETIOLOGY AND PATHOGENESIS

It is evident that immunologic mechanisms almost certainly mediate the development of lichen planus. No consistent alterations in immunoglobulins (Igs) have been shown in lichen planus, and humoral immunity most likely is a secondary response in the immunopathogenesis.

Cell-mediated immunity, on the other hand, plays the major role in triggering the clinical expression of the disease. Both $CD4^+$ and $CD8^+$ T cells are found in lesional skin of lichen planus. Progression of disease may lead to preferential accumulation of $CD8^+$ cells. The majority of the lymphocytes in the infiltrate of lichen planus are $CD8^+$ and CD45RO (memory) positive cells and express the α-β T-cell receptor (TCR), and in a minority, the γ-δ receptor. This later cell subtype is not normally found in healthy skin. These cells are considered responsible for the development of the most characteristic change observed in the lichenoid reaction, namely, apoptosis. The inflammatory process that leads to apoptosis is complex and not fully understood. The epithelial-lymphocyte interaction can be divided into three major stages: antigen recognition, lymphocyte activation, and keratinocyte apoptosis.

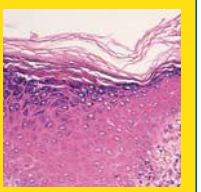
Lichen Planus–Specific Antigen Recognition

It is evident that the majority of T cells in the infiltrate of lichen planus, both within the epithelium and adjacent to damaged basal keratinocytes, are activated $CD8^+$ cytotoxic lymphocytes. Evidence from oral lichen planus suggests that $CD8^+$ lesional T cells recognize a lichen planus–specific antigen associated with major histocompatibility complex (MHC) class I on lesional keratinocytes. The nature of this antigen is unknown. Theoretically, the antigen may be an autoreactive peptide, thus classifying lichen planus as an autoimmune disease. Alternatively, it may represent an exogenous antigen such as an altered protein, drug, contact allergen, viral or infectious agent, or an unidentified immunogenic target.[5]

The role of T-helper (CD4) cells in the pathogenesis of lichen planus is not fully defined. T cells may become activated via antigen-presenting cells such as Langerhans cells or accessory cells such as epidermal keratinocytes in association with members of the MHC II and specific cytokines. T-helper lymphocytes may also propagate $CD8^+$ cytotoxic lymphocytes through cellular cooperation and release of cytokines.

The nature of antigenic stimulation is not known. Contact sensitizers such as metals could act as haptens and elicit an immunologic response. Enhanced lymphocyte reactivity to inorganic mercury, a component of dental amalgam, has been found in patients with oral lichenoid reactions. Low-grade chronic exposure to mercury, and possibly to other metals such as gold, may stimulate a lymphocytic reaction that manifests as lichen planus. A list of contact chemicals and drugs that can elicit lichenoid reactions is discussed in Drug-Induced Lichen Planus. The role of infection in the development of lichen

LICHEN PLANUS AT A GLANCE



- Worldwide occurrence: Less than 1 percent.
- Lesions: Symmetric, grouped, erythematous to violaceous, flat-topped, polygonal papules.
- Distribution: Widespread, predilection for flexural aspects of arms and legs.
- Variants: Based on configuration, morphology of lesion, and site of involvement.
- Pathology: Basal epidermal keratinocyte damage and lichenoid interface lymphocytic reaction.

planus has been repeatedly raised over the years. Though provocative, no conclusive evidence has molecularly linked lichen planus to any of the following infections or microorganisms: syphilis, herpes simplex virus 2, human immunodeficiency virus (HIV), amebiasis, chronic bladder infections, hepatitis C virus (HCV), *Helicobacter pylori*, or human papillomavirus.

Cytotoxic Lymphocyte Activation

Following antigen recognition, $CD8^+$ T cells are activated. Activated cytotoxic lymphocytes undergo lesional tissue clonal expansion, leading to oligoclonal and occasionally to monoclonal proliferation as detected by analysis of the TCR-γ chain gene products.[6]

Activated lymphocytes, both by helper subsets (Th1 and Th2) and cytotoxic-suppressor cells, release soluble mediators (cytokines and chemokines), such as interleukin (IL)-2, IL-4, IL-10, interferon (IFN)-γ, tumor necrosis factor (TNF)-α, and transforming growth factor-β1, that attract lymphocytes and regulate their biologic activities within and adjacent to the epithelium. Both pro- and anti-inflammatory cytokines, that is, mixed Th1 and Th2 cytokine products, are generated simultaneously. The balance between lymphocytic activation and downregulation determines the clinical behavior of the disease.[7] IFN-γ, produced by T-helper cells during the antigen recognition stage, induces keratinocytes to produce lymphotoxin-α and TNF-α, and to upregulate MHC class II, thus increasing interactions with T-helper cells. Furthermore, IFN-γ upregulates the expression of intercellular adhesion molecule-1 and vascular cell adhesion molecule-1 by basal keratinocytes, Langerhans cells, and other macrophage-dendritic cells.[8] Intercellular adhesion molecule-1 is a ligand for the β_2-integrin, leukocyte function–associated antigen-1, on the surface of lymphocytes, which further enhances the interaction of these lymphocytes with the antigen-presenting cells.[9] Laminin-5 and collagen types IV and VII are increased in lesional lichen planus and serve as ligands for β1-integrin on the surface of lymphocytes, thus allowing for enhanced association of lymphocytes with the basement membrane. Integrin α3 is present on activated, skin-homing T cells and may localize these effector cells to the epidermal-dermal interface and basement membrane, which contain epiligrin/laminin-5, a ligand for this integrin.[10] This close interaction between lymphocytes and basement membrane targets metalloproteinases produced by lymphocytes to alter extracellular matrix proteins and integrins, and the process eventuates in apoptosis, basement membrane disruption, reduplication, and subepidermal cleft formation (see Pathology). TNF-α upregulates the expression of matrix metalloproteinase (MMP)-9 mRNA in lesional T lymphocytes, thus further enhancing basement membrane disruption (see Keratinocyte Apoptosis).[11]

Keratinocytes also participate in the response by producing IL-1β, IL-4, IL-6, granulocyte-macrophage colony-stimulating factor, and TNF-α. These cytokines further activate tissue macrophages and peripheral blood mononuclear cells[12] and upregulate expression of cell surface adhesion molecules and migration activity. Keratinocyte-produced cytokines also upregulate expression of specific keratin genes. Keratin (K) 17, usually restricted to adnexal structures, is variably expressed in the basal and suprabasal layers of the interfollicular epithelium of affected epidermis. K6 and K16 also become detectable in the basal and suprabasal layers. K4 and K13 are reduced in the suprabasal compartment in areas with orthokeratosis, associated with increased production of K1 and K10.[13]

Keratinocyte Apoptosis

The exact mechanisms used by activated cytotoxic T cells to trigger apoptosis of keratinocytes is not completely known. Possible mechanisms include: (1) T-cell secreted TNF-α binding to the TNF-α R1 receptor on the keratinocyte surface, (2) T-cell surface CD95L (Fas ligand) binding CD95 (Fas) on the keratinocyte, and (3) T-cell secreted granzyme B entering the keratinocyte via perforin-induced membrane pores. All these mechanisms may activate the keratinocyte caspase cascade, resulting in keratinocyte apoptosis.[5]

Recruited lymphocytes may further contribute to apoptosis via a different mechanism, the loss of a basement membrane–derived cell survival signal that normally prevents the onset of apoptosis. Hence, basement membrane disruption may trigger apoptosis. Principle mediators are the MMPs, a family of zinc-containing endoproteinases that primarily function to degrade connective tissue matrix proteins. The action of these enzymes is also regulated by inhibitors such as tissue inhibitors of metalloproteinases (TIMPs) (see Chap. 61). It has been shown that lesional T cells in lichen planus have higher MMP-9 levels than peripheral blood T cells. Lesional T-cell MMP-9 activity increases following stimulation with TNF-α, but not TIMP-1, an inhibitor for MMP-9.[5] These observations suggest that T-cell secreted MMP-9 disrupts epithelial basement membranes, blocking cell survival signals to keratinocytes and inducing apoptosis.

Various other environmental, behavioral, or infectious factors have been observed on occasion to be associated with the development or exacerbation of lichen planus. However, no well-established association has been documented between emotional stress, tobacco use, or oral or gastrointestinal candidiasis and development of lichen planus.

CLINICAL FINDINGS

Cutaneous Lesions

The classic cutaneous lesion of lichen planus is a faintly erythematous to violaceous, flat-topped, polygonal papule, sometimes showing a small central umbilication (Fig. 26-1). Papules are grouped and tend to coalesce. A thin, transparent, and adherent scale may be discerned atop the lesion. Fine, whitish puncta or reticulated networks referred to as *Wickham striae* are present over the surface of many well-developed papules (see Fig. 26-1). These are considered to be highly characteristic and are more easily observed after applying oil, xylene, or water and visualizing the lesions with a magnifying lens or a handheld dermatoscope. The surface alteration may result from localized thickening of the keratohyalin-containing cell layers of the stratum granulosum, although a focal increase in the activity of lichen planus may account for the morphologic alteration of Wickham striae.

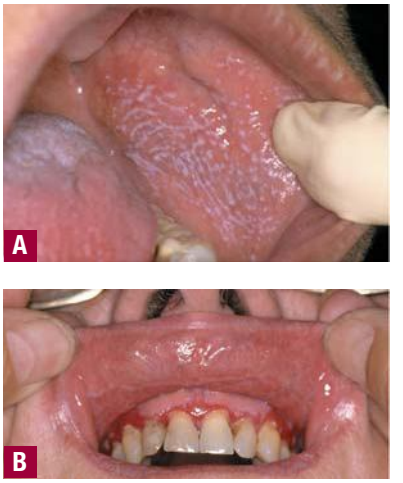
▲ **FIGURE 26-1** Flat-topped, polygonal, sharply defined papules of violaceous color, grouped and confluent. Surface is shiny and reveals fine white lines (Wickham striae). Note pigmentation of resolving lesions.

▲ **FIGURE 26-2** Generalized lichen planus. Small, flat-topped violaceous papules, some grouped, some disseminated, becoming confluent on the trunk.

Lichen planus begins as faintly erythematous macules that form purplish papules over several weeks. Sometimes multiple lesions develop rapidly over a short time, with dissemination following the initial appearance of only a few papules. Further spread of lesions after the initial limited expression occurs in approximately one-third of cases. In generalized disease (Fig. 26-2), the eruption often spreads within 1 to 4 months from onset. The initial lesions almost always appear on the extremities, with the lower extremities being somewhat more common.

The lesions are usually distributed symmetrically and bilaterally over the extremities. Lichen planus tends to involve the flexural areas of the wrists, arms, and legs (see Fig. 26-1). The thighs, lower back, trunk, and neck may also be affected. Oral mucous membranes (Fig. 26-3) and the genitalia (Fig. 26-4) are additional sites of involvement. The face is usually spared in typical cases, and palmoplantar involvement is unusual. Inverse lichen planus usually affects the axillae, groin, and inframammary areas.

Lichen planus tends to be quite pruritic, although some patients are completely asymptomatic. The degree of pruritus is generally related to the extent of involvement, with more intense pruritus in generalized cases. An exception is hypertrophic lichen planus, which is more localized but extremely pruritic. Oral involvement is generally asymptomatic unless erosions or ulcers developed. Erosive oral lichen planus is usually extremely painful. In the acute, evolving stages of the disease, scratching, injury, or trauma may induce an isomorphic (Koebner) response (Fig. 26-5). Lichen planus usually heals with hyperpigmentation (see Fig. 26-1), which is more prominent among patients with darker skin color. Hypopigmentation uncommonly develops after resolution of lesions.



▲ **FIGURE 26-3** Mucosal lichen planus. **A.** A typical lace-like whitish reticulated pattern of oral lesions is seen on the buccal mucosa. **B.** Erosive gingivitis. Here lichen planus manifests as painful erosions on the gingiva.

Although the clinical and pathologic features of childhood lichen planus are similar to those in adults, scalp, nail, and hair involvement are not common. Mucous membrane involvement, thought to be rare, may occur in up to one-third of patients. The hypertrophic variant occurs in one-fourth of children with lichen planus.

Clinical Variants

Many variations in the clinical presentation have been described and are generally categorized according to (1) the configuration of lesions, (2) the morphologic appearance, or (3) the site of involvement. These variations are patterned by subtle or unknown properties of the disease. The prototypic papule can be altered or modified in configuration, morphology, or anatomic distribution.

▲ **FIGURE 26-4** Lichen planus on the penis. Agminate pattern of lesions involving the glans, sulcus, and meatus (not seen) of the penis.

▲ **FIGURE 26-5** Lichen planus. Linear pattern with Koebner response adjacent to clustered papules on the flexural wrist.

CONFIGURATION OF LESIONS ***Annular Lichen Planus.*** Annular lesions occur in approximately 10 percent of cases and commonly develop as arcuate groupings of individual papules that develop rings or peripheral extension of clustered papules with central clearing. They tend to occur in blacks and are more common on the penis and scrotum (see Fig. 75-9, Chap. 75).[2] Another form of annular lichen planus occurs when larger lesions reach 2 to 3 cm in diameter and become hyperpigmented with a raised outer rim. This form may occur on the trunk or extremities. Actinic lichen planus, seen in subtropical zones on sun-exposed, dark-skinned young adults and children, is frequently annular in shape.

Linear Lichen Planus. Papules of lichen planus may develop a linear pattern secondary to trauma (koebnerization) (see Fig. 26-5) or, uncommonly, as a spontaneous, isolated eruption, usually on the extremities, and rarely on the face. This linear pattern should be differentiated from nevus unius lateris and lichen striatus. A zosteriform pattern has also been described.[14] Lichen planus can develop in the site of healed herpes zoster.

▲ **FIGURE 26-6** Hypertrophic lichen planus in the pretibial region of a dark-skinned individual. Lesions are almost nodular and very dark with the violaceous sheen of lichen planus. Lesions may later become hyperkeratotic.

MORPHOLOGY OF LESIONS ***Hypertrophic Lichen Planus.*** Hypertrophic lichen planus (lichen planus verrucosus) usually occurs on the extremities, especially the shins and interphalangeal joints, and tends to be the most pruritic variant (Fig. 26-6). Lesions are thickened and elevated, purplish or reddish-brown in color, and hyperkeratotic. Occasionally, verrucous plaques develop. Lesions may show accentuated and elevated follicular induration and chalk-like scale. This variant usually heals with scar formation and hyper- or hypopigmentation. Chronic venous insufficiency is frequently present.

Atrophic Lichen Planus. The atrophic variant is rare and is characterized by the presence of a few well-demarcated, white-bluish papules or plaques with central superficial atrophy.[2] Sometimes the lesions show more erythema. The lesions are a few millimeters wide but may coalesce to form larger plaques. They are most common on the lower extremities or trunk. The lesions often resemble lichen sclerosus et atrophicus. However, the histologic features are diagnostic.

Vesiculobullous Lichen Planus. Bullous lichen planus is a rare variant of the disease characterized by the development of vesicles and bullae within the lesions (Fig. 26-7). The bullae, which appear most commonly on the extremities, arise from papules of lichen planus and rarely from normal-appearing skin.

▲ **FIGURE 26-7** Vesiculo-bullous lichen planus. Vesicles and bullae with violaceous-erythematous papules and plaques on the foot.

They may appear suddenly during an acute flare of disease and are usually associated with mild constitutional symptoms. These lesions usually resolve in a few months. Bulla arising in oral lichen planus can lead to painful erosions. Histologically, the typical changes of lichen planus are seen in conjunction with subepidermal separation. The duration of this variant is no different from that of classic lichen planus. Bullae arising from normal skin are more characteristic of lichen planus pemphigoides and should be differentiated from bullous lichen planus by direct and indirect immunofluorescence (see below).

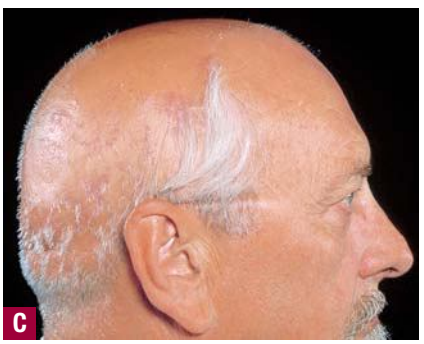
Erosive and Ulcerative Lichen Planus. Ulcerative lichen planus is a rare variant presenting with chronic, painful bullae and ulcerations of the feet. Often, cicatricial sequelae are evident (Fig. 26-8). This variant is usually associated with more typical lesions of the nails, mucosal surfaces, and skin, which often aids in establishing the diagnosis. Permanent loss of toenails and cicatricial alopecia of the scalp are common. Because squamous cell carcinoma (SCC) may develop in lesions of ulcerative lichen planus, persistent ulceration should raise suspicions of malignancy, and this potential complication should be ruled out by biopsy. Excision and skin grafting should be considered if conservative therapy is ineffective.[15]

▲ **FIGURE 26-8** Erosive-ulcerative lichen planus showing erosions, ulcers, and granulation tissue and scarring of toes, interdigital web spaces, and soles.

Erosive to ulcerative lesions of lichen planus are also seen with greater frequency in more severe cases of oral lichen planus. Lesions may involve the buccal mucosa, alveolar epithelium, and sulci, and may extend to the posterior pharynx and laryngeal area. Though rare, erosive esophageal disease may result in dysphagia and stenosis.

Follicular Lichen Planus. Follicular lichen planus may occur alone or in association with other forms of cutaneous or mucosal lichen planus.[16] The term *lichen planopilaris* has been used to describe this distinctive variant, but other terms include *lichen planus follicularis*, *peripilaris*, and *acuminatus*. Individual keratotic follicular papules and studded plaques are seen. Sites of predilection include the trunk and medial aspects of the proximal extremities. Follicular lichen planus may affect the scalp[2] with the development of cicatricial alopecia (see Lichen Planus of the Scalp; Fig. 26-9). The triad of follicular lichen planus of skin (lichen planus spinulosus) and/or scalp, multifocal cicatricial alopecia of the scalp, and nonscarring alopecia of the axillary and pubic areas, has been described as Graham-Little-Piccardi-Lassueur (or Graham-Little-Feldman) syndrome. Sometimes more typical lesions of the skin and nails are seen. Other variants of follicular lichen planus include the pseudopeladic form of Brocq, the lichen planus follicularis tumidus form with oval pseudotumoral plaques of the mastoid area, post-menopausal frontal fibrosing alopecia, and lichen planoporitis, with the lichenoid reaction centered over the acrosyringium and eccrine ducts entering the epidermis.[17]

Lichen Planus Pigmentosus. Lichen planus pigmentosus is characterized by hyperpigmented, dark-brown macules in sun-exposed areas and flexural folds. This entity tends to occur in Latin Americans and other patients with darker-pigmented skin. Histologically, an atrophic epidermis, a vacuolar alteration of the basal cell layer with a scarce lymphohistiocytic lichenoid infiltrate, and pigment incontinence are seen. This variant of lichen planus bears significant similarity to ashy dermatosis or erythema dyschromicum perstans and may represent overlap in the phenotypic spectrum of lichenoid inflammation in darkly pigmented skin, with ethnic and genetic factors influencing the expression of disease (see Chap. 73).[18] There are similar histopathologic findings among these diseases. However, distinct clinical, his-



▲ **FIGURE 26-9** Lichen planus. **A.** Irregular patches of alopecia with violaceous papules and coalescing plaque of lichen planus within scalp. **B.** Lichen planopilaris resulting in atrophic, scarred, porcelain-colored area centrally with bordering follicular involvement consisting of dusky erythema, perifollicular hyperkeratosis and scale, and follicular convergence resulting in doll's hair formation. **C.** Extensive hair loss leading to pseudopelade of Brocq appearance. Several remaining tufts of hair showing violaceous erythema and disease activity.

tologic, and immunopathologic differences among these three conditions have been emphasized by some investigators. Erythema dyschromicum perstans may be strongly influenced by environmental agents as well.

The sequela of healing (late waning, resolving) is often slightly atrophic, hyperpigmented skin. In cases where the inflammatory phase was minimal, such as lichen planus "invisible de Gougerot," the pigmentation may be long-lasting and one of the few signs of previously active disease.

Actinic Lichen Planus. Actinic lichen planus is also known as *lichen planus subtropicus, lichen planus tropicus, summertime actinic lichenoid eruption, lichen planus actinicus, lichen planus atrophicus annularis,* and *lichenoid melanodermatosis*. Actinic lichen planus is more common in Middle Eastern countries in spring and summer, where sunlight appears to have a precipitating effect. Exposed areas of the face, dorsal hands and arms, and the nape of the neck are usually affected. Papules are hyperpigmented with violaceous-brown color and a thready, rolled edge showing well-defined borders. Typical lichen planus lesions may be present over the extremities. Pruritus and scaling are minimal.

Other Variants. A perforating variant has been described. Transepidermal elimination of lichen planus–like inflammatory tissue is observed. Guttate lichen planus is another variant that resembles guttate psoriasis but with the characteristic lichenoid histology. Exfoliative and exanthematous forms are very rare and may represent manifestations of lichenoid drug reactions (Fig. 26-10). The rare entity of invisible lichen planus describes lesions that are not perceptible with visible light illumination but become apparent with Wood's lamp examination. Pruritus is present and biopsy evaluation shows lichenoid histology. This entity may be a minimal variant of lichen planus "invisible de Gougerot."

SITE OF INVOLVEMENT ***Lichen Planus of the Scalp.*** Lichen planopilaris or follicular lichen planus may affect the scalp in a distinctive clinical and histologic pattern.[16–18] Individual keratotic follicular papules that coalesce and merge over the scalp to form patches are typically seen. Cutaneous, nail, or mucous membrane involvement with lichen planus may also be present. This condition affects women more than men. Patients present with uni- or multifocal hair loss that may be extensive and involve the entire scalp (see Fig. 26-9). Perifollicular erythema and acuminate keratotic plugs are characteristic features. Follicular-centered lesions are usually observed under close inspection of the scalp and orifices, particularly at the margins of the alopecic area or within patches still bearing hair.

End-stage disease is characterized by a nondescript scarring alopecia that has led to the use of several clinical terms describing the entity: *lichen planopilaris, folliculitis decalvans et atrophicus, lichen spinulosus at follicultis decalvans,* and *Graham-Little syndrome* are different terms that likely describe the same entity.[16]

▲ **FIGURE 26-10** Lichen planus–like eruption. Generalized violaceous papules with superficial scale coalescing to form erythematous variant. History of associated drug exposure leading to lichenoid reaction.

Pseudopelade of Brocq is a rare clinical syndrome of scarring alopecia and fibrosis, in which distinct pathologic features are absent. It is generally accepted that pseudopelade of Brocq is the end stage of follicular fibrosis caused by a primary inflammatory dermatosis such as lichen planus, lupus erythematosus, pustular-scarring forms of folliculitis, or fungal infections, including favus, scleroderma, and sarcoidosis.

Mucosal Lichen Planus. Lichen planus can affect the mucosal surfaces of mouth, vagina, esophagus, conjunctiva, urethra, anus, nose, and larynx. Its prevalence is estimated at approximately 1 percent of the adult population. Oral involvement occurs in approximately 60 percent to 70 percent of patients with lichen planus. It may be the only manifestation in 20 percent to 30 percent of patients.

Different types of oral lichen planus have been described, including reticular, plaque-like, atrophic, papular, erosive-ulcerative, and bullous forms of the disease (see Fig. 26-3).[19] The reticular pattern is considered the most common, but in oral medicine clinics, erosive forms predominate as a consequence of the symptomatology and chronicity. Erosive lichen planus is more common in the elderly and tends to cause a painful, burning sensation. The buccal, gingival, and glossal mucosae are the most commonly affected areas. The palate, floor of the mouth, retromolar pads, and lips may also be affected. Gingival involvement may take the form of gingival stomatitis or desquamative gingivitis, and as a sole presentation, represents 8 percent to 10 percent of oral lichen planus. Oral lichenoid reaction may be seen on the buccal mucosa adjacent to amalgam dental fillings. Patch tests frequently show

positive reactions to mercury, gold, and other metals.[20,21] Because of the prolonged course and associated pain and discomfort, patients with oral lichen planus tend to be depressed, and psychological help should be offered to them.

Bilateral reticular keratotic or atrophic changes of the buccal mucosa and lichenoid atrophic patches over the dorsal tongue have been described in patients with HIV infection. The eruptions usually follow zidovudine or ketoconazole intake. Histologically, liquefaction degradation of basal keratinocytes and epithelial atrophy with lichenoid lymphocytic infiltrate are seen.

Male genitalia are involved in 25 percent of cases, and the glans penis is most commonly affected, with annular lesions frequently present (see Fig. 26-4). Female genital involvement consists of patches of leukoplakia or erythroplakia, sometimes with erosions, and, occasionally, as a more generalized desquamative vaginitis. Vaginal adhesions and labial agglutination may result. Anal lesions of mucosal lichen planus present with leukokeratosis, hyperkeratosis, fissuring, and erosions (Fig. 26-11).

A special form of mucosal lichen planus characterized by involvement of vulvar and gingival tissues has been described.[22] The characteristic features include erythema and erosions of the gingivae and tongue and, occasionally, white reticulated plaques, in association with pain and discomfort. Desquamation and erosions of vulva and vagina in association with burning pain, dyspareunia, and vaginal discharge mirror the oral findings.

Conjunctival lichen planus may manifest as cicatricial conjunctivitis. Histologically, irregular thickening with reduplication of the basement membrane is seen. Direct immunofluorescence distinguishes ophthalmic lichen planus from cicatricial pemphigoid.

▲ **FIGURE 26-11** Lichen planus. Perianal leukoand hyperkeratosis with hypertrophic, folded violaceous epithelium, fissures, and healing biopsy site.

Lichen Planus of the Nails. (See also Chap. 87) Nail involvement occurs in 10 percent to 15 percent of patients.[23] Lichen planus limited to the nails is uncommon, and the initial involvement is followed, in many cases, by the development of typical lesions elsewhere. Lichen planus of nails is infrequent in children. Thinning, longitudinal ridging, and distal splitting of the nail plate (onychoschizia) are the most common findings. Onycholysis, longitudinal striation (onychorrhexis), subungual hyperkeratosis, or even absence (anonychia) of the nail plate can also be seen. Twenty-nail dystrophy (trachyonychia) may represent an isolated nail finding of lichen planus. Psoriasis and alopecia areata can also lead to these distinctive nail changes. Nail loss may result from ulcerative lichen planus involving the nail unit. Pterygium or forward growth of the eponychium with adherence to the proximal nail plate is a classic finding of lichen planus of the nail (Fig. 26-12). An atrophic cicatrizing form of lichen planus with random and progressive nail loss in Asians and blacks has also been reported. The tenting or pup-tent sign is observed as a result of nail bed involvement that elevates the nail plate and may cause longitudinal splitting.[2]

Inverse Lichen Planus. The inverse pattern occurs only rarely and is characterized by red-brownish, discrete papules and nodules. The eruption occurs mainly in the flexural areas such as axillae, inframammary, groin, and, less likely, the popliteal and antecubital areas. koebnerized lesions are occasionally present.

Palmoplantar Lichen Planus. Palmoplantar lichen planus, an acral, localized variant, is rare and may create difficulty in diagnosis if it is present as an isolated finding. Very pruriginous, erythematous, scaly plaques with or without hyperkeratosis are characteristic. Lesions are often seen on the internal plantar arch.[24] Yellowish, compact keratotic papules or papulonodules are seen on the lateral margins of the fingers and hand surfaces; however, they are less likely to affect the fingertips. They appear like callosities with an inflammatory, erythematous halo. The lesions resemble psoriasis vulgaris, warts, calluses, porokeratosis, hyperkeratotic eczema, tinea, or secondary syphilis. Histologically, findings are identical to those of classic lichen planus.[24] Palmoplantar lichen planus may also present as erosive-ulcerative type (see the section Erosive and Ulcerative Lichen Planus).

▲ **FIGURE 26-12** Lichen planus. Classic pterygium formation and tenting of several fingers with loss of nail plates.

SPECIAL FORMS OF LICHEN PLANUS OR LICHENOID ERUPTIONS

Drug-Induced Lichen Planus. Lichen planus–like or lichenoid eruptions describe a group of cutaneous reactions identical or similar to lichen planus (see Fig. 26-10).[25] Lichenoid drug eruptions have been reported after ingestion, contact, or inhalation of certain chemicals (Table 26-1).

A lichenoid drug eruption may be typical or atypical for classic lichen planus, with localized or generalized eczematous papules and plaques and variable desquamation. Lichenoid drug eruptions typically manifest post-inflammatory hyperpigmentation and alopecia, and do not exhibit classic Wickham striae. The eruptions usually appear symmetrically on the trunk and extremities, unlike the flexural distribution of classic lichen planus. A photodistributed pattern is often found, and several drugs frequently induce this reaction. Mucous membrane involvement is less common and is often associated with specific drugs and chemicals.

The latency period for development of a lichenoid drug eruption by these agents varies from months to a year or more based on the dosage, host response, previous exposure, and concomitant drug administration. Resolution of the eruptions is quite variable, but most disappear in 3 to 4 months. Resolution of a gold-induced lichenoid eruption may require up to 2 years after discontinuation of the drug. For many inciting drugs, the severity and extent of the eruption influences the rate of clearance. Occasionally, the lichenoid drug eruption disappears or may recur intermittently despite continuation of treatment.

Lichenoid contact dermatitis may result from contact with compounds such as color film developers, dental restoration materials, metals (e.g., mercury, silver, and gold), and aminoglycoside antibiotics.[25] Oral lichenoid drug eruptions

TABLE 26-1
Agents Inducing Lichen Planus and Lichenoid Reactions

Common inducers
- Gold salts
- β blockers
- Antimalarials
- Thiazide diuretics
- Furosemide
- Spironolactone
- Penicillamine

Less common
- ACE inhibitors
- Calcium channel blockers
- Sulfonylurea
- Nonsteroidal anti-inflammatory drugs
- Ketoconazole
- Tetracycline
- Phenothiazine
- Sulfasalazine
- Carbamazepine
- Lithium
- Antituberculosis
- Iodides
- Radiocontrast media
- Methyldopa (Aldoclor)
- Heavy metals

Inducers of lichen planus by contact
- Color film developers
- Dental restorative materials
- Musk ambrette
- Nickle
- Gold

Inducers of photodistributed lichenoid eruption
- 5-Fluorouracil (Efudex)
- Carbamazepine (Tegretol)
- Chlorpromazine (Compazine, Thorazine)
- Diazoxide (Proglycem)
- Ethambutol
- Pyritinol
- Quinine
- Quinidine (Quinaglute)
- Tetracycline
- Thiazide
- Furosemide (Lasix)

Inducers of oral lichen planus and lichenoid eruption
- Allopurinol (Zyloprim)
- ACE inhibitors
- Cyanamide
- Dental restorative materials
- Gold salts
- Ketoconazole (Ketoconazole)
- Nonsteroidal anti-inflammatory drugs
- Penicillamines (Cuprimine)
- Sulphonylurea

ACE = angiotensin-converting enzyme.

related to amalgam seem to be caused by mercury, although gold may be the more common metal sensitizer in oral lichenoid eruptions.

Lichen Planus–Lupus Erythematosus Overlap Syndrome. Lichen planus–lupus erythematosus overlap syndrome, a rare variant, is characterized by lesions that share features of lichen planus and lupus erythematosus. Atrophic plaques and patches with hypopigmentation and a livid red to blue-violet color with telangiectasia and minimal scaling are characteristic. Transient bullae may develop. Classic lesions of lichen planus are not usually seen. Photosensitivity, pruritus, and follicular plugging are also not common. Lesions may develop anywhere, but are most common on the extremities (Fig. 26-13). Some patients with this overlap syndrome may progress to systemic lupus erythematosus. In other instances, laboratory evaluation may reveal only a weak-positive antinuclear antibody. This disease variant is characterized by a prolonged course and lack of response to treatment. Histologically, a lichenoid reaction typical for lichen planus and histologic features of lupus erythematosus are usually present in the same biopsy.[26] By direct immunofluorescence, the most common finding is the presence of cytoid bodies staining with IgG, IgM, and C3 intraepidermally or at the dermal-epidermal junction, as seen in classic lichen planus. Linear to granular deposition of IgM and C3 (as seen in lupus erythematosus, but not in lichen planus) has been observed occasionally. Shaggy deposition of fibrinogen at the basement membrane zone, typical of lichen planus, is sometimes found.[26]

Lichen Planus Pemphigoides. Lichen planus pemphigoides is characterized by the development of tense blisters atop lesions of lichen planus or the development of vesicles de novo on uninvolved skin (Fig. 26-14). It is important to differentiate this entity from bullous lichen planus, in which blisters develop in lesions of long-standing lichen planus as a result of intense lichenoid inflammation and extensive liquefaction degeneration of basal keratinocytes. The etiology of this variant is not clear. It was proposed that basal cell keratinocyte damage by lymphocytes in lichen planus may unmask hidden antigenic determinants and lead to autoantibody formation and induction of bullous lesions. Histologic findings resemble those of lichen planus. Direct immunofluorescence shows linear deposition of IgG and C3 at the dermal-epidermal junction. Sera from these patients react with the epidermal side of NaCl-split human skin. Circulating IgG autoantibodies react to the major noncollagenous extracellular domain (NC16A) of the 180-kd bullous pemphigoid antigen within the basement membrane zone. Further mapping showed that lichen planus pemphigoides serum reacts with amino acids 46 to 59 of domain NC16A, a protein segment that was previously

shown to be unreactive with bullous pemphigoid sera. This newly described epitope is designated *MCW-4*.[27]

Keratosis Lichenoides Chronica (Nekam Disease)

Lichenoid Reaction of Graft-Versus-Host Disease. (see Chap. 28) Chronic graft-versus-host disease (GVHD) (occurring 100 days after transplant) may present as a lichenoid eruption indistinguishable clinically and histologically from lichen planus. Lichenoid GVHD favors the trunk, buttocks, hips, thighs, palms, and soles. In oral mucosa, xerostomia and oral ulcerations are occasionally seen. Histologically, the findings in lichen planus and oral GVHD are similar, although infiltrating $CD3^+$ T lymphocytes are present in larger numbers in oral lichen planus than in lichenoid lesions of oral GVHD.[29] In a comparative study between those two entities, the number of natural killer cells, Leu-8–positive T cells (homing receptor: CD62L, LECAM), CD25-positive lymphocytes, and the CD4:CD8 ratio were not different. Langerhans cells are often increased in both conditions.

Lichenoid Keratosis. Lichenoid keratoses are brown to red, scaling maculopapules found on sun-exposed skin of extremities. Histologic features of lichen planus are present, with the additional finding of focal parakeratosis. They frequently occur with solar lentigo, seborrheic keratosis, and actinic keratosis and likely represent an "involuting lichenoid plaque."[30]

Lichenoid Dermatitis

Related Findings

Lichen planus is seen with increased frequency in association with liver diseases such as autoimmune chronic active hepatitis, primary biliary cirrhosis, and postviral chronic active hepatitis.[32] The association with primary biliary cirrhosis is observed regardless of treatment with D-penicillamine, a drug that may cause an exacerbation of lichen planus.

The role of infection in development of lichen planus has been repeatedly raised over the years. Association of lichen planus with syphilis, herpes simplex virus 2, HIV, amebiasis, and chronic bladder infections has been reported.[2] HCV has also been implicated in triggering lichen planus.[7] The prevalence of HCV infection varied between 16 percent and 29 percent in southern European patients with lichen planus.[33,34] On the other hand, many studies from northern Europe and the United States did not substantiate any link.[35,36] Genetic factors controlling disease susceptibility and prevalence of certain HCV genotypes in certain geographic areas may have significantly influenced these results.

Recently, several reports described lichen planus–like eruptions after hepatitis B vaccination.[37]

There is no evidence to link lichen planus to diabetes mellitus, autoimmune diseases, or internal malignancies. Cases of severe erosive gingivitis and stomatitis with histologic appearance of lichen planus in association with internal malignancies may represent cases of paraneoplastic pemphigus (see Chap. 53). The pathologic spectrum of findings and target organ involvement in this condition is broad, ranging from lichenoid dermatitis to frank acantholysis, such that a preferred term is *paraneoplastic autoimmune multiorgan syndrome*.[38]

Lichen Planus and Malignant Transformation

There has been considerable controversy as to whether oral lichen planus inherently harbors malignant potential.[39] It is currently believed that the risk of malignant transformation is fairly low (Fig. 26-15). Risk factors that increase the likelihood of developing oral cancer are long-standing disease, erosive or atrophic types, and tobacco use. It is generally accepted that 0.5 percent to 5.0 percent of patients with oral lichen planus develop SCC. The majority of these cases are in situ carcinoma or with microinvasive pattern. The most common site for malignant transformation is the tongue, followed by buccal mucosa, gingiva, and, rarely, the lip. Clinically, the lesions appear as indurated, non-healing ulcers or exophytic lesions with a keratotic surface in the majority of cases. Red atrophic plaques could also be seen and often correlate with SCC in situ. Advanced cases could result in nodal metastases and occasionally death.[39]

▲ **FIGURE 26-15** Lichen planus and squamous cell carcinoma. Long-standing oral lichen planus with scarring changes of tongue. Circumscribed erythroplakia and erosions of the right lateral tongue was biopsied and confirmed squamous cell carcinoma.

The risk of skin malignancy in cutaneous lichen planus is extremely low. Most patients developing SCC in cutaneous lichen planus had a history of either arsenic or x-ray exposure.

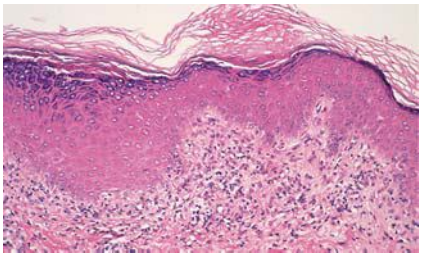
Laboratory Tests

No specific abnormalities of laboratory analyses are seen in lichen planus. The total white blood cell count and lymphocytes may be decreased. This could be related to cytokine activation and local trafficking of cells to skin or other tissue compartments.

Patch tests in patients with oral or cutaneous lichen planus usually reveal positive results in a majority of patients.[5] Sensitivity to mercury and gold is often positive in one-half of the cases. Chromate, flavoring agents, acrylate, and thimerosal are common sensitizers.[20,21]

Pathology

The two major pathologic findings in lichen planus are basal epidermal keratinocyte damage and lichenoid-interface lymphocytic reaction. The epidermal changes include hyperkeratosis, wedge-shaped areas of hypergranulosis, and elongation of rete ridges that resemble a sawtooth pattern (Fig. 26-16). Multiple apoptotic cells or colloid-hyaline (Civatte) bodies are seen at the dermal-epidermal junction. Eosinophilic colloid bodies are present in the papillary dermis. They are periodic acid-Schiff–positive and measure approximately 20 μm in diameter. A band-like lymphocytic infiltrate is seen in the papillary dermis that abuts the epidermis. Many histiocytes and few plasma cells are seen. Plasma cells are more prominent in mucous membrane specimens. Few eosinophils are seen in drug-induced lichen planus or lichenoid drug eruptions. Melanin pigmentation is invariably present and is more pronounced in older, waning lesions and in dark-skinned individuals. Separation of the epidermis in small clefts (Max Joseph cleft formation) is occasionally seen (Fig. 26-17).



▲ **FIGURE 26-16** Lichen planus. Typical hyperkeratosis, hypergranulosis, early sawtooth changes, and lichenoid interface reaction of classic lichen planus.

Direct immunofluorescence shows numerous apoptotic cells at the dermal-epidermal junction staining with IgM and, occasionally, with IgG and IgA. Shaggy deposition of fibrinogen at the dermal-epidermal junction is characteristic of lichen planus (Fig. 26-18). Immunocytochemical studies show that the majority of the cells in the infiltrate are T lymphocytes, with scattered B lymphocytes. An increased density of Langerhans cells, dermal dendritic cells, and histiocytes have also been seen, especially in early active lesions.

Features that may be seen in lichenoid drug eruptions, but not in lichen planus, include the presence of abundant plasma cells and eosinophils in the infiltrate, focal parakeratosis and hypogranulosis, and the presence of cytoid bodies high in the stratum corneum. Furthermore, lymphocytic infiltration is less dense and not as band-like as that seen in classic lichen planus.

The differential diagnosis of lichen planus is shown in Boxes 26-1 and 26-2.

PROGNOSIS AND CLINICAL COURSE

Lichen planus is an unpredictable disease that typically persists for 1 to 2 years, but which may follow a chronic, relapsing course over many years. The duration varies according to the extent and site of involvement and morphology of lesions. Generalized eruptions tend to have a rapid course and heal spontaneously faster than limited cutaneous disease. Lichen planopilaris is one of the most chronic and often progressive disease variants with little potential for hair regrowth after follicular inflammation and destruction.[16] Hypertrophic lichen planus typically follows a protracted, unremitting course.[2] Spontaneous regression is also an uncommon feature of oral lichen planus. The mean duration for oral lichen planus is 5 years. The reticular variant has a better prognosis than erosive disease that does not heal spontaneously. Generally, the duration of disease conforms to the following order, from shortest duration to longest duration: (1) generalized, (2) cutaneous, (3) cutaneous + mucous membrane, (4) mucous membrane, and (5) hypertrophic = lichen planopilaris.

Relapse of disease occurs in 15 percent to 20 percent of cases and tends to occur in the same area as the initial episode. Recurrences are more common in generalized lichen planus and are usually of shorter duration.

Malignant transformation may occur, and SCC usually develops in fewer than 1 percent of persistent oral-mucous lesions on long-term follow-up.[41]

discomfort and disability. Hence, treatment options should be assessed for attendant risks and benefits and tailored to the extent and severity of disease. Avoidance of exacerbating drugs, unless necessary, and minimizing trauma to skin and mucosal tissues are routinely recommended.

Various drugs have been proposed for the treatment of oral[42–52] and cutaneous lichen planus[53–66] and the majority of these consist of small series of patients or anecdotes. Many of the advocated treatments lack conclusive evidence for efficacy.[67]

Oral Lichen Planus (Box 26-3)

GENERAL MEASURES For oral lichen planus, good oral hygiene and regular personal and professional dental care need to be encouraged. Several treatment approaches are useful for oral or mucous membrane lichen planus. Replacement of amalgam or gold dental restorations with composite material is frequently of considerable benefit in patients with oral lichenoid reactions, even in the apparent absence of relevant patch test results. Chronic lesions on the buccal mucosa in contact with metal or other contact sensitizers frequently heal promptly after replacement,[20,21] and, occasionally, lesions at sites distant to oral lesions may also clear after removal of metal restorations. Gingival lesions may respond less favorably. The decision to undergo removal and restoration is often difficult and usually depends on the chronicity, severity, and clinical and patch test evidence for involvement by the metal/prosthesis as well as the level of frustration of the patient.

Topical Steroids. Topical steroids are the first-line therapy in mucosal lichen planus.[44] A variety of topical glucocorticoids have been shown to be effective. Use of occlusive materials suitable for mucous membranes, such as Orabase, may provide protection and sustained tissue contact with the glucocorticoid, as well as alleviate the discomfort associated with erosive lesions. Fluocinonide in an adhesive gel or base, 0.1% fluocinolone acetonide, and 0.05% clobetasol propionate in Orabase showed good results. Application four to six times/day is recommended. Treatment may be complicated by frequent infections with oral candidiasis. The use of chlorhexidine gluconate mouthwashes and topical anti-candidal medications is recommended during therapy.

In some situations where secondary irritation and inflammation of oral tissues appear to be related to colonization of the mouth by candida, an antifungal treatment course (troche or oral) may be indicated.

Topical anesthetics also provide symptomatic benefit for patients with difficulty eating and chewing. It is often compounded with topical corticosteroids. Glucocorticoids containing vaginal and rectal suppositories are usually helpful for mucosal involvement in these areas.

Glucocorticoids can be administered by intralesional injection. Triamcinolone acetonide 40 mg/mL or at diluted concentrations if effective and safe.[68]

SYSTEMIC GLUCOCORTICOIDS. Systemic glucocorticoids provide effectiveness in erosive oral and vulvovaginal lichen planus. Systemic dosing can be used alone, or, more commonly, in conjunction with topical glucocorticoids. A dose range from 30 to 80 mg/day, tapered over 3 to 6 weeks, shows benefit. Relapses are common after dose reduction or discontinuation. Higher doses are often needed for esophageal lichen planus. Oral candidiasis is a common complication.

RETINOIDS. Topical retinoic acid (tretinoin gel) has been shown to be effective in erosive as well as plaque-like oral lesions. Irritation often makes this localized approach to therapy less attractive. Isotretinoin gel is also effective, especially in nonerosive oral lesions. Improvement is usually noted after 2 months; however, recurrence is common after discontinuation of therapy.[69] Topical retinoids are often used in conjunction with topical glucocorticoids. Although not proven in clinical trials, this may improve the efficacy and lessen the side effects.

Etretinate orally has been used at 75 mg/day (0.6 to 1.0 mg/kg/day) in erosive oral lichen planus with significant improvement in the majority of patients. Relapses are common after discontinuation of medication.[45] Two-thirds of patients showed marked improvement or complete remission within 8 weeks of instituting acitretin, 30 mg/day.[46] Only the aromatic retinoid acitretin is currently available by prescription after the removal of etretinate from the U.S. market. There is no conclusive data on the efficacy of oral tretinoin or isotretinoin.

CYCLOSPORINE, TACROLIMUS, AND PIMECROLIMUS. Topical application of cyclosporine, 100 mg/mL, 5 mL three times daily has shown benefit for oral li-

				Methotrexate	Refractory lichen planus

chen planus. Application modalities include mouthwashes and manual administration with local massage. Topical cyclosporine washes seem to be effective in oral lichen planus, especially the severe erosive forms,[47] but they do not appear to be better than local glucocorticoid therapy. Lack of effectiveness in a few cases[48] and the high cost of this medication, as well as the lack of a commercial formulation for topical application limit its use. Availability of alternate topical immunosuppressive agents, tacrolimus and pimecrolimus, currently provides useful substitutes to topical cyclosporine.[70–72] Tacrolimus, a member of the immunosuppressive macrolide family that suppresses T-cell activation is effective in erosive mucosal disease, providing rapid relief from pain and burning with minimal side effects.[49] Oral cyclosporine at dose regimens of 3 to 10 mg/kg/day has been used for severe ulcerative disease.

Miscellaneous. The polyene antifungal griseofulvin lacks clear effectiveness. Newer antifungal agents (e.g., fluconazole, itraconazole) may be useful in oral lichen planus with evidence of candida overgrowth, especially concomitantly with systemic glucocorticoids.

Hydroxychloroquine at 200 to 400 mg/day for at least 6 months is also used cautiously because antimalarials are implicated as possible inducers of lichen planus.[50]

Thalidomide should be reserved for cases recalcitrant to other remedies. The dose could be started at 50 mg/day and increased gradually to 200 mg/day.[51]

Dapsone can be used orally at 100 to 200 mg daily and has proved effective in two-thirds of patients with cutaneous and oral disease.

Extracorporeal photochemotherapy twice a week for 3 weeks and then tapered has had favorable results.[52] Other experimental therapies include efalizumab,[73] alefacept,[74] and even low-dose excimer 308-nm laser[75] and photodynamic therapy.[76] Azathioprine, cyclophosphamide, and mycophenolate mofetil have shown benefit in oral lichen planus, but randomized clinical trials are lacking.

Cutaneous Lichen Planus (Box 26-4)

TOPICAL GLUCOCORTICOIDS A large variety of topical and systemic therapies are available for the treatment of cutaneous lichen planus, and this range of options may be attributed to the chronicity, symptomatology, and variable responsiveness of the dermatosis. Topical glucocorticoids are typically used for limited cutaneous disease. Potent topical glucocorticoids, with or without occlusion, are occasionally beneficial in cutaneous lichen planus.

Intralesional triamcinolone acetonide (5 to 10 mg/mL) is effective in treating oral and cutaneous lichen planus. This may also be used in lichen planus of the nails with injection of the proximal nail fold every 4 weeks. Regression of lesions occurs within 3 to 4 months. For hypertrophic lichen planus, higher concentrations of intralesional glucocorticoid (10 to 20 mg/mL) may be required. Regular and close observation should be performed to monitor for any signs of atrophy or localized hypopigmentation that may develop; treatment should be discontinued promptly with development of these complications.

Systemic glucocorticoids are often useful and effective in doses greater than 20 mg/day (e.g., 30 to 80 mg prednisone) for 4 to 6 weeks with subsequent taper over 4 to 6 weeks. Other regimens include prednisone 5 to 10 mg/day for 3 to 5 weeks. Symptoms are often alleviated, and patients in the early stages of evolution or experiencing a flare have marked benefit and attenuation or aborted progression of disease. However, the rate of relapse after termination of therapy is unknown. In lichen planopilaris, potent topical glucocorticoids in conjunction with oral glucocorticoids, 30 to 40 mg/day, for at least 3 months, seems to be successful; however, relapse typically occurs following discontinuation. Long-term, chronic continuation of oral or injected glucocorticoids is contraindicated in most cases because of the high risk of complications.

RETINOIDS The systemic retinoids demonstrate anti-inflammatory activity and have been used in the treatment of lichen planus. Remission and marked improvement was achieved with 30 mg/day of acitretin for 8 weeks.[46] Oral tretinoin is used at 10 to 30 mg/day with marked improvement and mild side effects.[53] Low-dose etretinate (10 to 20 mg/day) use has been associated with complete remission of cutaneous, oral, and nail lichen planus after 4 to 6 months of treatment. Prompt beneficial response was noted with the use of 75 mg/day of etretinate,[54] but side effects of retinoids are dose related and may limit use of higher dose therapeutic regimens.

PHOTOCHEMOTHERAPY Psoralen and ultraviolet A (UVA) light photochemotherapy is usually successful in generalized cutaneous lichen planus. It has been used in conjunction with oral glucocorticoids to hasten the response. Bath psoralen and UVA light therapy

with 50 mg trioxsalen, added to 150 L of water, then exposing the patients to UVA after 10 minutes of bathing gave good results.[55] Recurrence of disease was noted. UVA-1 phototherapy may also benefit more protracted lichen planus.[77] Narrowband UVB is also beneficial in the treatment of disseminated cutaneous lichen planus.[56,78]

IMMUNOSUPPRESIVE AGENTS Systemic cyclosporine has been used successfully in recalcitrant lichen planus.[57] The administered dose can range from 3 to 10 mg/kg/day. Pruritus usually disappears after 1 to 2 weeks. Clearance of the rash is seen in 4 to 6 weeks. Low doses (1.0 to 2.5 mg/kg/day) are probably sufficient to achieve remission. Adverse effects on renal function, development of hypertension, and other significant side effects, as well as relapse after discontinuation of the drug, limit its use to severe cases.[58]

Azathioprine is useful in recalcitrant, generalized cutaneous lichen planus and in lichen planus pemphigoides.[59] Similar results are seen with mycophenolate mofetil at a dose of 1500 mg twice daily.[60]

MISCELLANEOUS Antimalarials, especially hydroxychloroquine at 200 to 400 mg/day, have been reported to be particularly useful in actinic lichen planus.[61]

IFN-α2b has been administered for treatment of generalized lichen planus with improvement, but this biologic response modifier also has been implicated in development or exacerbation of lichen planus.[62]

Thalidomide can be used in lichen planus unresponsive to other therapies.[63] Oral metronidazole 500 mg twice daily for 1 to 2 months also reportedly clears the majority of cases of generalized lichen planus.[64]

Based on the benefit in bullous pemphigoid, combination therapy with tetracycline or doxycycline and nicotinamide has been reported as useful in the treatment of lichen planus pemphigoides.[65]

Low molecular weight heparin in low doses has lymphoid antiproliferative and immunomodulatory properties.[66,79] At a dose of 3 mg weekly, heparin injections have been reported to significantly improve the symptoms of pruritus and activity of the disease. Four to six injections of heparin induced complete regression of lesions within 4 to 10 weeks. Cutaneous involvement and reticulated oral lesions had the best response. Oral lichen planus showed minimal improvement with this regimen.

Skin grafting has been beneficial in the management of ulcerative lichen planus of the feet that is recalcitrant to other treatments. Cyclophosphamide, methotrexate, and phenytoin reportedly are useful but should be reserved for cases refractory to less toxic drugs.

CHAPTER 27

Lichen Nitidus

Mark R. Pittelkow
Mazen S. Daoud

Lichen nitidus (Latin nitidus, "shiny" or "glistening") is an uncommon, usually asymptomatic cutaneous eruption first described by Felix Pinkus in 1901 and further characterized by him in 1907.[1,2] The dermatosis consists of small, glistening, flesh-colored to pink or reddish-brown papules that may be limited to the penis, genitalia, abdomen, and extremities or, less frequently, may occur as a generalized condition. The histopathologic findings are characteristic. Although the condition is often chronic, the prognosis is good, and no clearly associated systemic illnesses have been documented.

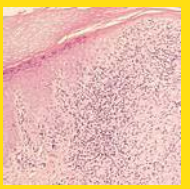
EPIDEMIOLOGY

Because the disease is uncommon, accurate epidemiologic characteristics of lichen nitidus have not yet been defined. Lichen nitidus is a dermatosis that occurs infrequently and has been reported to affect blacks more than Caucasians, although no strong predisposition for any race is clearly evident. Perhaps the relative prominence of pale lesions on dark skin accounts for the reported increased incidence in blacks. A predilection for children, young adults, and males has also been reported, but, again, these data are not well established. The incidence is estimated to be approximately 3.4 cases/10,000 population, based on a 25-year survey of skin diseases in African Americans.[3] Compared to the more common lichen planus, the crude ratio of lichen nitidus to lichen planus is 1.7:100, based on pathologic diagnosis of cases evaluated over several decades at the Mayo Clinic.

ETIOLOGY AND PATHOGENESIS

Once considered a tuberculoid reaction, lichen nitidus is currently regarded as a disorder of unknown etiology. The relationship between lichen nitidus and lichen planus has been debated for many

LICHEN NITIDUS AT A GLANCE



- Small, glistening, flesh-colored to pink or reddish-brown papules of unknown etiology.
- Distinctive, circumscribed infiltrate of lymphocytes and histiocytes in papillary dermis situated directly beneath thinned epidermis.
- There is no associated systemic disease.
- Prognosis is good.

TABLE 27-1
Comparison of Features between Lichen Nitidus and Lichen Planus

	Lichen Nitidus	Lichen Planus
Incidence	Rare	Common
Lesion		
Size	Usually 1–2 mm	Variable, usually larger
Shape	Round	Polygonal
Color	Flesh, pink, red-brown	Erythematous to violaceous
Wickham striae	Absent	Present
Mucosal changes	Rare	Variably present
Pruritus	Uncommon	Usually present, marked
Histopathology		
Hyperkeratosis	Variable and focal	Usually present
Parakeratosis	Mostly present	Not found
Infiltrate	Focal in one to three papillary bodies	Band-like, extends through many rete ridges
Lymphocytes	Variable	Vast majority of cells
Histiocytes	Variable, almost always present	Almost none
Giant cells	Occasional	None
Dyskeratotic	Occasional	Very common
Immunopathology		
Cytoids	Usually negative	Immunoglobulin M and other conjugates
Basement membrane	Usually negative	Fibrinogen, other conjugates
Immunohistochemistry		
$CD4^+$ lymphocytes	Majority of cells	Majority of cells
$CD68^+$ cells	Common	Uncommon

years.[4] The co-existence of both diseases in some patients and the observation that the discrete, tiny papules of lichen planus are indistinguishable from those of lichen nitidus were used to support the view that lichen nitidus is a variant of lichen planus. However, most experienced clinicians, as well as research studies, favor the separation of these two diseases as distinct entities based on both clinical and immunodermatopathologic differences and the characteristic and distinctive histologic changes. Table 27-1 summarizes some of these differences and similarities. Another etiologic theory of lichen nitidus proposes that an allergen may cause epidermal and dermal antigen-presenting cells (e.g., Langerhans cells) to activate a cell-mediated response, initiate lymphocyte accumulation, and form discrete inflammatory papules. The presence of large numbers of Langerhans cells in the infiltrate supports this theory.[5] Specific cytokines produced by the inflammatory cells influence the immune response and may shift the T lymphocyte response toward the T helper 2 subset that has the potential to produce the superficial dermal granulomas seen in lichen nitidus.[6] Functional impairment in cellular immunity has been reported in generalized lichen nitidus,[7] and lichenoid photoeruptions similar to lichen nitidus were seen in a patient with HIV infection.[8] Rare cases of lichen nitidus associated with atopic dermatitis, Crohn disease, and juvenile chronic arthritis have been reported. Induction of allergic contact dermatitis by topical application of dinitrochlorobenzene in a patient with lichen nitidus cleared the eruption, presumably by altering the cellular immunity, cellular infiltration, and cytokine expression.[6]

A rare familial presentation of lichen nitidus has been reported, although no genetic factors of the disease have been identified.[9]

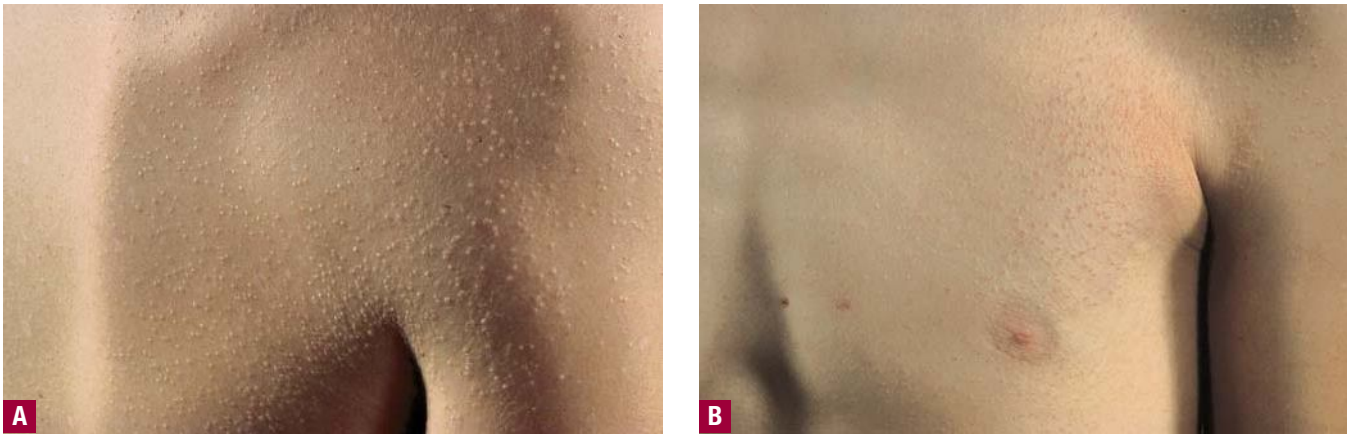
CLINICAL FINDINGS

Lichen nitidus is composed of multiple, discrete, smooth, flat, round papules. Individual papules are 1 to 2 mm in size, flesh-colored to slightly pink or, in blacks, hypopigmented, with a glistening appearance (Fig. 27-1). Sometimes, minimal scale is present or can be elicited by rubbing the surface of the papules. Occasionally, the papules are grouped and the isomorphic or Koebner phenomenon is observed. Lesions may occur anywhere over the skin surface; however, the most frequent sites of predilection are the flexural surfaces of the arms and the wrists, lower abdomen, breasts, the glans and shaft of the penis, and other areas of the genital region. Rare sites of involvement include mucous membranes, nails, palms, and soles. Rare clinical variants include vesicular, hemorrhagic, spinous follicular, linear, generalized, and actinic types.[10–16]

Palmo-plantar involvement may manifest several morphologic forms. Bilateral hyperkeratosis of palms and soles with erythema, fissuring, and a texture resembling fine sandpaper has been observed.[13,14] Occasionally, minute keratotic spicules on the palmar surfaces or multiple pinpoint papules that extend to the dorsa of the extremities occur (Fig. 27-2). Nail abnormalities usually manifest as longitudinal, beaded ridging, and terminal splitting with or without irregular pitting. Lesions of lichen planus may infrequently be present simultaneously.[17] Lichen nitidus is usually asymptomatic; however, pruritus is occasionally present and sometimes intense. There are no constitutional symptoms or systemic abnormalities associated with the disease. Lichen nitidus has been reported after hepatitis B vaccination.[18]

PATHOLOGY

A dense mass of infiltrating lymphohistiocytic cells is situated immediately below the epidermis and results in widening of the papillary dermis with elongation and the appearance of embracement by neighboring rete ridges (Fig. 27-3). Occasionally, two or three papillary spaces merge together as part of the inflamma-

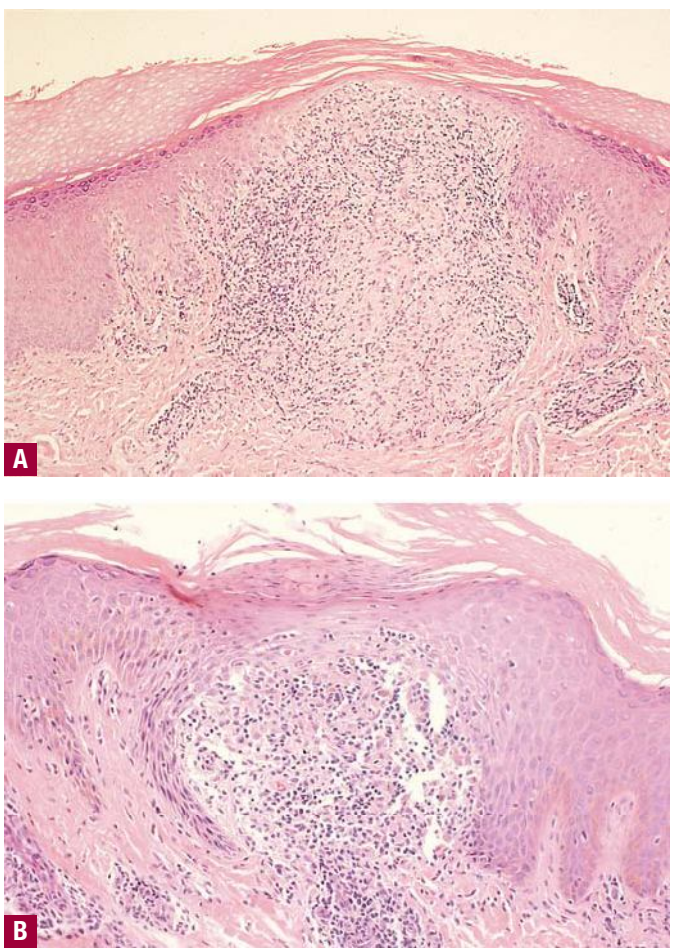


▲ **FIGURE 27-1** Lichen nitidus. **A.** Pinpoint to pinhead, discrete, dome-shaped papules over upper back, shoulder, and arm. Side-lighting, as performed here, enhances visualization of multiple small lesions. **B.** Individual papules, flesh- to pink-colored over chest and arm, becoming more grouped over anterior axilla.

tory infiltrate. The overlying epidermis is thinned and occasionally demonstrates central parakeratosis without hypergranulosis. This is a characteristic diagnostic finding, when observed (see Fig. 27-3B). Minimal hydropic degeneration with few dyskeratotic cells is usually observed within the basal epidermal layer adjacent to the papillary dermal infiltrate. With the development of hydropic degeneration, basal cell disruption, and epidermal thinning, the epidermis may partially detach from the dermis. Colloid bodies are rarely seen in lichen nitidus, in contrast to their frequent occurrence in lichen planus. The dermal infiltrate is well circumscribed and composed of closely associated histiocytes, lymphocytes, and occasional foreign body or Touton-type giant cells. Usually, no plasma cells or eosinophils are seen. In some cases, the majority of the cells in the infiltrate are histiocytic. Palmar lesions may show a deep parakeratotic plug. Transepithelial elimination of the inflammatory infiltrate has been described.[5] Purpuric or hemorrhagic lesions are associated with capillary wall degeneration and red blood cell extravasation.[11]

The majority of the cells in the infiltrate are T lymphocytes intermixed

▲ **FIGURE 27-2** Lichen nitidus. Wrist and palmar involvement with development of hyperkeratotic lesions.



▲ **FIGURE 27-3** Lichen nitidus. **A.** Distinctive, circumscribed infiltrate of papillary dermis situated directly beneath thinned epidermis. Many histiocytes mingle with lymphocytes that are enveloped by bordering rete ridges. (Hematoxylin and eosin.) **B.** Central parakeratosis, epidermal thinning, and loss of granular layer with focus of granuloma-appearing, inflammatory cells and reactive, finger-like extensions of epidermis. (Hematoxylin and eosin.)

with few to many histiocyte–macrophages that stain with CD68, as well as epidermal Langerhans cells and indeterminate cells that express S100 protein. $CD4^+$ cells predominate over $CD8^+$ T lymphocytes. Many cells in the infiltrate express HLA-DR antigen, which implicates them as antigen-presenting cells.[5]

Direct immunofluorescence examination of lichen nitidus is usually negative for deposition of immunoglobulins at the dermal-epidermal junction, in contrast to the vast majority (95 percent) of cases of lichen planus (see Table 27-1).[19] Cytoids are also not usually observed in lichen nitidus. The results of ultrastructural studies coincide with light microscopic findings and also show activated lymphocyte morphology with convoluted nuclei, resembling Sézary cells.[20]

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of lichen nitidus is summarized in Box 27-1. The most important differential diagnosis is lichen planus and is detailed in Table 27-1.

PROGNOSIS AND CLINICAL COURSE

Lichen nitidus is typically a focal, asymptomatic, chronic inflammatory reaction that eventually resolves spontaneously after months to 1 year in two-thirds of patients or, less frequently, over a few years. Rarely, the eruption may persist indefinitely. New lesions may continue to develop as older lesions resolve. Lesions heal without scar formation or pigmentary abnormalities.

Box 27-1

Differential Diagnosis of Lichen Nitidus

Most Likely

- Lichen planus
  - CD8 lymphocytes predominate
  - No granulomatous inflammation
- Psoriasis
  - Plaques has silvery scale
- Verruca plana
  - Variable in size
  - Verrucous surface
  - Fewer lesions than lichen nitidus
  - Less likely to involve multiple anatomic areas
- Keratosis pilaris
  - More keratotic and scaling
  - Hand dermatitis
  - Palmo-plantar involvement of lichen nitidus

Consider

- Lichen spinulosus
- Papular eczema
- Lichen scrofulosorum
- Lichenoid syphilitic lesions
- Bowenoid papulosis
- Sarcoidosis
- Lichen amyloidosus

TREATMENT

Because the disease is asymptomatic and self-limiting, no intervention is required in most cases. Treatment of lichen nitidus is warranted when it is associated with protracted pruritus or when the appearance interferes with the patient's daily activities and outlook. Topical glucocorticoids may yield favorable results. A short course of oral glucocorticoids may also be helpful and hasten resolution of more extensive, generalized, or symptomatic disease.[22] Psoralen and ultraviolet A light,[21] ultraviolet A and B phototherapy,[22] astemizole,[23] acitretin or etretinate,[14,17] low-dose cyclosporine,[24] and oral itraconazole[25] have also been used successfully when indicated for more problematic disease.

Narrowband ultraviolet B could be a safe and effective treatment in generalized lichen nitidus.[26,27] Tacrolimus ointment was also reported to be effective after 1 month of therapy.[28] History of exposure to tuberculosis in the setting of lichen nitidus should be investigated and when appropriate treated with antituberculous medications. Complete clearance of lichen nitidus was seen in one case.[29]

CHAPTER 28

Graft-Versus-Host Disease

Misty T. Sharp
Thomas D. Horn

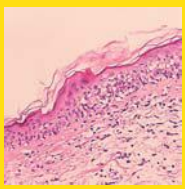
Dermatologists play an important role in the evaluation and management of patients at risk for or diagnosed with graft-versus-host disease (GVHD). Of all organs that may be affected in GVHD, the skin is the earliest and most frequent target. To evaluate patients optimally, the dermatologist must know the type of marrow transplant, any manipulation of marrow before infusion, the preparative regimen used, the date of marrow infusion, the peripheral white blood cell count, the medications administered, and the course of hospitalization.

The clinical manifestations, histopathologic features, treatment, and pathogenesis of GVHD with emphasis on the skin are considered in this chapter. Table 28-1 provides definitions for several commonly used terms.

ERUPTION OF LYMPHOCYTE RECOVERY

The concept of development of cutaneous eruptions at the time of peripheral recovery of lymphocytes after marrow-ablative therapy unifies all diagnoses considered in this chapter.[4] As defined initially, the eruption of lymphocyte recovery occurred with the earliest return of lymphocytes to the peripheral circulation of patients with acute leukemia who did not receive a marrow transplant.[5] The eruptions consisted of erythematous coalescing macules, predominantly on the trunk and proximal extremities. Skin biopsy specimens revealed non-specific changes, with an upper dermal perivascular infiltrate of lymphocytes and variable epidermal spongiosis but no significant epidermal cell necrosis. An acute elevation in temperature accompanied the cutaneous eruptions. Resolution of the eruption occurred with multi-line hematologic recovery.

GRAFT-VERSUS-HOST DISEASE AT A GLANCE



- Acute cutaneous graft-versus-host reaction (GVHR) develops in 20 percent to 80 percent of patients undergoing allogeneic bone marrow transplantation, usually 10 to 30 days after infusion.
- Skin is the earliest and most frequent target. Liver and gastrointestinal disease are also common; the presence of elevated total bilirubin levels and diarrhea can aid in establishing the diagnosis.
- Predisposing factors include mismatch in major histocompatibility complex antigens, transplantation between unrelated individuals, older age, and certain prophylactic regimens, among others.
- The eruptions of acute GVHR consist of faint, erythematous macules on any skin surface, which may begin in a perifollicular pattern (early stages) and progress to erythroderma (later stages) or bullae (stage 4).
- Pathologic features of acute GVHR consist of an infiltrate of lymphocytes in the dermis, basal vacuolar alteration, and necrosis of epidermal cells at a frequency of at least four per linear millimeter of epidermis (grade 2).
- Chronic GVHR generally occurs longer than 60 days after allogeneic marrow transplantation at an incidence of roughly 25 percent; it is divided into lichenoid and sclerodermoid forms.
- Cutaneous eruptions simulating acute allogeneic GVHRs occur after autologous and syngeneic transplantation in up to 10 percent of patients.

This concept of lymphocyte recovery eruption has application to the field of stem cell transplantation, because graft-versus-host reactions (GVHRs) develop at the time of peripheral lymphocyte recovery and represent this phenomenon with immunologic differences between donor and recipient or in the setting of some immunologic manipulation. Indeed, some histologically non-specific cutaneous eruptions among patients at risk for GVHD may represent an eruption of lymphocyte recovery rather than a true GVHR, because acute cutaneous GVHR requires the epidermis to be targeted for cytotoxic damage by an effector lymphocyte population.

EPIDEMIOLOGY AND INCIDENCE

Marrow-ablative regimens vary. Combinations of cyclophosphamide, busulfan, total-body exposure to ionizing radiation, methotrexate, and thiotepa are used. Acute cutaneous GVHR develops in 20 percent to 80 percent of patients, usually 10 to 30 days after stem cell infusion. Factors that predispose to the occurrence of GVHD include mismatch in major histocompatibility complex (MHC) antigens, transplantation between unrelated individuals (Table 28-2), older age, and prophylactic regimen, among others. Patients receive cyclosporine in high doses at the time of stem cell infusion to promote engraftment and prevent maximal expression of GVHD. Other modalities used to diminish the severity of GVHD require the use of various antibodies to remove putative effector cell populations from the graft.

Chronic GVHD is categorized into lichenoid and sclerodermoid forms. The lichenoid phase generally develops earlier than the sclerodermoid phase, and both usually occur longer than 60 days after transplantation. Some patients experience both forms of the disease sequentially or concurrently. The greatest predictor for the development of chronic GVHR is prior acute GVHD.[6] The incidence of chronic cutaneous GVHR is roughly 25 percent. Rare reports of chronic GVHR after autologous transplantations exist.[7]

Cutaneous eruptions simulating acute allogeneic GVHRs occur after autologous and syngeneic transplants in up to 10 percent of patients.[8] Prospective evaluation of eruptions in patients receiving peripheral stem cell transplants has not been undertaken, but mild eruptions do occur at the time of peripheral lymphocyte recovery. The long-term administration of low-dose cyclosporine in the setting of autologous marrow transplantation promotes a graft-versus-host (GVH)–like eruption in roughly 60 percent of patients. Theoretically, cyclosporine, given in low dosage, promotes escape from thymic and peripheral mechanisms regulating expression of self-targeted mechanisms and thus allows expression of autoimmunity.[9] This autoimmunity resembles a mild acute cutaneous allogeneic GVHR. Again with the goal of enhancing graft-versus-tumor effect, protocols exist that add interferon-γ (IFN-γ) and interleukin 2 to cyclosporine regimens. These cytokines support general immunologic reactions and expand T-cell populations, and it is hoped they will prime any graft-versus-tumor effect that may accrue with autologous transplantation. Eruptions in this setting are more common and more severe, leading to erythroderma (stage 3 disease), an otherwise uncommon finding after autologous transplantation.[10]

Whether these eruptions are truly GVHRs as seen after allogeneic transplantation is uncertain. Because autologous marrow and peripheral stem cell transplant programs increasingly are performed outside university centers, dermatologists will encounter these eruptions more frequently. To assess clinical trial outcomes adequately, dermatologists and pathologists in academic centers must assess the occurrence of GVH-like reactions accurately.

ETIOLOGY AND PATHOGENESIS

Acute Cutaneous Graft-Versus-Host Reaction after Allogeneic Stem Cell Transplantation

The precise pathophysiology of GVHD is not known. A distillation of many lines of evidence implicates allostimulation of donor lymphocytes by major and/or minor

TABLE 28-1
Terms and Definitions

TERM	DEFINITION
• Allogeneic	Between two individuals
• Autologous	From the same person
• Syngeneic	Between two individuals with identical genetic material
• Xenograft	Transplanted tissue from another species
• Graft-versus-host disease (GVHD)	The totality of organ dysfunction attributable to the targeting of the recipient's tissues by immunocompetent lymphocytes
• Graft-versus-host reaction (GVHR)	The expression of GVHD in a specific organ (e.g., cutaneous GVHR)
• Stage	A term referring to clinical findings
• Grade	A term referring to histopathologic findings

TABLE 28-2
Overview of Acute Graft-Versus-Host Disease (GVHD) by Type of Transplant

Marrow Transplant	Incidence and Severity of GVHD	Cutaneous Manifestations	Treatment	Histopathology
Allogeneic, matched	++	Erythematous macules and papules, variable distribution; bullae rare	Prednisone FK-506 Anti-thymocyte globulin Monoclonal antibodies	Dermal infiltrate of lymphocytes, more than four necrotic epidermal cells per linear millimeter, sub-epidermal bulla
Allogenic, mismatched	+++	Generally greater distribution and intensity than for allogeneic, matched	Same	Same
Allogenic, unmatched	++++	Generally greater distribution and intensity than for allogeneic, matched	Same	Same
Allogenic, unmatched, unrelated	++++	Generally greater distribution and intensity than for allogeneic, matched	Same	Same
Syngeneic	+	Generally less widely distributed than for allogeneic, matched	Usually none	Fewer lymphocytes, fewer necrotic keratinocytes than for allogeneic, matched
Autologous	+	Generally less widely distributed than for allogeneic, matched	Usually none	Changes resemble eruption of lymphocyte recovery
Autologous with cyclosporine	++	Generally less widely distributed than for allogeneic, matched	Usually none	Fewer lymphocytes, fewer necrotic keratinocytes than for allogeneic, matched
Autologous with cyclosporine and interferon-γ	++	Eruption more widespread, erythroderma more common than for autologous with or without cyclosporine	Prednisone rarely for erythroderma	Spongiosis often a prominent feature with fewer necrotic epidermal cells than for allogenic, matched

+ to ++++ = less common/severe to most common/severe.

transplantation antigens, with subsequent targeting of host tissues, mostly epithelial, for cytotoxic damage. It is unclear whether direct lymphocyte-mediated damage occurs via molecules such as granzyme and perforin, whether cytokines are the main mediators of cell death, or whether both mechanisms are operative.[11] Epithelial cell death ensues by apoptosis, with evidence implicating T cell–mediated mechanisms as well as noncellular triggers.[12,13]

It is unlikely that a specific lymphocyte subset consistently mediates GVHD. Many epitopes on major and minor histocompatibility antigens are likely to promote allostimulation, resulting in numerous populations of effector lymphocytes in target organs. Indeed, several cytotoxic T-cell clones have been isolated and identified from the skin of a single patient.[14] $CD4^+$ and $CD8^+$ cell lines are capable of mediating epidermal damage. In a murine model of GVHD, the effector population mediating the cutaneous GVHR varied with the strains used in the transplant,[15] which suggests that among humans each donor-recipient pair is nearly unique, with the potential to use different lymphocyte subsets in subsequent GVHD. Evidence exists to implicate $CD4^+$ T cells as major mediators of human disease.[16] These considerations are likely to explain the variability of disease expression, irrespective of MHC match or mismatch.

Other cell types are likely involved in mediating GVHD. The presence of numerous natural killer cells in the dermal and epidermal infiltrates of cutaneous GVHRs suggests that these cells are recruited once the antigen-specific recognition phase of the immunologic reaction has occurred in a target tissue.[17] Mast cells and dermal dendrocytes increase in number in the superficial dermis during acute phases of the disease.[18]

Why cutaneous involvement in GVHD is so frequent and early compared with liver and gastrointestinal disease is unknown.

Chronic Cutaneous Graft-Versus-Host Reaction after Allogeneic Stem Cell Transplantation

Chronic GVHD in the skin bears great similarity to various diseases presumed to be autoimmune in origin. Empirical observation suggests the connection between lichen planus, scleroderma, and Sjögren's syndrome with phases of cutaneous GVHR. Improper regulation of autoreactive elements of the immune system is proposed as an explanation for the development of these disorders.[19] Strong evidence links transforming growth factor-β to the development of skin and visceral changes in sclerodermoid GVHD, with neutralizing antibodies capable of reversing the fibrosis in a mouse model.[20] In women with scleroderma, persistent chimerism of male fetal tissue is identified. A fetal antimaternal immunologic reaction is proposed as the GVH-like mechanism mediating the disease.[21] Cutaneous fibroblasts in sclerodermatous skin express MHC class II molecules and make abnormally large amounts of type I collagen.

As the use of peripheral blood stem cell transplantation increases, it is important to note a possible higher associated incidence of chronic GHVD.[22]

Acute Cutaneous Graft-Versus-Host Reaction after Autologous and Syngeneic Marrow and Peripheral Stem Cell Transplantation

In rodents and humans, evidence exists that autoimmunity is directed against one or more epitopes on the MHC class II molecule.[23] Because IFN-γ upregulates MHC class II expression (ideally on tumor cells), and because cyclosporine promotes MHC class II–reactive T lymphocytes, this therapy combined with the dose intensification of autologous transplants leads to enhanced GVH-like cutaneous reactions and possibly the beneficial graft-versus-tumor effect.

▲ **FIGURE 28-1** Acute cutaneous graft-versus-host reaction (GVHR). Erythematous macules involving the pinna (**A**), palms (**B**), and soles are typical in early stages of cutaneous GVHR after allogeneic and autologous marrow transplantation.

▲ **FIGURE 28-3** Acute cutaneous graft-versus-host reaction (GVHR). Diffuse erythema may evolve in acute cutaneous GVHR and is often faint.

CLINICAL FINDINGS

History

The optimal evaluation of a patient with suspected GVHD should begin with the identification of certain key factors in the patient's history. The type of stem cell transplantation, any manipulation of stem cells before infusion, the preparative regimen used, the date of stem cell infusion, the white blood cell count, any medications administered, and the hospitalization course are all important aspects of the history to consider. Although the most common clinical scenario resulting in an acute cutaneous GVHR is allogeneic stem cell transplantation, an acute cutaneous GVHR may arise after maternal-fetal transfer of lymphocytes[24] as well as after blood transfusion[25] and solid organ transplantation, most commonly of a liver containing numerous immunocompetent lymphocytes.[26]

The presence of any signs indicative of extracutaneous GVHD, such as diarrhea, can be helpful. However, the absence of such signs should not dissuade the clinician from a diagnosis of GVHD given the proclivity for early, isolated skin involvement. These things, coupled with the clinical and histologic findings, as discussed later, can aid the dermatologist in establishing a diagnosis of either acute or chronic GVHD, which facilitates early intervention.

Cutaneous Lesions

ACUTE CUTANEOUS GRAFT-VERSUS-HOST REACTION AFTER ALLOGENEIC TRANSPLANTATION The eruption of an acute GVHR generally begins with faint erythematous macules on any skin surface but often the palms, soles, and pinnae (stage 1) (Fig. 28-1). The specificity of palmoplantar erythema in the diagnosis of a cutaneous GVHR is questionable because chemotherapy alone, in the absence of stem cell support, may cause acral erythema.[27] Edema and tenderness often accompany the erythema regardless of cause. Pruritus is an uncommon complaint. As the acute GVHR evolves, the distribution of erythematous macules increases, and they become confluent over broad surfaces, commonly the upper back (stages 2 to 3). On the trunk, the erythematous macules may be observed in a perifollicular array at a very early stage (Fig. 28-2). At later stages, erythroderma may ensue (Fig. 28-3). Development of bullae (stage 4) portends a poor prognosis. These bullae are sub-epidermal with a necrotic roof and greatly resemble toxic epidermal necrolysis (Fig. 28-4). The staging scheme is detailed in Table 28-3. This progression of acute cutaneous GVHR generally occurs over several weeks. An explosive variant is described in which erythroderma evolves rapidly, with subsequent quick evolution to a lichen planus–like eruption resembling chronic disease.[28] Factors predisposing to this form of acute cutaneous GVHR are not known.

With successful treatment, the eruption resolves with desquamation in the same general progression as its appearance. A brown-gray discoloration of the skin may evolve as a post-inflammatory change with very slow or, in some cases, no resolution.

Differential Diagnosis of Acute Cutaneous Graft-Versus-Host Reaction after Allogeneic Transplantation. The clinical differential diagnosis of acute cutaneous GVHR includes drug hypersensitivity eruption, viral exanthem, transient acantholytic dermatosis, and, in the presence of bullae, toxic epidermal necrolysis. Findings in a

▲ **FIGURE 28-2** Follicular graft-versus-host reaction (GVHR). In some patients, the earliest manifestation of acute cutaneous GVHR is perifollicular erythema, as seen in this photograph at day 15 after marrow transplantation.

▲ **FIGURE 28-4** Stage 4 graft-versus-host reaction showing ruptured bullae, erosions, and crusts resembling toxic epidermal necrolysis.

TABLE 28-3
Clinical Staging Scheme for Acute Cutaneous Graft-Versus-Host Reaction

STAGE	DESCRIPTION
1	Cutaneous eruption involving less than 25% of body surface area
2	Cutaneous eruption involving 25%–50% of body surface area
3	Erythroderma
4	Vesicles and bullae

Adapted from Glucksberg H et al: Clinical manifestations of graft-versus-host disease in human recipients of marrow from HLA-matched sibling donors. *Transplantation* **18**:295, 1974.

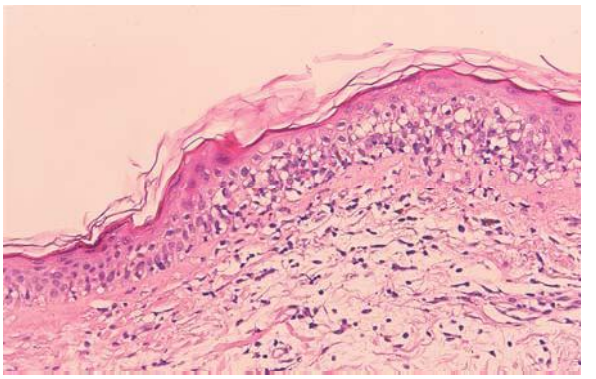
skin biopsy specimen may help to differentiate a GVHR from a drug eruption or a viral exanthem. Transient acantholytic dermatosis is an incidental finding in febrile patients receiving antineoplastic chemotherapy, with or without stem cell support.[29] Sampling of more palpable lesions predisposes to obtaining this spurious diagnosis. Confident differentiation between stage 4 acute cutaneous GVHR and toxic epidermal necrolysis generally is not possible, although dermatologists are often asked to try. Affected patients have received numerous medications known to cause toxic epidermal necrolysis, but rational criteria to exclude a GVHR in this setting do not exist.

Histopathology of Acute Cutaneous Graft-Versus-Host Reaction after Allogeneic Transplantation. The changes of an interface dermatitis appear in all phases of a cutaneous GVHR, including chronic sclerodermoid disease. The grading scheme for the histopathologic features of acute cutaneous GVHR is given in Table 28-4. Minimal criteria for the diagnosis include an infiltrate of lymphocytes in the dermis, basal vacuolar alteration, and necrosis of epidermal cells at a frequency of at least four per linear millimeter of epidermis (grade 2).[30] Extension of lymphocytes into the epidermis is common (Fig. 28-5). The direct apposition of a lymphocyte to a necrotic keratinocyte is known as *satellite cell necrosis* and may occur in many types of interface dermatitis in which cell death is mediated by lymphocytes. Some quantitation of necrotic epidermal cells is advised, because changes referable to the preparative regimen clearly include this finding, but numbers are lower than in a GVHR.[30] Other histologic findings attributable to marrow-ablative measures include loss of polarity of keratinocytes, large and bizarrely shaped keratinocytes with unusual mitotic figures, and irregular nuclear forms.[31] This "dysmaturation" should be ignored when seeking to establish the diagnosis of a GVHR because it may prevent adequate assessment of the specimen. Significant infiltration by lymphocytes typically does not accompany changes due to the preparative regimen, provided there is no erosion or ulceration.

TABLE 28-4
Histologic Grading Scheme for Acute Cutaneous Graft-Versus-Host Reaction

GRADE	DESCRIPTION
0	Normal skin or changes not referable to graft-versus-host disease
1	Basal vacuolization of the dermal-epidermal junction
2	Basal vacuolization, necrotic epidermal cells, lymphocytes in the dermis and/or epidermis
3	Sub-epidermal cleft formation plus grade 2 changes
4	Separation of epidermis from dermis plus grade 2 changes

Adapted from Lerner KG et al: Histopathology of graft-versus-host reaction (GVHR) in human recipients of marrow from HLA-matched sibling donors. *Transplantation* **18**:367, 1974.



◀ **FIGURE 28-5** Histopathologic features of acute cutaneous graft-versus-host reaction, grade 2. Inflammation of the upper dermis is evident, with extension of lymphocytes into the epidermis and interface change.

Evaluations of the immunologic changes in the skin during acute cutaneous GVHD document upregulation of keratinocyte expression of MHC class II molecules and intercellular adhesion molecule 1. Inflammatory infiltrates contain a mixture of $CD4^+$ (helper/inducer), $CD8^+$ (cytotoxic/suppressor), and $CD56^+$ natural killer cell lymphocytes with extension of all subsets into the epidermis.[33] After the preparatory regimen, the number of Langerhans cells gradually diminishes over 1 to 4 weeks to undetectable levels.[34] Repopulating cells are derived from the donor. In a murine model, Langerhans cell number and function decreased more in animals developing GVHD than in those undergoing the preparative regimen alone.[35]

CHRONIC CUTANEOUS GRAFT-VERSUS-HOST REACTION AFTER ALLOGENEIC TRANSPLANTATION The lichenoid form of GVHD greatly resembles lichen planus, with erythematous to violaceous polygonal, variably keratotic papules arising on flexor surfaces. Subsequent greater distribution occurs in some patients (Fig. 28-6). The lichenoid phase resolves with post-inflammatory hyperpigmentation.

The sclerodermoid phase greatly resembles scleroderma in that variably distributed plaques of thickened skin arise that have a shiny, somewhat atrophic appearance and varied hyperpigmentation and hypopigmentation (Fig. 28-7A). The plaques display erythema and progressive loss of the pilosebaceous apparatus. Some patients develop very few sclerodermoid plaques and do not require therapy. Other patients develop widespread disease associated with joint contractures, chronic cutaneous ischemia with erosion (see Fig. 28-7B), alopecia, and a syndrome of general wasting. Bacterial skin infections recur, consonant with the general immunodeficiency that characterizes chronic GVHD. This immunocompromise pro-

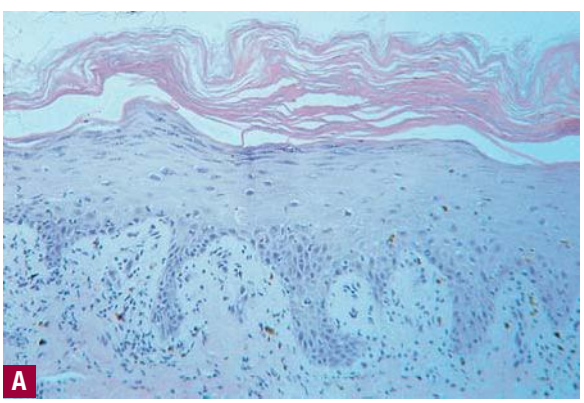
▲ **FIGURE 28-6** Chronic graft-versus-host disease. Violaceous to brownish lichen planus–like, perifollicular papules that are becoming confluent on the trunk, occurring 3 months after allogeneic bone marrow transplantation.

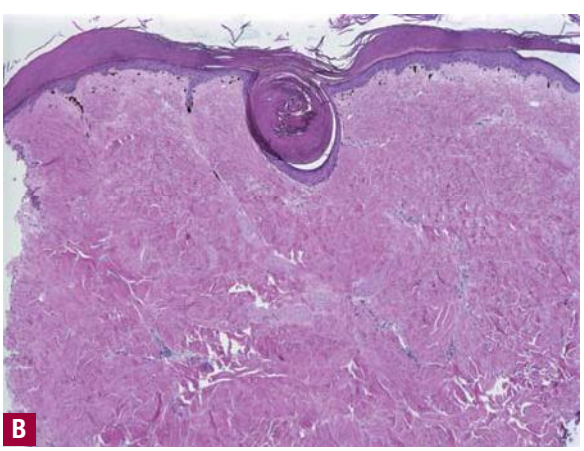
▲ **FIGURE 28-7** **A.** Sclerodermoid graft-versus-host reaction. Shiny bound-down skin with variable pigmentation is evident. **B.** Chronic graft-versus-host disease, sclerodermoid type. There is sclerosis and poikiloderma involving the entire skin. The porcelain white areas reflect sclerosis, the red is massive telangiectasias and erosions, and the brown is residual pigmentation after a lichenoid eruption with which the whole condition started. Sclerosis of the tissue now supervenes and the skin feels bound down on palpation, similar to progressive systemic sclerosis (diffuse systemic scleroderma).

motes sepsis, a common cause of death in these patients.

The sharp separation between the lichenoid and sclerodermoid phases of chronic GVHD is artificial. The two forms of disease clearly overlap in many patients. Furthermore, lichen planus–like forms of GVHD occur soon after transplantation.[36] Because immunomodulation and variability in histocompatibility are likely to result in differing clinical expression of all forms of cutaneous GVHR, rigid adherence to the concept of time as an accurate discriminant of the phases of GVHD may not be appropriate.

Histopathology of Chronic Cutaneous Graft-Versus-Host Reaction after Allogeneic Transplantation. Fully evolved histologic features of lichen planus may occur in lichenoid chronic GVHR. In general, the degree of inflammation is less in GVHR, but acanthosis, orthohyperkeratosis, wedge-shaped hypergranulosis, sharply pointed rete ridges, basal vacuolization, necrotic epidermal cells, and melanophages in the upper dermis characterize the fully evolved lesion (Fig. 28-8A). The only distinction between a lichenoid chronic GVHR and acute GVHR lies in recognition of the lichen planus–like epidermal changes, because





◀ **FIGURE 28-8** **A.** Histopathologic features of lichenoid graft-versus-host reaction (GVHR). Epidermal features of lichen planus are present with acanthosis, hypergranulosis, hyperkeratosis, and pointed rete ridges. The inflammatory infiltrate in the upper dermis is less intense than in the typical case of idiopathic lichen planus. **B.** Histopathologic features of sclerodermoid GVHR. The epidermis shows mild, compact hyperkeratosis and keratotic plugging. There is hyalinization of the collagen throughout the dermis with loss of the appendageal structures.

both entities are considered to represent interface dermatitides.

Sclerodermoid chronic GVHR displays thickened bundles of collagen with loss of interstices, entrapment of eccrine coils, and progressive loss of pilosebaceous units (see Fig. 28-8B). The dermal-epidermal junction is ill defined with basal vacuolization and melanophages. Necrotic epidermal cells are rare. Unlike in scleroderma, the progression of collagen alteration in sclerodermoid GVHR is from the papillary dermis downward.[9] Panniculitis is an uncommon finding.

Mucosal Histopathology of Chronic Cutaneous Graft-Versus-Host Reaction after Allogeneic Transplantation. Specimens of oral mucosa and minor salivary glands may aid in the diagnosis of chronic GVHD.[37] Interface changes along the epithelium may occur, but generally without associated acanthosis and other epidermal features of lichenoid chronic GVHR in the skin. Similar to the changes in Sjögren's syndrome, lymphocytes infiltrate glandular elements of the salivary glands, with progressive destruction and loss of acini. Lacrimal glands are sampled less often but show similar changes.

ACUTE CUTANEOUS GRAFT-VERSUS-HOST REACTION AFTER AUTOLOGOUS AND SYNGENEIC MARROW AND PERIPHERAL STEM CELL TRANSPLANTATION Erythematous macules and papules appear in variable locations and distributions at the time of peripheral lymphocyte recovery and are self-limited. Resolution with desquamation occurs without therapy. Stage 1 and stage 2 disease is most common after the administration of cyclosporine, whereas stage 3 disease is common after the addition of IFN-γ and is accompanied by significant pruritus. Stage 4 disease, manifestations of chronic GVHD, and extra-cutaneous involvement are exceedingly rare. Erythroderma with histologic features of spongiotic dermatitis occurs uncommonly after infusion of unmodified transplants but is generally persistent and difficult to treat.

Infusion of unmodified autologous transplants result in eruptions that are histologically indistinguishable from those of lymphocyte recovery.[38] The administration of cyclosporine results in some cutaneous eruptions that histopathologically resemble grade 2 acute cutaneous GVHR after allogeneic transplantation, but the findings are usually mild without evolution to grade 3 or grade 4 GVHR. Use of transplants modified by the administration of cyclosporine and IFN-γ results in eruptions that combine the histologic features of a GVHR and eczematous dermatitis, as evidenced by more marked exocytosis and intercellular edema.[10]

Related Physical Findings

Although the skin is the earliest and most commonly involved organ in GVHD, liver and gastrointestinal disease are frequent; the presence of elevated total bilirubin levels and diarrhea often aids in establishing the diagnosis when skin findings are not specific. Isolated liver or gastrointestinal involvement is uncommon. Retrospective analysis of a large series of patients revealed that the extent of the cutaneous eruption, total bilirubin value, and stool output per day provided significant prognostic information when considered separately or together.[39]

Ocular and oral involvement may occur in the acute phase but is less common than in chronic GVHD. Oral involvement is typical in chronic cutaneous GVHD, characterized by white lacy patches on the buccal mucosa. Rare patients display oral changes only. Sicca symptoms resembling Sjögren's syndrome often accompany the sclerodermoid phase because of diminished lacrimal and salivary output. In certain patients with the chronic form of cutaneous GVHD, the main anatomic site of collagen alteration is fascial. This fasciitis is similarly debilitating and is suggested in patients in whom the skin seems supple but the deeper soft tissue is hard. Joint contracture is quite common in this group of patients.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

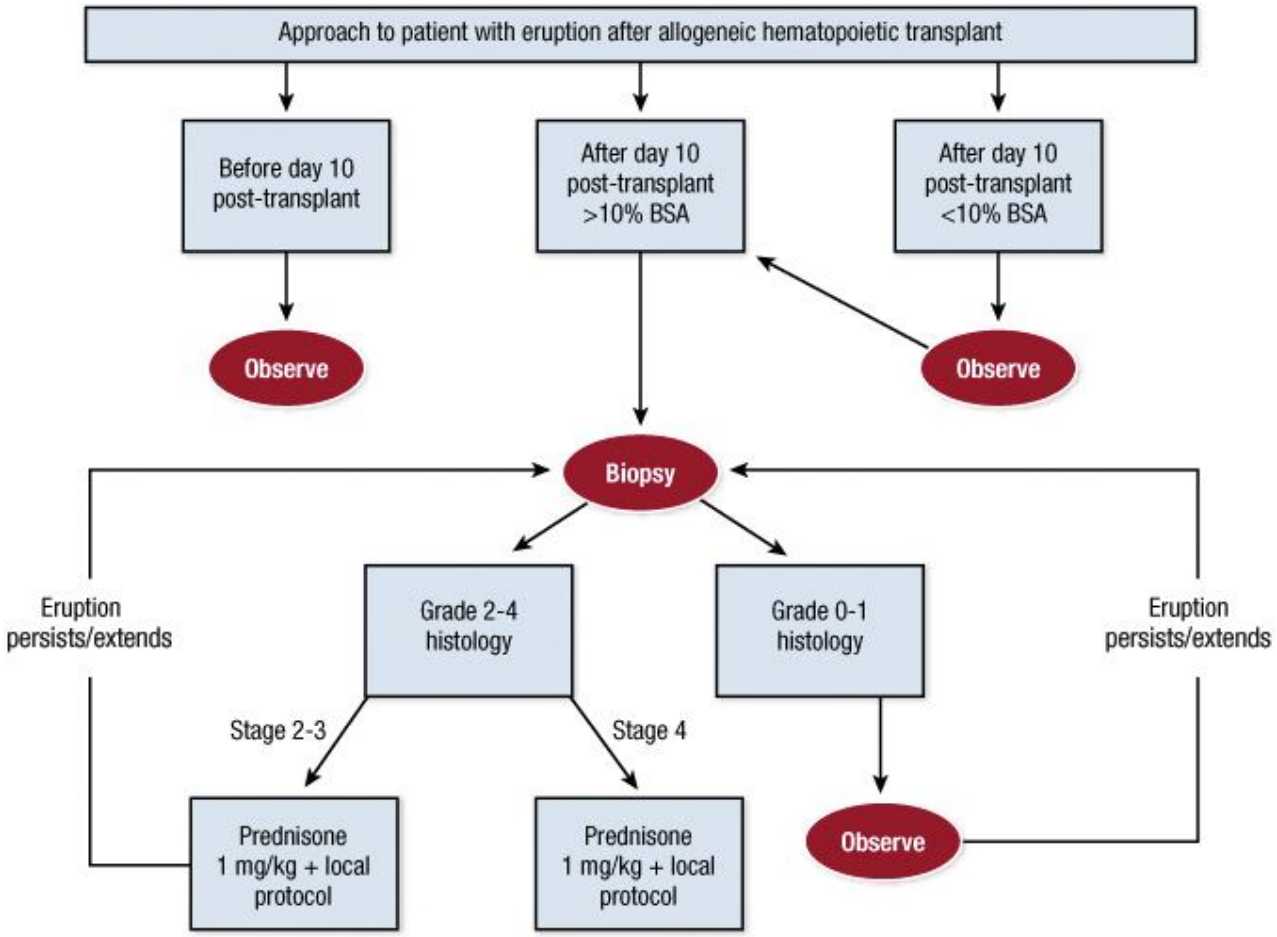
An algorithm outlining an approach to the patient with cutaneous GVHD is shown in Fig. 28-9.

The diagnosis of acute cutaneous GVHR rests on the combination of clinical findings, including the onset of variably distributed erythematous macules and papules at the time of peripheral lymphocyte recovery (generally longer than 10 to 14 days after transplantation), and a minimum of grade 2 histopathologic changes. Because stage 1 disease generally is not treated, eruptions with limited distribution may not warrant sampling. If eruptions persist or progress despite initial non-specific histopathologic changes, resampling is very helpful, because diagnostic changes evolve as the rash evolves.

Despite some distinguishing clinical features, acute allogeneic cutaneous GVHR lacks absolutely specific findings. Other diagnostic considerations include a drug hypersensitivity reaction and a viral exanthem. Differentiation of stage 4 cutaneous GVHR from toxic epidermal necrolysis was discussed earlier. In addition, in some patients a poorly characterized cutaneous eruption seems to occur at the time of marrow engraftment but before the appearance of peripheral lymphocytes. This eruption develops before day 14 after transplantation and consists of variably distributed erythematous macules. It should not be confused with a GVHR, because this "engraftment" or "cytokine-release" eruption clearly occurs very early and without a discernible rise in the number of peripheral leukocytes (Box 28-1).

What is the role of the biopsy specimen? It is easier to establish a diagnosis of GVHR than to exclude drug eruption and viral exanthem from consideration. The causes that may underlie grade 1 changes generally defy identification. It is sufficient to report "not GVHD" rather than to speculate about the cause when objective criteria are lacking. Holding to the standard of an infiltrate of lymphocytes, basal vacuolization, and at least four necrotic epidermal cells per millimeter of epidermis helps to diminish the effects of the preparative regimen and heighten the specificity, and thus the significance, of the histologic changes. This standard should be used in diagnostic dermatopathology as well as in prospective and retrospective investigations of the specificity of the histologic changes of acute cutaneous GVHR. Although it is not documented in the literature, rare patients display early clinical and histologic features of a drug hypersensitivity reaction, including eosinophils in the tissue, only to manifest typical histopathologic features of grade 2 GVHR 7 to 10 days later, after engraftment. Once allogeneic lymphocytes predominate and infiltrate the site of prior inflammation, effector function changes, which allows expression of GVHR.

Controversy exists regarding the use and timing of skin biopsy to aid in the diagnosis of acute cutaneous GVHD. Some clinicians feel that withholding treatment while awaiting results of a biopsy can potentially lead to rapid progression of



▲ **FIGURE 28-9** Approach to the patient with eruption after allogeneic hematopoietic transplantation. BSA = body surface area.

disease and adverse outcomes. Others maintain that immunosuppressive therapy must be used cautiously in the stem cell transplant population given the high risk of sepsis in these patients. The absence of specific histopathologic changes in early GVHD adds to the confusion. A published decision analysis used expert opinion to estimate the sensitivity and specificity of skin biopsy results to help determine relative benefit-risk ratios of appropriate versus inappropriate treatment of GVHD. This model predicted that in patient populations with a prevalence of GVHD of 30 percent or higher, as is typical for patients receiving allogeneic stem cell transplants, the best outcomes were reached with empiric treatment of GVHD without obtaining results of a skin biopsy. However, when prevalence of GVHD was 30 percent or less, it was advisable to await results of a skin biopsy to help guide treatment.[40]

The diagnosis of sclerodermoid GVHR is generally apparent on the basis of the clinical and histologic findings detailed earlier. If superficial biopsy specimens fail to show changes consistent with sclerodermatous disease, then consideration should be given to fascial involvement, which requires incisional sampling. Distinguishing between acute cutaneous GVHR and some cases of lichenoid chronic GVHR is more challenging. Rigid adherence to time after transplantation as a reliable discriminant between the two phases results in confusion.[36] Clinical and histologic features resembling lichen planus should lead to the diagnosis of lichen planus–like GVHR, with less emphasis placed on whether the disease is necessarily acute or chronic. Separation of autologous GVHR from the eruption of lymphocyte recovery may be difficult. Applying the same histologic criteria as for acute allogeneic GVHR is recommended.

LABORATORY TESTS

As previously discussed in Diagnosis and Differential Diagnosis, the diagnosis of acute cutaneous GVHD rests predominantly on the combination of characteristic cutaneous lesions appearing within the appropriate clinical setting (typically longer than 10 to 14 days after transplantation) and a minimum of grade 2 histologic changes. A peripheral white blood cell count can be helpful in determining whether peripheral lymphocyte recovery has occurred, which makes the diagnosis of acute GVHD more likely. Evaluation of liver function test results and total bilirubin levels helps to determine the presence and extent of liver involvement.

In rare circumstances, rapid histologic confirmation of acute GVHD may be warranted. In these cases, skin biopsy with frozen tissue diagnosis may be necessary to help guide patient management and treatment decisions.

COMPLICATIONS

In patients with acute GVHD, the risk of sepsis is high as a result of profound immunosuppression from pre-transplant preparative regimens or from immunosuppressive treatment in the setting of a GVHR. Significant blister formation in some patients may result in widespread denudation with exposed dermis, which places the patient at an even greater risk of sepsis as well as fluid and electrolyte imbalance. The risk of systemic infec-

Box 28-1

Differential Diagnosis of Graft-Versus-Host Disease

Most Likely

- Acute graft-versus-host reaction (GVHR)
  - Eruption of lymphocyte recovery
  - Drug eruption
  - Radiation effect
  - "Engraftment" or "cytokine-release" eruption (before day 14)
- Chronic GVHR
  - Lichenoid
    Lichenoid drug reaction
  - Sclerodermoid
    Radiation dermatitis

Consider

- Acute GVHR
  - Viral exanthem
  - Transient acantholytic dermatosis
  - Toxic epidermal necrolysis (stage IV disease)
- Chronic GVHR
  - Lichenoid
    Lichen planus
    Pityriasis lichenoides chronica
  - Sclerodermoid
    Morphea
    Scleroderma
    Lichen sclerosus
    Eosinophilic fasciitis
    Nephrogenic fibrosing dermopathy
    Sjögren's syndrome (with sicca symptoms)

Always Rule Out

- Acute GVHR
  - Sepsis
- Chronic GVHR
  - Bacterial, fungal, or viral skin infections
  - Sepsis
  - Squamous cell carcinoma (oral or cutaneous)

tion is also high in patients with chronic GVHD and represents the most common cause of death in these patients. In long-term survivors with chronic GVHD, the incidence of cutaneous and oral mucosal squamous cell carcinoma is increased in the presence of risk factors that include older age, treatment with cyclosporine, and prior administration of ionizing radiation.[41,42]

PROGNOSIS

A graft-versus-tumor effect is recognized in patients who develop GVHD.[43] The incidence of tumor relapse is reduced, which results in a dichotomous view of the disease. GVHD is the most common cause of morbidity and mortality after allogeneic stem cell transplantation, yet mild disease modulated by immunosuppression increases the chance of cure. As previously stated, systemic infection is the most common cause of death in patients with chronic GVHD. Patients with sclerodermoid disease demonstrate better survival than patients with lichenoid disease because they have overcome the earlier phases of acute and chronic GVHD and have lived longer, on average. Patients with skin biopsy specimens showing fully evolved features of lichenoid disease have a 5.6-fold increased risk for death due to GVHD.[36] No other histologic finding is known to correlate with outcome, specifically not in the early phases of GVHD. Degree of organ involvement in acute GVHD has been used to create a clinical staging system [grades 0 (best) to IV (worst)]. This system has been used as a prognostic indicator.[44]

TREATMENT

Acute Cutaneous Graft-Versus-Host Reaction after Allogeneic Transplantation

Standard therapies are listed in Box 28-2. Anti–tumor necrosis factor-α drugs, such as etanercept and infliximab, have been used with some success.[45,46] Dosages and specific regimens vary among transplantation centers.

Ultraviolet radiation must be administered cautiously to avoid increasing the erythema of the GVHR and thereby inciting more inflammation. One study found phototherapy with long-wavelength ultraviolet A light (340 to 400 nm) to be a safe, effective adjunct treatment for cutaneous manifestations of both acute and chronic GVHD.[47] There are no published data regarding the use of narrow-band ultraviolet B therapy in GVHD. Extracorporeal photopheresis has reported benefit in acute disease, including steroid-refractory GVHD, possibly by promoting a shift from a T helper 1 to T helper 2 lymphocyte distribution.[48–50] Pre-treatment of the graft with ultraviolet A radiation prevented disease in a murine model of transfusion GVHD.[51]

Chronic Cutaneous Graft-Versus-Host Reaction after Allogeneic Transplantation

Although most chronic GVHR is manifested only in the skin, oral immunosuppressive therapy is used because the disease is considered to be systemic (Box 28-3).

Intermittent cultures for bacteria and fungi should be performed as necessary. Long-term administration of antibiotics becomes necessary in cases of recurrent pyoderma.

For the lichenoid manifestations, ultraviolet light therapy generally controls widespread disease effectively.[52,53] Tapering phototherapy is recommended after several months of clearance. Therapies claiming efficacy in treating sclerodermoid GVHR are difficult to evaluate because the disease is relatively rare and remits spontaneously in some cases. It is unclear whether ultraviolet irradiation is able

Treatment of Acute Graft-Versus-Host Disease

	TOPICAL	PHYSICAL		SYSTEMIC	
First Line	Corticosteroids	Psoralen plus ultraviolet A		Corticosteroids-Methylprednisolone	2 mg/kg/day[56]
Second Line		Extracorporeal photopheresis	2 consecutive days q2wk	Tacrolimus	4–20 mg/day[57]
		Ultraviolet A1 (340–400 nm)		Cyclosporine	12–15 mg/kg/day PO or 3–5 mg/kg/day IV[58]
				Mycophenolate mofetil	2 g/day[59]
				Antithymocyte globulin	15 mg/kg/day[60]
				Etanercept	25 mg biw[45]
				Infliximab	10 mg/kg/wk[46]
				OKT3 (anti CD3 mAb)	5 mg/day[61]

Box 28-3

Treatment of Chronic Graft-Versus-Host Disease

	TOPICAL	PHYSICAL		SYSTEMIC	
First Line	Corticosteroids	Psoralen plus ultraviolet A		Prednisone	1 mg/kg qd–qod[62]
				Cyclosporine	10 mg/kg in 2 divided doses qd-qod[62]
Second Line	Tacrolimus	Ultraviolet A1 (340–400 nm)	20 J/cm^2 qiw[63]	Methotrexate	7.5 mg/m^2/wk[64]
		Ultraviolet B		Mycophenolate mofetil	2 g/day
		Extracorporeal photopheresis	2 consecutive days q2wk[65]	Tacrolimus	0.05 mg/kg IV or 0.15mg/kg PO bid[66]
				Thalidomide	200–800 mg/day[67]
				Azathioprine	1.5 mg/kg/day[68]
				Hydroxychloroquine	800 mg/day (12 mg/kg/day)[69]
				Acitretin[62]	

to reverse the cutaneous changes in sclerodermoid disease. Extracorporeal photopheresis has proven beneficial in both lichenoid and sclerodermoid steroid-resistant chronic GVHD.[54,55]

Acute Cutaneous Graft-Versus-Host Reaction after Autologous and Syngeneic Transplantation

No significant morbidity is associated with autologous GVHR, and the cutaneous eruptions resolve without therapy. Patients with erythroderma after autologous stem cell transplantation may require systemic glucocorticoids to control the intense itching that accompanies the eczematous changes seen histologically.

PREVENTION

Attempts to prevent acute GVHD are essential, because treatment of established disease is difficult, and, as previously mentioned, prior acute GVHD is the greatest predictor for the development of chronic GVHD.[6] Three prophylactic strategies are used: optimal donor selection, pre-treatment manipulation of donor marrow or stem cells, and pharmacoprophylaxis. Ideally, the donor should be a young, sex-matched, human leukocyte antigen–identical sibling or monozygotic twin. Prophylactic treatment of allogeneic donor marrow to deplete effector T cells is also effective in preventing and reducing the severity of acute GVHD; however, this manipulation has been associated with an elevated risk of tumor recurrence and graft failure. Various pharmacologic prophylactic regimens are generally used in the post-transplantation period, including combinations of methotrexate, tacrolimus, cyclosporine, and cyclophosphamide. Because of improved treatment of GVHD, there is increasing use of MHC-mismatched and unrelated donors.

CHAPTER 29

Skin Disease in Acute and Chronic Immunosuppression

Lynda Kauls
Andrew Blauvelt

This chapter focuses on dermatologic manifestations in immunosuppressed patients without human immunodeficiency virus (HIV) disease, predominantly immunosuppression induced by drugs, conditions surrounding bone marrow transplantation, and hematologic malignancy. Skin manifestations of HIV disease are described in Chap. 198. Other chapters cover graft-versus-host disease (see Chap. 28), skin signs associated with primary immunodeficiency disorders (see Chap. 144), and side effects of cancer chemotherapeutic agents and cytokines (see Chaps. 228, 234, and 235). Because relatively few skin diseases manifest exclusively in immunosuppressed hosts, many conditions discussed in this chapter occur in immunocompetent individuals as well. Salient clinical features particularly associated with immunosuppression are emphasized here.

The diversity of cutaneous infections that occur in immunosuppressed patients can pose a significant diagnostic challenge. To aid in evaluation, it is helpful to understand the underlying immune defects associated with the medical conditions of each patient (Table 29-1), which helps to focus the history taking and physical examination toward skin manifestations of specific pathogens. This chapter is divided into two major subsections based on this concept: acute immunosuppression and chronic immunosuppression. When patients are acutely immunosuppressed, usually from iatrogenic ablation of the immune system or from acute leukemia, infections occur that are normally controlled by neutrophils and macrophages.

SKIN DISEASE IN ACUTE AND CHRONIC IMMUNOSUPPRESSION

AT A GLANCE

- Skin manifestations in patients who have hematologic malignancies, have undergone bone marrow transplantation, or are immunosuppressed by drugs are common and varied.
- Many of these skin diseases occur in immunocompetent individuals as well.
- In patients with acute immunosuppression, infections occur that are normally controlled by neutrophils and macrophages.
- In patients who have long-term immunosuppression, T-cell function is impaired and skin diseases are often similar to those seen in patients with human immunodeficiency virus infection.
- Salient dermatologic features particularly associated with immunosuppression are important diagnostic signs and indicators for therapy.

In chronically immunosuppressed individuals, such as transplant patients and those taking corticosteroids on a long-term basis, T-cell function is impaired, and diseases will often be similar to those observed in HIV disease.

In ill immunosuppressed patients a disease often manifests in the skin. Appropriate evaluation and diagnosis of skin lesions are critical to the overall health of these individuals, because the skin is often a window to more severe systemic infections or illnesses. In particular, in these patients, unusual presentations of infection with typical pathogens and infections with rare opportunistic pathogens are common. Diagnosis is also made more difficult by the variety of organisms that share similar morphologies and the wide variety of morphologic presentations of a single organism (Table 29-2). This makes prompt clinical evaluation and extensive use of skin biopsy and culture necessary to make an accurate diagnosis and initiate prompt treatment to obviate significant morbidity and mortality.

ACUTE IMMUNOSUPRESSION

The prototype of an acutely immunosuppressed patient needing dermatologic evaluation is a neutropenic patient undergoing chemotherapy or transplantation. Neutropenia and resultant opportunistic infection are side effects of many cancer therapies that often pose a more immediate threat to survival than the malignancy itself. Moreover, individuals with cancer often have immune system defects before aggressive cytotoxic, radiation, or surgical therapy.[1] For example, tumors can secrete immunosuppressive factors (e.g., transforming growth factor-β1 and interleukin 10) that help them evade normal immune responses and lead to further systemic immunosuppression. In the past two decades, overall mortality due to infection among patients undergoing hematopoietic transplantation has decreased significantly, but it still represents an ongoing risk to survival. The causes of infection-related death have remained relatively stable, with death due to bacterial infections being the most common (36 percent), followed by deaths due to infection or infestation by viruses (31 percent), fungi (28 percent), and parasites (5 percent).[2,3]

Bacterial Infections

Empiric therapy for fever and neutropenia was first introduced in the 1970s when 60 percent to 70 percent of infections were due to Gram-negative bacteria such as *Escherichia coli*, *Pseudomonas aeruginosa*, and *Klebsiella* species. Since that time, bacteremia caused by Gram-positive organisms has become more prevalent.[4] Acutely immunocompromised hosts are at risk for becoming bacteremic from skin and soft-tissue infections such as folliculitis, furuncles, and wound infections. The use of indwelling intravascular catheters is also thought to play a role in the shift to Gram-positive organisms, such as coagulase-negative staphylococci and methicillin-resistant *Staphylococcus aureus*.[5] Rapid empiric therapy is typically instituted in these patients. Bone marrow transplant patients and other patients with neutropenia are prone to streptococcal bacteremia and may develop facial flushing, a widespread erythematous eruption of macules and papules, and desquamation of the palms and soles. Staphylococcal scalded-skin syndrome, which typically occurs in children (see Chap. 178), can occur in immunosuppressed adults.[6]

Ecthyma gangrenosum is the most characteristic lesion of *Pseudomonas* septicemia. Patients with neutropenia, cystic fibrosis, or extensive burns are particularly susceptible to systemic *P. aeruginosa* infection (see Chap. 180).[7] Ecthyma gangrenosum appears as a painful erythematous to dusky nodule or plaque that rapidly develops a central pustule or hemorrhagic vesicle, followed by a central area of necrosis (Fig. 29-1). The classic and most common form is due to hematogenous spread of *Pseudomonas*, but similar-appearing lesions can represent primary cutaneous infection, usually at the site of a medical procedure. As is common with other infections in neutropenic hosts, primary lesions can lead to bacteremia and should be treated aggressively. The groin, perianal area, and axillae are the most common locations for ecthyma gangrenosum. There may be one or many lesions. Other bacterial organisms are also capable of causing ecthyma gangrenosum–like lesions, including *S. aureus*, *Aeromonas hydrophilia*, *Serratia marcescens*, *K. pneumoniae*, and *E. coli*. Fungal organisms such as *Aspergillus* can also cause similar lesions. These organisms should be ruled out by culture. Other cutaneous manifestations of *Pseudomonas* septicemia may appear initially as grouped vesicles, cellulitis, subcutaneous nodules, petechiae, purpura, or folliculitis.[8] All these types of lesions can progress to ulcerative and necrotic lesions that are more characteristic of ecthyma gangrenosum. Necrosis is secondary to underlying focal vasculitis, which can be observed in skin biopsy specimens. Diagnosis is made by culture of the organism from skin or blood. The mortality rate of *P. aeruginosa* bacteremia is high at 33 percent to 75 percent.[9] Better outcomes have been shown with the initial use of combination antimicrobial therapy until susceptibilities can be identified, such as an antipseudomonal β-lactam antibiotic or a carbapenem in combination with an aminoglycoside or a fluoroquinolone.[10]

Fungal Infections

Candidiasis and aspergillosis represent the two most common fungal infections

TABLE 29-1
Opportunistic Infections That Are Commonly Associated with Specific Underlying Immune Defects

Immune Defect	Usual Conditions	Common Bacterial Pathogens	Common Viral Pathogens	Common Fungal Pathogens
Defective cell-mediated immunity	Organ transplantation, metastatic cancer, Hodgkin disease, glucocorticoid or cyclosporine therapy	*Listeria, Salmonella, Nocardia, Mycobacterium avium-intracellulare, M. tuberculosis, Legionella*	Cytomegalovirus, herpes simplex virus, varicella-zoster virus	*Candida, Cryptococcus, Histoplasma, Coccidioides*
Defective humoral immunity	Multiple myeloma, chronic lymphocytic leukemia	*Streptococcus pneumoniae, Haemophilus influenzae, Neisseria meningitidis*	Enteroviruses	—
Neutropenia	Cancer chemotherapy, acute leukemia, adverse drug reaction	Aerobic Gram-negative bacteria; *Staphylococcus aureus, Streptococcus viridans, Staphylococcus epidermidis*	Herpes simplex virus	*Candida, Aspergillus*
Defective neutrophil function	Chronic granulomatous disease, myeloperoxidase deficiency	Catalase-positive bacteria: *S. aureus, Escherichia coli*	—	*Candida*
Defective chemotaxis	Diabetes, alcoholism, renal failure, systemic lupus, trauma	*S. aureus, Streptococcus*	—	*Candida*
Hyposplenism	Splenectomy, hemolytic anemia	*S. pneumoniae, H. influenzae*	—	—
Defective complement components	Congenital or acquired deficiencies	*S. pneumoniae* (C2, C3, C5 alternate), *H. influenzae* (C2, C3, alternate), *S. aureus* (C5), Enterobacteriaceae (C5), *Salmonella* (alternate), *N. meningitidis* (C6–C8)	—	—
Skin barrier disruption	Intravascular catheters, decubitus ulcers, burns	*Staphylococcus, M. fortuitum,* Gram-negative bacteria, anaerobes	—	*Candida, Aspergillus, Mucor*

that occur in patients who are undergoing cytotoxic chemotherapy or stem cell transplantation or who have acute myeloproliferative disorders. They are not unique to the neutropenic patient, however, and are encountered in settings such as surgical and neonatal intensive care units, and in patients with cell-mediated immune dysfunction such as those undergoing long-term immunosuppression after solid organ transplantation. Additional risk factors for opportunistic fungal infection include hyperalimentation, antibiotic use, hyperglycemia, and central venous catheter use. Mortality rates for fungal bloodstream infections are highest in neutropenic hosts and range from 40 percent to 90 percent.[11] Recovery from disseminated fungal infections is rare unless neutropenia resolves. Other fungal organisms causing infection in hosts with acute neutropenia include *Trichosporum* species, *Fusarium* species, and organisms in the Zygomycetes class.

[a]Each organism has a wide variety of presentations, and not all are included in this table.

CANDIDIASIS (See Chap. 189) Candidiasis is the most common fungal infection in immunosuppressed patients.[12] His-

▲ **FIGURE 29-1** Ecthyma gangrenosum secondary to *Pseudomonas aeruginosa* infection in the groin area.

torically, most candidal infections were due to *Candida albicans*, but there has been an emergence of other organisms in recent years, including *C. glabrata*, *C. krusei,* and *C. tropicalis*.[11,12]

The classic triad of fever, myalgias, and erythematous skin lesions in a septic patient not responding to antibiotic therapy is highly suggestive of disseminated candidiasis. Fungi may seed numerous organs, causing myositis, meningitis, endocarditis, pneumonitis, cerebritis, esophagitis, bursitis, osteomyelitis, arthritis, and endophthalmitis. Cutaneous lesions are present in only 5 percent to 10 percent of individuals with disseminated candidiasis. *C. tropicalis* is more likely than other strains to cause skin lesions (up to 25 percent of patients). Lesions are characteristically non-painful, non-blanching, discrete, erythematous macules, papules, or nodules (Fig. 29-2) and may become purpuric, pustular, or necrotic within the centers of the lesions. They are usually generalized, but occasionally patients have very few lesions limited to the proximal extremities. The major clinical differential diagnosis includes infections caused by other opportunistic pathogens and drug eruptions. Histologically, periodic acid-Schiff–positive yeast forms are seen in the dermis, usually in association with vascular damage and mild inflammation. *Candida* can be grown from skin lesion samples in approximately 50 percent of patients. Tissue scrapings from dermal skin can be obtained at the time of biopsy with a scalpel or small-diameter curette for slide examination and can be an invaluable aid in making a rapid diagnosis in an acutely ill patient.

The treatment of choice for disseminated candidiasis is intravenous amphotericin B, which is less toxic when liposomal and lipid-complex forms are used. *C. glabrata*, *C. albicans*, *C. tropicalis*, and *C. parapsilosis* are showing resistance to fluconazole, and *C. krusei* is naturally resistant.[13,14] Newer antifungals including voriconazole and caspofungin are effective against *Candida* species, although breakthrough infections with resistant *C. glabrata* have already been reported with voriconazole[15] (see Chap. 233).

ASPERGILLOSIS After candidiasis, aspergillosis is the most common opportunistic fungal infection in immunosuppressed patients.[8,11] Persistent neutropenia and neutrophil dysfunction is a risk factor for disseminated infection, and patients with acute leukemia have the highest incidence of infection.[16] Infection rates are also high for patients undergoing allogeneic stem cell transplantation, although risk factors in this group are expanded to include immunosuppression for graft-versus-host disease prophylaxis, graft-versus-host disease itself, and other infectious diseases, especially cytomegalovirus (CMV) infection. Systemic infection is classically seen during the period of neutropenia caused by the conditioning regimen, whereas invasive infection is more common 30 to 40 days after transplantation. This observation emphasizes that immune defenses other than those mediated by granulocytes are important for protection against invasive fungal infections, and against *Aspergillus* infections in particular. The incidence of invasive aspergillosis is also increasing in non-classic immunocompromised hosts such as critically ill patients in the intensive care unit. Environmental factors also clearly contribute to the development of aspergillosis, especially in primary cutaneous disease. These include hospital construction (which increases spore counts in ventilation systems), the use of indwelling catheters (which provide portals of entry for organisms), and contamination of tape and arm boards used to secure catheters.

▲ **FIGURE 29-2** Early cutaneous lesion of disseminated candidiasis in a neutropenic patient after chemotherapy for non-Hodgkin lymphoma.

▲ **FIGURE 29-3** Ecthymatous lesion of primary cutaneous aspergillosis under tape occlusion from previous central line in an oncology patient.

A. fumigatus is the most common cause of disseminated infections, whereas *A. flavus* is associated most commonly with primary cutaneous disease.[17] Emerging strains are evolving in aspergillosis as in candidiasis. *A. terreus* is more likely to be health care associated, more resistant to amphotericin B, and has a lower response rate to antifungal therapy than *A. fumigatus*.[16]

Primary cutaneous aspergillosis often develops at sites of intravenous catheters or under areas of occlusion. Lesions initially appear as small cellulitic areas and progress quickly to necrotic ulcers with black eschars (Fig. 29-3). In patients with *Aspergillus* sinusitis, necrotic ulcers with black eschars can occur in the anterior nares and on the nasal septum, palate, and skin overlying the nasal bridge. Cutaneous necrosis caused by *Aspergillus* is secondary to invasion of fungi within deep blood vessels.

Primary cutaneous, pulmonary, or sinus infection can easily become invasive and lead to disseminated disease in immunocompromised hosts. Patients with disseminated aspergillosis often present with unremitting fever despite antibiotic use. The central nervous system, heart, kidneys, and gastrointestinal tract also may be involved. Cutaneous manifestations of disseminated aspergillosis are uncommon, occurring in 5 percent to 10 percent of patients.[17] Lesions begin as single or multiple painful, erythematous papules, nodules, or plaques. They rapidly expand and develop central hemorrhagic vesicles or bullae, which in turn quickly progress to central ulcers with black eschars. In disseminated disease, the prognosis is very poor (usually higher than 90 percent mortality). In tissue sections, diagnosis can be made by demonstration of nonpigmented septated hyphae that branch at acute angles. Blood culture results often are not positive or reliable because *Aspergillus* is found commonly as a laboratory contaminant. Traditionally, the treatment of choice has been liposomal amphotericin B, although studies now show that voriconazole and, to a lesser degree, caspofungin may be more effective and better tolerated.[18] Surgical removal of isolated lesions of primary cutaneous aspergillosis can be attempted, although this may not necessarily prevent secondary disseminated infection in patients with persistent neutropenia.

ZYGOMYCOSIS (See Chap. 190) Zygomycosis is the third most common opportunistic fungal infection in immunosuppressed hosts, accounting for 5 percent to 15 percent of all fungal infections.[19] The term *zygomycosis* is used to describe a group of fungal infections caused by ubiquitous Zygomycetes found in soil and decaying matter. Infections in humans are mostly caused by the order Mucorales (mucormycosis) and include the genuses of *Mucor*, *Rhizopus*, *Absidia*, *Mortierella*, and *Cunninghamella*. The term *zygomycosis* is now preferred over *mucormycosis* because it is broader and more relevant when organisms are not identifiable. Like aspergillosis, zygomycosis is rare in individuals without underlying immunodeficiency or predisposing conditions. Host defenses usually prevent the germination of the spore unless the inoculation is too great, as in trauma or surgical wounds. Chronic medical conditions that affect macrophage function, such as diabetes or corticosteroid-induced immunosuppression, lead to an inability to inhibit spore germination, and these patients are at increased risk of infection. Additional risk factors besides immunosuppression include iron overload, burns, intravenous illicit drug use, and malnourishment.

Primary infection can occur by inhalation, by direct inoculation into damaged skin, or by ingestion. Patients with prolonged neutropenia present most often with pulmonary disease and dissemination. The mortality rate in these individuals is very high. Diabetic patients with sustained hyperglycemia and metabolic acidosis are predisposed to primary rhinocerebral (66 percent) and pulmonary (16 percent) infections.[19] Malnutrition and gastrointestinal disease predispose patients to primary gastrointestinal tract infection. Wounds and burn injuries predispose to primary cutaneous infection. Each type of primary infection can lead to hematogenous spread and disseminated infection of numerous organs (especially the brain).

The clinico-pathologic hallmarks of cutaneous zygomycosis are vascular invasion, ischemic infarction, and necrosis, which result in painful erythematous nodules and plaques that ulcerate rapidly and form central black eschars.[20] Rhinocerebral zygomycosis typically begins with facial edema and erythema (Fig. 29-4), bloody nasal discharge, and ulceration of the palate or nasal septum. Within a few days, necrotic skin lesions, headache, focal neurologic defects, exophthalmos, and altered vision develop and can progress to seizures, stupor, coma, and death. Clinical manifestations of primary cutaneous disease range from necrotic papules to cellulitis, subcutaneous nodules, bullae, and eschars. Diagnosis of zygomycosis usually is made by demonstration of non-septated hyphae (with branching at right angles) within infected tissue. The treatment of choice for disseminated disease is lipid preparations of intravenous amphotericin B and surgical débridement. If possible, reversal or removal of underlying predisposing conditions should be attempted.

▲ **FIGURE 29-4** Rapidly progressing zygomycosis in a man with diabetes.

FUSARIOSIS *Fusarium* is a filamentous mold found in soil and plants. Disseminated infections are found in severely immunocompromised individuals, whereas immunocompetent patients have localized lesions at areas of skin breakdown. Neutropenic patients are particularly susceptible to infection and rapid dissemination.[21] The source of infection in patients undergoing acute immunosuppressive therapy is often the skin, especially from cellulitis developing at the site of onychomycosis, local trauma, or insect bites. Nasal sinuses are another source of primary infection that can lead to dissemination after acute immunosuppression. In disseminated disease, patients present with multiple painful erythematous papules and nodules, some with central necrosis. Lesions are often at different stages of development, and a specific presentation of papules evolving into target-like lesions with a ring of normal-appearing skin and an outer rim of erythema has been observed. Skin lesions often precede fungemia and are the single source of diagnosis in a majority of patients.[22] The mortality rate in patients who are persistently neutropenic is 100 percent, compared with 30 percent in patients whose immune systems recover. Newer triazole antifungals such as voriconazole have some efficacy against infection with *Fusarium* sp., for which treatment options have traditionally been limited. Granulocyte transfusions may also play a role in treatment.

TRICHOSPORONOSIS *Trichosporon beigelii*, a yeast-like organism that causes white piedra in the tropics, may produce acute systemic infection in immunosuppressed patients, most commonly in the setting of neutropenia.[23] Patients with disseminated trichosporonosis are acutely ill. They may have fever, hypotension, pulmonary infiltrates, renal involvement, and hepatosplenomegaly. Skin lesions occur in 30 percent of patients and appear similar to cutaneous lesions of disseminated candidiasis. Definitive diagnosis is made by culture, and the treatment of choice is fluconazole; amphotericin B resistance is common.

Viral Infections

Viral infections are predominantly associated with defects in cellular immune function and are not typically expected to cause problems in patients whose main immunologic defect is neutropenia.[24] The most common viral infection that occurs in patients who are undergoing induction chemotherapy for lymphoma or an acute leukemia or who are in the first few weeks after a bone marrow transplantation is reactivation of latent herpes simplex virus (HSV) infection (see Chap. 193). Clinical presentations in acutely immunosuppressed patients include an increased severity of oral mucositis, intra-oral ulcers outside of the gingival margin, and necrotizing gingivitis.[24] Pneumonitis can occur from either contiguous spread from the oropharynx or from viremia. Antiviral prophylaxis is approximately 90 percent effective in preventing disease during chemotherapy or hematologic transplantation. When disease does occur in transplant patients, 5 percent to 10 percent of cases are resistant to acyclovir because of mutation in the gene coding for thymidine kinase, which is the enzyme required for efficacy of acyclovir, valacyclovir, and famciclovir (see Chap. 232). The treatment of choice in these patients is foscarnet.

Reactivation of varicella-zoster virus (VZV) (see Chap. 194) usually occurs 3 months or longer after transplantation and is relatively rare in the acutely immunosuppressed patient. VZV infection in adults with leukemia or after solid organ

▲ **FIGURE 29-5** Disseminated varicella in a patient after induction chemotherapy.

transplantation is rarely primary but more often represents reactivation of latent virus. In this setting, patients are at increased risk for both skin and systemic dissemination of virus (Fig. 29-5). Of note, before the use of antiherpesvirus prophylaxis in children who had lymphoma or acute leukemia or underwent bone marrow transplantation, primary varicella was a classic opportunistic infection associated with mortality rates of 7 percent to 30 percent.

CHRONIC IMMUNOSUPPRESSION

Patients with chronic immunosuppression include those that are iatrogenically immunosuppressed because they are taking medications that impair the immune system and those with chronic diseases that are associated with immune dysfunction, such as diabetes mellitus. The population of patients who are taking immunosuppressive medications over the long term is growing as solid organ transplantation becomes a therapeutic option for many human diseases. The overall incidence of solid organ transplantation continues to increase, and the survival of patients in the short and long term has improved. These individuals require lifelong therapy with immunosuppressive drugs to maintain function of the transplanted organ. Cyclosporine, tacrolimus, sirolimus, prednisone, mycophenolate mofetil, and azathioprine (see Chaps. 228 and 234) are the drugs used most commonly to prevent graft-versus-host disease, predominately by inhibiting cell-mediated immunity (i.e., T-cell function).[25] Humoral immunity (i.e., B-cell function) remains relatively intact in these patients. Thus, opportunistic diseases in most transplant patients are dominated by viral and fungal infections, intracellular bacterial infections, and virus-associated malignancies, conditions that are controlled predominantly by cell-mediated immune mechanisms in immunocompetent hosts.

Bacterial Infections

MYCOBACTERIAL INFECTIONS (See Chap. 184) Atypical mycobacteria are ubiquitous organisms found in soil and water. The most common organisms in this group include *Mycobacterium marinum*, *M. chelonae*, *M. fortuitum*, *M. kansasii*, *M. haemophilum*, and *M. avium-intracellulare*. Before the epidemic of acquired immunodeficiency syndrome (AIDS), most cases occurred in persons with underlying pulmonary disease. However, mycobacterial infections after transplantation are increasing in frequency and severity, with the highest incidence in recipients of hematopoietic stem cell transplants. These patients usually present with catheter-related infections, although skin lesions are rare in this population. Skin involvement is the most commonly reported manifestation of nontuberculous mycobacterial infections in solid organ recipients except lung transplant recipients, who are more likely to have pulmonary involvement. Manifestations include both localized and disseminated cutaneous disease.[26] Atypical mycobacterial infections in the skin are characterized by diverse morphologies, including reddish brown nodules and plaques (Fig. 29-6), abscesses (Fig. 29-7), and ulcers.[26] *M. avium-intracellulare* and *M. haemophilum* commonly cause disseminated infection, which can involve the lungs, lymph nodes, liver, spleen, bone marrow, and skin. Organisms can be identified by special stains or by culture of specimens from affected skin. Specific antimycobacterial antibiotic treatment regimens are complex and depend on the mycobacterial species, results of sensitivity testing, extent and severity of disease, and presence or absence of underlying immune defects.

▲ **FIGURE 29-6** Cutaneous *Mycobacterium avium-intracellulare* infection in a child with an inherited interleukin 12 receptor deficiency.

▲ **FIGURE 29-7** *Mycobacterium chelonae* infection in a patient receiving long-term, high-dose glucocorticoid treatment.

M. tuberculosis infection is a common worldwide problem, especially in individuals with impaired immunity. For example, individuals receiving high-dose corticosteroids are prone to active pulmonary tuberculosis. Cutaneous tuberculosis is usually more common in the setting of immunosuppression. Specifically, scrofuloderma (tuberculous lymphadenitis with extension to overlying skin) and numerous cutaneous lesions of miliary tuberculosis may occur more commonly in patients with underlying immune defects.

NOCARDIOSIS (See Chap. 185) *Nocardia* sp. are ubiquitous filamentous bacteria found in soil. *N. asteroides* is the most common species associated with human disease; however, *N. brasiliensis* can be seen in the southern United States and is more often associated with primary cutaneous disease. *N. farcinica* is less commonly isolated but is more likely to cause disseminated disease and has a higher risk of drug resistance.[27] Infection can be seen in immunocompetent hosts, but the majority of infections involve patients with immune compromise, particularly solid organ or bone marrow transplant recipients, those receiving long-term corticosteroid therapy, AIDS patients, intravenous drug users, and individuals with chronic pulmonary disease. In particular, long-term corticosteroid use doubles the risk of infection in susceptible individuals.[27] In transplant patients, the mean onset of infection is 9 months after transplantation, although it can occur as early as 1 month afterward. Before the use of cyclosporine to prevent rejection, infection rates were much

◀ **FIGURE 29-8** Nocardiosis in a man with glioblastoma.

higher in transplant recipients, and this decline is attributed to decreased use of corticosteroids. Most cases of nocardiosis in transplant patients (80 percent to 90 percent) present as primary pulmonary disease and dissemination occurs in up to 40 percent of cases. The skin is involved as a focus in one-third of cases with disseminated infection. More rarely, the skin is the primary location of infection.

Several types of skin lesions have been described, including abscesses with sinus tract formation, subcutaneous nodules with pustules (Fig. 29-8), mycetoma, sporotrichoid nodules, and cellulitis.[28] Diagnosis is based on demonstration of Gram-positive, partially acid-fast, branching bacilli in tissue or tissue exudate or is determined by tissue culture, although it often takes several weeks for organisms to grow. The treatment of choice is trimethoprim-sulfamethoxazole. Numerous other antibiotics have been reported to be efficacious as well, such as minocycline, carbapenems, and amikacin. Transplant patients may require long-term prophylactic therapy to prevent recurrent disease. In addition, incision and drainage of cutaneous abscesses should be performed.

BACILLARY ANGIOMATOSIS (See Chap. 182) Bacillary angiomatosis is caused by infection with the bacterium *Bartonella henselae* or *B. quintana* and usually occurs in AIDS patients and other immunocompromised hosts.[29] Cutaneous lesions appear as painful, dome-shaped vascular papules and nodules (often resembling pyogenic granulomas) (see Fig. 182-3). Disseminated infection may occur and involve the liver, spleen, bone marrow, and brain. Patients often have a history of scratches or bites by cats, the natural reservoir for *B. henselae* and *B. quintana*. Diagnosis is made by demonstration of pleomorphic bacilli in tissue specimens with Warthin-Starry silver stain. Preferred treatments include oral erythromycin and doxycycline.

OTHER BACTERIAL INFECTIONS (See Chaps 179, 180, and 183) Cellulitis caused by *Streptococcus pyogenes*, *Streptococcus pneumoniae*, or *S. aureus* may progress rapidly and cause necrotizing fasciitis in immunosuppressed patients (Fig. 29-9). Solid organ recipients also may develop recurrent cellulitis of the elbow, a condition termed *transplant elbow* that has been attributed to staphylococcal infection.

Individuals with underlying complement deficiencies (loss of late-phase components C5 to C9) or alcoholism are susceptible to infection with *Neisseria meningitidis*.[30] Patients have acute septicemia, meningitis, disseminated intravascular coagulation, and widespread petechiae and purpura (Fig. 29-10).

Persons with underlying hepatic disease (commonly alcoholic cirrhosis or hemochromatosis) are prone to infection with *Vibrio vulnificus*, a Gram-negative bacillus commonly found in seawater, shellfish, clams, and oysters.[31] Infection occurs by ingestion of contaminated seafood or by direct cutaneous inoculation after contact with contaminated seawater. Patients classically present with rapidly evolving septicemia and painful cellulitis, bullae, or ulcers on the lower extremities (Fig. 29-11).

Capnocytophaga canimorsus is a commensal bacterium found in the saliva of dogs and cats that is transmitted to humans by bites or scratches.[32,33] Hosts particularly susceptible to septicemia and widespread organ involvement include alcoholics, asplenic patients, and those taking glucocorticosteroids.[32] Skin lesions occur commonly and include macules, papules, purpura, and gangrene. In immunosuppressed patients, *Salmonella enteritidis* has been associated with cutaneous abscesses of the head and neck.[34]

Fungal Infections

CANDIDIASIS (See Chap. 189) Although mucocutaneous candidiasis is less serious than disseminated candidiasis in the setting of acute immunosuppression (as described in the earlier Candidiasis section), it is the most common complication observed in hosts with chronic cell-mediated immune dysfunction.[35] Approximately 10

▲ **FIGURE 29-9** Early (**A**) and late (after surgical débridement, **B**) lesions of necrotizing fasciitis caused by *Streptococcus pyogenes* in an intravenous drug abuser with underlying Job syndrome.

▲ **FIGURE 29-10** Acute meningococcemia in a man with acquired complement deficiency.

▲ **FIGURE 29-12** White superficial onychomycosis in a renal transplant patient receiving cyclosporine.

percent of patients with organ transplants exhibit oral candidiasis.[36] Patients with chronic mucocutaneous candidiasis have specific underlying immune deficits in fighting candidal infections and usually have chronic widespread disease without systemic involvement.

Patients with oral mucosal candidiasis most commonly have pseudomembranous, white, friable plaques that leave a raw, erythematous undersurface when scraped. Less common oral lesions include erythematous or atrophic plaques as well as angular cheilitis. Esophageal involvement should be suspected in any patient with oral candidiasis complaining of pain or difficulty swallowing. Moist intertriginous areas are common locations of cutaneous lesions and are characterized by tender erythematous papules and plaques, often with satellite pustules. Onychomycosis and paronychia caused by *Candida* sp. are common in patients with chronic mucocutaneous candidiasis. For mucocutaneous disease, topical therapy with nystatin or clotrimazole and oral fluconazole are the treatments of choice. Prophylactic treatment with fluconazole is often recommended for patients at high risk for infection, such as those who have recently undergone organ transplant surgery.

DERMATOPHYTOSIS (See Chap. 188) Dermatophytoses are common uncomplicated infections in normal hosts, but immunosuppressed patients may have widespread, aggressive infection that can be resistant to topical and systemic therapy.[37,38] Interestingly, the incidence of dermatophyte infection was not found to be higher in renal transplant patients than in normal hosts in one study.[39] Specific presentations seen in immunocompromised patients include multiple lesions, a wide distribution, and Majocchi granuloma. Manifestations more suggestive of immunosuppression include both white superficial onychomycosis and proximal subungual onychomycosis. In the former, the surfaces of affected nails have a white, chalky appearance (Fig. 29-12), and hyphae are observed readily in superficial nail plate scrapings. These conditions should prompt a search for underlying immune deficiency.

CRYPTOCOCCOSIS (See Chap. 190) *Cryptococcus neoformans* is a yeast-like encapsulated fungus that is ubiquitous and is found commonly in soil enriched with bird feces. Primary infection is acquired via the respiratory tract by inhalation of airborne spores and usually is asymptomatic in healthy individuals. Organ transplant recipients are now the population at highest risk of developing disseminated disease, because improved antiretroviral agents have decreased the incidence in those with HIV disease.[40] Other immunosuppressed patients, particularly those receiving high-dose systemic corticosteroids, are susceptible to hematogenous spread and disseminated infection.[41] Also at increased risk include those with diabetes mellitus, chronic lymphocytic leukemia, chronic myeloid leukemia, multiple myeloma, and Hodgkin disease. The central nervous system is most commonly involved, although infection may occur throughout the body, including the lungs, bone marrow, heart, liver, spleen, kidneys, thyroid, lymph nodes, and adrenal glands. The skin is the most commonly affected site in disseminated disease in those with organ transplants receiving systemic tacrolimus.[40]

Classically, cutaneous lesions occur in up to 15 percent of patients with disseminated infection; however, skin lesions are manifest in 67 percent of patients receiving tacrolimus. In transplant patients, erythematous, edematous, warm, painful plaques on the extremities (clinically indistinguishable from bacterial cellulitis) have been reported most frequently.[40] Umbilicated papules (resembling mollus-

▲ **FIGURE 29-11** *Vibrio vulnificus* infection in an alcoholic patient after minor trauma sustained while swimming in the ocean.

▲ **FIGURE 29-13** Molluscum-like lesions of cutaneous cryptococcosis. (Used with permission from Yale Residents' slide collection.)

cum contagiosum), nodules, pustules, vesicles, and ulcers also may occur (Fig. 29-13). Oral mucosal cryptococcal nodules and ulcerations also have been described. Lesions may be isolated or multiple and can be quite painful. Although any area of the skin and oral mucosa may be affected, there is a predilection for disseminated disease to involve the head and neck region.

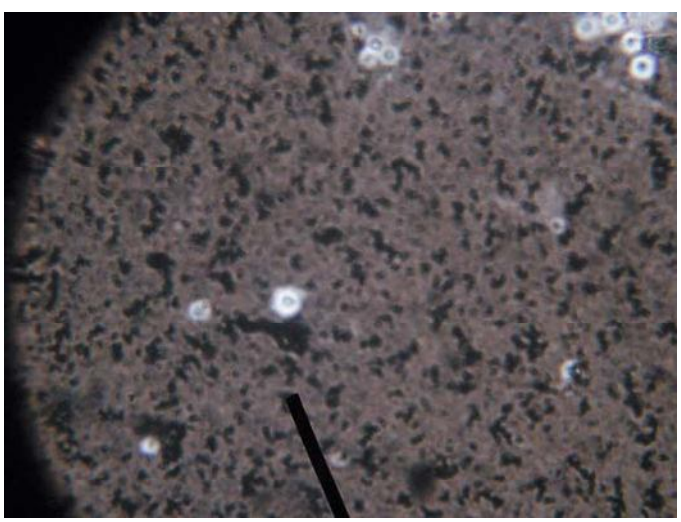
Although primary skin disease may occur in the absence of pulmonary infection, diagnosis of cutaneous cryptococcosis always warrants an investigation for systemic infection, especially because disseminated disease may not always be evident clinically. This is usually accomplished by examining cerebrospinal fluid for cryptococcal polysaccharide antigens. For skin lesions, budding encapsulated yeasts can be identified readily in tissue biopsy specimens as well as in material obtained by a scraping of skin lesions. The yeast stain red with periodic acid-Schiff and mucicarmine stains and black with methenamine silver stain. India ink can be used to accentuate the capsule in a skin scraping (Fig. 29-14). *Cryptococcus* can be isolated in culture of cutaneous tissue. The treatment of choice for cryptococcosis is intravenous amphotericin B with or without flucytosine. Fluconazole is used as alternative primary treatment and is the treatment of choice for prophylaxis in individuals at high risk for primary or recurrent infection.

HISTOPLASMOSIS (See Chap. 190) *Histoplasma capsulatum* is a dimorphic fungus that is found commonly in soil in central and eastern regions of the United States. As with cryptococcosis, inhalation of airborne spores causes primary pulmonary infection that usually leads to self-limited disease in otherwise healthy individuals. Disseminated disease most often occurs in individuals with deficiencies in cell-mediated immunity.[42] In addition to pneumonia, immunosuppressed hosts may show fever, renal failure, central nervous system involvement, hepatosplenomegaly, lymphadenopathy, and myelosuppression.

Skin lesions occur in 5 percent to 25 percent of patients with disseminated infection and may be an initial sign of disease.[43] Mucocutaneous lesions commonly manifest as painful nodules or plaques that progress to ulcers with indurated borders. Numerous other morphologic forms have also been described, including molluscum-like papules, acneiform papules and pustules, and cellulitis. In addition, as with cryptococcosis, the head and neck region is involved most frequently. In fact, the oropharynx is the most common site for lesions of mucocutaneous histoplasmosis. Because the organism grows very slowly in culture, histoplasmosis is best diagnosed by direct examination of tissue. Numerous small, oval, yeast-like fungi can be seen within the cytoplasm of dermal macrophages. Antigen testing is also available, but cross-reaction can occur with blastomycosis and other fungal infections (though not with cryptococcus). The treatment of choice for disseminated histoplasmosis in an immunosuppressed host is intravenous amphotericin B. For patients who are not acutely ill, oral itraconazole may be used; itraconazole is also recommended for immunosuppressed patients to prevent recurrent disease.

COCCIDIOIDOMYCOSIS (See Chap. 190) *Coccidioides immitis*, the causative agent of coccidioidomycosis, is endemic to soil in the southwestern United States, and infection is usually acquired through inhalation of spores, which causes pulmonary disease.[44] Although progressive primary infection may occur in immunosuppressed patients, reactivation of a prior, clinically unapparent infection appears to be more common. The risks of dissemination and fatal infection are greater among pregnant women, non-Caucasians, and immunosuppressed patients with defects in cell-mediated immunity. Thus, disseminated coccidioidomycosis can occur in any immunocompromised patient who lives or has lived previously in an endemic area.

Immunosuppressed patients with disseminated disease may have fever, pneumonia, bone involvement, and meningitis. Mortality is high. Skin lesions are varied, but include multiple verrucous papules, abscesses, and ulcerated papules and plaques. Distinguishing primary cutaneous lesions (which are rare) from disseminated disease is important and may require serologic testing.[45] Primary cutaneous lesions usually resolve in healthy individuals, whereas lesions persist in immunocompromised patients. Other cutaneous lesions seen in systemic disease include erythema multiforme, urticaria, a maculopapular rash, and erythema nodosum. Definitive diagnosis of coccidioidomycosis is made by demonstrating characteristic endosporulating spherules in smears or biopsy specimens or by culture of infected tissue. In disseminated infections in immunosuppressed hosts, treatments for life-threat-



▲ **FIGURE 29-14** Low-power microscopic examination of a skin scraping from the patient in Fig. 29-13 stained with India ink. The capsule resists the stain and appears as a halo around the organism. Slide preparations can help confirm the diagnosis rapidly. (Used with permission from Yale Residents' slide collection.)

ening disease include amphotericin B until infection is controlled, followed by itraconazole or fluconazole. Immunosuppressed patients with meningeal disease may require lifelong therapy.[46]

BLASTOMYCOSIS (See Chap. 190) *Blastomyces dermatitidis* is endemic to the soil of the Ohio and Mississippi river valleys. Infection is acquired through inhalation of spores. Immunosuppressed patients are prone to disseminated disease involving the lungs, bone, genital tract, and skin. Skin is the most common extrapulmonary site of involvement.[47,48] Lesions appear as verrucous or ulcerated plaques with serpiginous borders located on the head, neck, or distal extremities. Ulcerative lesions begin as subcutaneous nodules and pustular lesions. Subcutaneous, tender lesions can also occur that mimic panniculitis.[47] Diagnosis is made on demonstration of broad-based, budding, thick-walled yeasts in exudates or skin scrapings from the edges of lesions or by tissue culture. In life-threatening disseminated infection, intravenous amphotericin B is the treatment of choice, whereas less severe disease is treated with oral itraconazole.

OTHER FUNGAL INFECTIONS *Alternaria* is a common saprophytic fungus that can cause opportunistic infection in the setting of organ transplantation, Cushing syndrome, autoimmune bullous disease, and lymphoproliferative disorder. Over half of the patients reported to have cutaneous alternariosis were taking systemic corticosteroids, and secondary increased skin fragility has been implicated as a risk factor. There are two routes of infection: traumatic inoculation and secondary colonization of a pre-existing skin lesion.[49]

Penicillium marneffei is a dimorphic fungus that is common in Southeast Asia (see Chap. 190). Most infections are associated with HIV disease, although disseminated infection has been reported in immunosuppressed travelers to endemic areas.[50] Tinea versicolor and folliculitis caused by *Pityrosporum ovale* (also known as *Malassezia furfur*) (see Chap. 189) may be widespread and persistent in immunosuppressed hosts. In addition, *Malassezia* has been reported to cause indwelling catheter–associated fungemia in immunosuppressed hosts, especially in those receiving parenteral lipid preparations.

Viral Infections

HERPESVIRUS INFECTION (See Chaps. 192, 193, and 194) Herpesviruses include HSV-1, HSV-2, VZV, human herpesvirus 6 (HHV-6), HHV-7, Epstein-Barr virus (EBV), and Kaposi sarcoma–associated herpesvirus (KSHV). Infections are most prevalent in patients with acquired defects in cell-mediated immunity. Herpesviruses infect hosts for life and remain dormant in the nuclei of latently infected cells. Suppression of immunity often leads to reactivation (i.e., a latent to lytic switch).

Recurrent HSV-1, HSV-2, and VZV infections are common in cancer and post-transplant patients, with 70 percent to 80 percent experiencing reactivation with at least one of these three viruses. Herpes zoster (recurrent VZV infection) is most likely to occur during the first year after transplantation, and the incidence ranges from close to 6 percent in liver transplant recipients to 16 percent in heart transplant patients.[51] Although presentations can be identical to those in immunocompetent hosts, presentations atypical in morphology and distribution can occur. For example, in immunosuppressed hosts recurrent lesions due to HSV or VZV may be isolated, nondermatomal, disseminated, necrotic, ulcerative, or verrucous (Figs. 29-15 and 29-16). In the mouth, chronic recurrent HSV infection can form white plaques and can be confused clinically with candidiasis. Lesions can occur in atypical locations, such as the tongue. Severe pain often is associated with both skin and oral lesions, and postherpetic pain is common. Protracted clinical courses of recurrent HSV or VZV infection are also more common in the setting of immunosuppression. In short, any painful, eroded lesion in an immunocompromised patient, regardless of its distribution or age, should be evaluated for both HSV and VZV by Tzanck preparation, immunofluorescence testing for viral antigen, polymerase chain reaction testing, and/or viral culture. Importantly, systemic infection involving the lungs, central nervous system, liver, heart, and gastrointestinal tract may occur. Treatment with systemic acyclovir or a related antiherpesvirus drug is always necessary. Prophylactic treatment to prevent recurrent episodes should be considered for individual patients if warranted. Foscarnet is the drug of choice for acyclovir-resistant viruses.

▲ **FIGURE 29-15** Severe chronic herpes simplex infection in a patient receiving long-term, high-dose glucocorticoids for autoimmune disease.

▲ **FIGURE 29-16** Severe recurrent varicella-zoster virus infection in a child with acute lymphocytic leukemia.

Reactivation and recurrent disease associated with CMV (see Chap. 192) are major causes of morbidity and mortality in patients with marked immunosuppression, occurring in up to one-third of transplant patients.[52] In this population, disease is most commonly caused by reactivation of pre-existing CMV infection, although CMV may be transmitted from donor to host via the transplanted organ. CMV retinitis, gastroenteritis, hepatitis, and pneumonitis are the most common clinical disease manifestations. Cutaneous lesions are varied and non-specific, including ulcers, papules, vesicles, petechiae, and morbilliform eruptions. Oral ulcers caused by CMV, particularly on the lateral aspects of the tongue, are most common. Painful, punched-out perianal ulcers have been reported and are probably the most specific type of skin lesion attributable to CMV infection. Tzanck preparations of specimens

from the bases of ulcers may show multinucleated giant cells, and CMV-infected dermal endothelial cells may be seen in tissue sections by routine microscopy, appearing as large cells with intranuclear inclusions surrounded by clear halos (owl-eye nuclei). In addition, CMV can be cultured from infected skin. Ulcers containing both CMV and HSV also have been reported. The treatment of choice for systemic CMV disease is intravenous ganciclovir, although intravenous foscarnet, cidofovir, or CMV immunoglobulin also may be effective. HHV-6 and HHV-7, herpesviruses closely related to CMV, also can cause widespread multiorgan infection in immunosuppressed individuals.

EBV and KSHV infections (see Chaps. 128 and 192) are distinguished from the other herpesviruses infections in that they are associated with malignancies in the setting of immunosuppression. Specifically, chronic reactivated EBV infection is associated with non-Hodgkin lymphoma and other lymphoproliferative disorders, whereas chronic KSHV infection is associated with Kaposi sarcoma (KS), primary effusion lymphoma, and the plasmablastic variant of Castleman disease. Their neoplastic potential is discussed further later. Oral hairy leukoplakia is a unique presentation of EBV reactivation within oral mucosal epithelial cells, classically seen in patients with AIDS but also seen in other immunosuppressed individuals (see Chap. 198).[52] Lesions appear as adherent, white, corrugated plaques on the lateral aspects of the tongue. Histologically, there is hyperkeratosis and vacuolated suprabasal epithelial cells. Oral hairy leukoplakia may respond to topical podophyllin or high-dose acyclovir; however, it is usually asymptomatic and does not require treatment. Although it has been regarded as a poor prognostic indicator in HIV-infected individuals, the clinical significance of oral hairy leukoplakia in transplant patients is not known.

HUMAN PAPILLOMAVIRUS INFECTION (See Chap. 196) Warts caused by human papillomavirus (HPV) infection are a common problem in post-transplant patients and in others receiving long-term immunosuppressive drug therapy. The prevalence of warts is higher in patients taking cyclosporine-based regimens than in immunosuppressed patients not taking cyclosporine. In addition, the prevalence of warts increases with longer duration of immune compromise, with up to 95 percent of individuals affected 5 years after transplant surgery. In this setting, lesions are numerous, persistent, and difficult to eradicate. The morphology of the lesions may be typical or atypical. Atypical lesions appear as scaly macules and plaques, occur more commonly in sun-exposed areas, and are associated with HPV types observed in patients with epidermodysplasia verruciformis (e.g., HPV types 5 and 8). Several studies have reported that systemic retinoids (i.e., isotretinoin or acitretin) can prevent or decrease wart formation and prevent a variety of pre-malignant and malignant cutaneous lesions in post-transplant patients. In these patients, the association between HPV infection and cutaneous genital and non-genital squamous cell carcinoma (SCC) is complex, as discussed in Non-Melanoma Skin Cancer.

▲ **FIGURE 29-17** Norwegian (crusted) scabies in a man with non-Hodgkin lymphoma.

Parasitic Infestations: Norwegian Scabies (See Chap. 208)

Norwegian (or keratotic or crusted) scabies infection typically occurs in the settings of mental deficiency, malnutrition, or immunosuppression. Clinically, patients present with multiple widespread, thick, gray or yellowish scaly plaques (Fig. 29-17), with numerous mites present within lesions. Unlike in common scabies, pruritus may be minimal. Several courses of treatment with topical permethrin, as well as keratolytics, may be necessary to cure patients. Oral ivermectin is useful in these patients.

Cancer

NON-MELANOMA SKIN CANCER (See Chaps. 114 and 115) Non-melanoma skin cancer is the most common malignancy in adult solid organ transplant patients and causes significant morbidity and mortality. The overwhelming majority of these neoplasms are SCCs; however, the incidences of basal cell carcinomas and other cutaneous malignancies are also increased.[53] For SCC, the risk is at least 65 times higher in transplant patients than in the general population and increases exponentially with length of immunosuppression.[53,54] The cumulative incidence is a staggering 80 percent after 20 years of immunosuppressive therapy in renal transplant patients.[55] The incidence of other epithelial proliferative diseases, including actinic keratoses, keratoacanthomas, porokeratosis, appendageal tumors, and sebaceous carcinomas, is greatly increased as well.

The pathogenesis of non-melanoma skin cancers in post-transplant patients is multifactorial and has been studied and reviewed extensively.[53,56,57] The distribution of lesions and the populations at highest risk suggest that sun exposure is one of the most important risk factors.[58] Risk also increases with age and is greater for those with fair skin type, those living near the equator, and those with documented histories of significant sun exposure. In addition, gene mutations in tumor suppressor gene p53 characteristic of those caused by ultraviolet radiation are found within non-melanoma skin cancers in transplant patients.[59,60] The role of immunosuppressive medications is dual. Some of the most common agents (azathioprine and cyclosporine) are directly carcinogenic, and their additional effects on the immune system diminish immune surveillance mechanisms that potentially serve to eradicate pre-cancerous lesions. The role of HPV infection in organ transplant recipients is unclear. HPV is known to cause cervical SCC and can be detected in cutaneous cancers of transplant patients. Furthermore, epidermodysplasia verruciformis–associated HPV types (5, 8, and others) have been detected in cutaneous SCC, and there is suspicion that in-

fections by these viruses may occur at an increased rate in immunosuppressed patients. Asymptomatic infection has been identified in the general population, however, and thus it is unclear whether these HPV types are transcriptionally active and pathogenic in forming skin cancers in the setting of immunosuppression.[61–63]

Importantly, SCC in post-transplant patients can be clinically aggressive. Local invasion, recurrence after primary treatment, and distant metastases are not uncommon and are all associated with a higher rate of mortality in organ transplant recipients.[56,64] The mortality rate from skin cancers in this population should not be underestimated. Skin cancers accounted for up to 27 percent of deaths in heart transplant recipients after the fourth year post-transplantation.[65]

Oral mucosal leukoplakia and oral SCC also occur more commonly in immunocompromised individuals.[66] Lip lesions are particularly common, which suggests a pathogenic role for sunlight in lesion formation.

The incidence of Merkel cell carcinoma (see Chap. 120) is increased and the cancer presents at a younger age in transplant recipients. Sentinel lymph node biopsy has become the standard of care in this population due to the high rate of lymph node metastases.[67,68] The mortality rate is high at 56 percent 2 years after diagnosis, which is nearly twice the rate for immunocompetent individuals.

Careful and regular examination of skin and oral mucosa by both patients and dermatologists is required for all transplant patients, with an emphasis on monitoring of potentially pre-malignant lesions (e.g., actinic keratoses, porokeratosis, leukoplakia) for morphologic changes and initiation of treatment as indicated. Ideally, patients would be treated for pre-cancerous lesions before transplant surgery. All transplant patients should be advised to maximize sun precautions. Oral retinoids, especially acitretin, have been used successfully to decrease the occurrence of new SCCs and actinic keratoses in transplant patients but can be difficult to tolerate.[69] A range of dosages has been used, and good effects with minimal side effects have been reported at daily dosages of 0.2 to 0.4 mg/kg/day.[70] It is a common clinical observation that when the medication is discontinued, numerous cancerous lesions arise (described as a rebound effect).[71] Thus, when retinoids are considered for prophylaxis of non-melanoma skin cancers, they should be considered as a long-term treatment.

MELANOMA (See Chap. 124) The incidence of melanoma and widespread atypical melanocytic nevi may be increased in transplant recipients and in other immunosuppressed patients.[72] In particular, children who have had transplants appear to be at higher risk for the development of melanoma (14 percent of all skin cancers) compared with adults (5 percent of skin all cancers).[73] Most melanomas arise from precursor nevi in these patients. Melanomas have also been reported to originate from donor organs causing metastatic disease in graft recipients.[74]

LYMPHOMA (See Chap. 146) Lymphoproliferative disorders are common after transplantation and are often related to EBV-mediated proliferation of B cells. Extra-nodal involvement is common, including involvement of the gastrointestinal tract, lungs, central nervous system, the transplanted organ, and skin.[75,76] Lesions present as violaceous macules to firm papules and plaques, similar to presentation in immunocompetent individuals. Lymphoma with purely cutaneous involvement is rare after transplantation. Most reported cases represent lymphomas of B-cell origin and are occasionally $CD30^+$. The presence of EBV is often detected. Prognosis is generally better if there is cutaneous involvement alone, perhaps due to the ease of detection. Cutaneous T-cell lymphomas account for 30 percent of cases of cutaneous lymphomas in transplant patients. EBV is not associated with development in these patients. Clinical presentation is similar to that in non-transplant patients, except that there is an increased incidence of erythroderma. Prognosis is also worse than for cutaneous T-cell lymphoma in the general population.[77]

KAPOSI SARCOMA (See Chap. 128) The occurrence of KS is increased in patients receiving immunosuppressive therapy after organ transplantation, with an incidence of 0.5 percent to 5.0 percent. Risk factors in transplant recipients include male sex and Mediterranean, Jewish, Arabic, Caribbean, or African descent, as in the classic form of the disease.[78,79] All cases of KS, regardless of clinical or geographic setting, are associated with KSHV infection.[80] The vast majority of patients with post-transplant KS are KSHV seropositive before transplantation. Rarely, post-transplant KS can occur when KSHV-infected organs are transplanted into KSHV seronegative recipients.[81,82]

Clinically, skin lesions of post-transplant KS are identical to other forms of KS. As in classic KS, transplant-associated disease is found most commonly on the lower legs and feet, although the groin and oral cavity are also common locations. Typically, early KS lesions are deep red to violaceous macules or patches. With time, lesions develop into papules, plaques, nodules, or tumors. Visceral involvement occurs in 25 percent of renal transplant patients and 50 percent of those with heart or lung transplants.[83] Reduction in immunosuppressive treatment often causes disease regression, although these patients remain at risk for developing KS at a later time if immunosuppressive therapy is reinstituted. Additional treatments include local excision or radiation therapy, intralesional therapy, and systemic chemotherapy.

SECTION 5

INFLAMMATORY DISEASES BASED ON NEUTROPHILS AND EOSINOPHILS

CHAPTER 30

Regulation of the Production and Activation of Neutrophils and Eosinophils

Steven M. Holland
James Loveless
Lisa A. Beck

NEUTROPHILS

This section presents an overview of neutrophil biology and function and uses a few well-characterized defects of myeloid function as illustrations.

Ontogeny and Development

Similar to the other components of the hematopoietic system, the neutrophil is ultimately derived from a pluripotent hematopoietic stem cell. The development of the myeloid stem cell is largely determined by ambient cytokines and reflected in its surface markers, morphology, and functional characteristics. The myeloblast is fully committed to the neutrophil lineage and is the first morphologically distinct cell in neutrophil development. Subsequent stages of neutrophil development occur under the influence of granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF). Four to six days are required for maturation through the mitotic phase to the myelocyte, and 5 to 7 days more for the myelocyte to develop into a mature neutrophil, including the metamyelocyte and band stages, before emerging as a fully developed neutrophil. Development of neutrophils through the myelocyte stage normally occurs exclusively in the bone marrow, which is composed of approximately 60 percent developing neutrophils. The mature neutrophil measures 10 to 12 μm and has a highly condensed, segmented, multi-lobulated nucleus, usually with three to five lobes. Although 10^{11} neutrophils are generated daily, this number can rise 10-fold in the setting of infection. The calculated circulating granulocyte pool is 0.3×10^9 cells/kg blood and the marginated pool is 0.4×10^9 cells/kg blood, comprising only 3 percent and 4 percent of the total granulocyte pool, respectively. The bone marrow releases 1.5×10^9 cells/kg blood/day to this pool but keeps 8.8×10^9 cells/kg blood in the marrow in reserve. An additional reserve of immature and less competent neutrophils, 2.8×10^9 cells/kg blood, is also available.

G-CSF is critically important for neutrophil production.[1] Mice deficient in G-CSF show reduced neutrophil numbers and cannot upregulate neutrophil numbers in response to infection.

Biologic Functions

GRANULE CONTENT AND FUNCTION (Table 30-1) Neutrophils are characterized by cytoplasmic granules and partially condensed nuclei. Granules are first found at the promyelocyte stage.[2] Primary (azurophilic) granules are the first to arise, measure approximately 0.8 μm in diameter, and contain numerous antimicrobial products including lysozyme, myeloperoxidase, and defensins.[3] Primary granules are only synthesized at the promyelocyte stage. The promyelocyte gives rise to the myelocyte, the last cell of the neutrophil lineage with proliferative potential. Therefore, cytokines or agents which increase total neutrophil production must act at or before the myelocyte stage. The smaller eosinophilic secondary (specific) granules appear during the myelocyte stage. These granules measure about 0.5 μm in diameter and contain lactoferrin, collagenase, gelatinase, vitamin B_{12}–binding protein, and complement receptor 3 (CR3; CD11b/CD18). $gp91^{phox}$ and $p22^{phox}$ comprise the specific granule component cytochrome b_{558}, defects in which cause chronic granulomatous disease

NEUTROPHILS AT A GLANCE

- Human bone marrow commits enormous resources to the creation of neutrophils, producing approximately 10^{11} daily with a circulating half-life of approximately 7.5 hours and tissue survival for 1 to 2 days.
- Neutrophils are absolutely required for the prevention of infection and are not yet amenable to significant external replacement therapy.
- The neutrophil not only plays a central role in host defense, it can be responsible for significant tissue damage as well.
- The pathophysiology of the neutrophil indicates pathways, which can be exploited to enhance protection from infection. Selective abrogation of those pathways that are injurious in certain settings is also possible.
- Regulation of neutrophil responses in the skin is a major concern.

(CGD), characterized by infections with particular catalase-producing bacteria. Gelatinase also cleaves and potentiates the activity of the chemokine interleukin 8 (IL-8). Because primary granules are synthesized early and distributed to daughter cells during division, they are eventually outnumbered by about 3:1 by the specific granules, which are produced throughout the myelocyte stage.

Granules fuse in a sequential fashion with incoming phagocytic vacuoles, such as those containing ingested bacteria. Secondary granules fuse to the phagosome within the first 30 seconds after ingestion and release their enzymes, many of which function best at neutral or alkaline pH. By 3 minutes after ingestion, the primary granules have fused to the phagolysosome leading to rapid lowering of the intravacuolar pH. For objects too large to be ingested, or certain stimuli, degranulation to the cell surface occurs with release of granule contents into the surrounding environment. This can be inferred by detection of lactoferrin levels in blood.

An example of disordered granule biogenesis is Chédiak-Higashi syndrome (CHS), a rare autosomal recessive disorder with abnormal pigmentation due to a generalized abnormality of primary granule and lysosome formation (see Chap. 144).

NEUTROPHIL-SPECIFIC GRANULE DEFICIENCY

Neutrophil-specific granule deficiency is a rare, autosomal recessive condition clinically characterized by a profound susceptibility to bacterial infections. There is a paucity or absence of neutrophil-specific granules, specific granule proteins (e.g., lactoferrin), and their respective messenger RNAs, and very low levels of the primary granule products defensins and their messenger RNAs. Specific granule deficiency is due to loss of the transcriptional factor CCAAT/enhancer binding protein e (CEBPe), which is essential in normal myeloid development. Acquired abnormalities of neutrophil granules are seen in some myeloid leukemias, in which primary granule contents may be aberrantly accumulated (e.g., Auer rods in acute myelogenous leukemia).

Tissue Trafficking

CHEMOATTRACTANTS AND CHEMOTAXIS

Metchnikoff discovered over a century ago that neutrophils move toward very slight gradients of chemical signals, now termed *chemoattraction*. The "classic" chemoattractants are *N*-formyl-methionyl-leucyl-phenylalanine, complement factor 5a (C5a), leukotriene B_4, and platelet-activating factor (PAF). More recently, chemokines (*chemo*attractant cyto*kines*), a class of small (< 10 kd) extremely active chemoattractant proteins have been identified (see Chap. 12).

IL-8 is a potent chemoattractant and neutrophil activator (see Chap. 11). Its blockade by neutralizing antibody in rabbit models of pulmonary inflammation prevented neutrophil accumulation and reperfusion injury, confirming its central role in neutrophil recruitment to sites of inflammation. Cellular sources for IL-8 include neutrophils, monocytes, T cells, B cells, natural killer cells, basophils, eosinophils, fibroblasts, endothelial cells, keratinocytes, and smooth muscle. Exudative neutrophils are particularly effective at synthesizing IL-8, probably through a calcium-regulated mechanism.

Exuberant neutrophil function is implicated in Sweet syndrome (acute febrile neutrophilic dermatosis) as shown by the frequent association of the syndrome with hematologic malignancies, dysmyelopoiesis, and sometimes with the use of G-CSF (see Chap. 31).

The classic chemoattractants and chemokines use similar receptors that have in common seven transmembrane regions, an extracellular amino terminal domain, and transduce their signals through pertussis-toxin sensitive heterotrimeric G proteins. These are the same type of receptors through which light, neuropeptides, and neurotransmitters signal. Chemoattractant receptor signaling entails exchange of bound guanine diphosphate for guanine triphosphate by the α subunit of the heterotrimeric G protein, which in turn leads to the dissociation of the β-γ subunit of the complex, stimulation of phospholipase C, and generation of inositol triphosphate and diacylglycerol from phosphatidylinositol bisphosphate. Inositol triphosphate stimulates the release of calcium from intracellular "calciosomes," whereas diacylglycerol activates protein kinase C. Extracellular calcium also enters the cell, preparing it for subsequent movement, generation of oxidants, and secretion of vesicles.

Ras-related guanosine triphosphatases of the rho superfamily are also involved in actin cytoskeletal regulation and adhesion. Phosphatidylinositol 3-kinase is activated by rho and ras and is necessary for the neutrophilic respiratory burst, adhesion, endothelial transmigration, and chemotaxis. Mitogen-activated protein (MAP) kinases are serine/threonine kinases that include p38, Erk1, Erk2, and Jnk and are involved in neutrophil signaling and adhesion. Inhibition of p38 impairs chemotaxis and tumor necrosis factor (TNF)-α–mediated superoxide production, adhesion, and release of secondary granules. Erk activation is required for neutrophil homotypic aggregation. Salicylates also inhibit neutrophil adhesion through Erk inhibition.

Several chemokine receptors also function as necessary human immunodeficiency virus (HIV) co-receptors. Mutations in the chemokine receptor CCR5 that are protective against HIV infection have spawned investigation into chemokine receptor blockade for prevention of HIV infection.

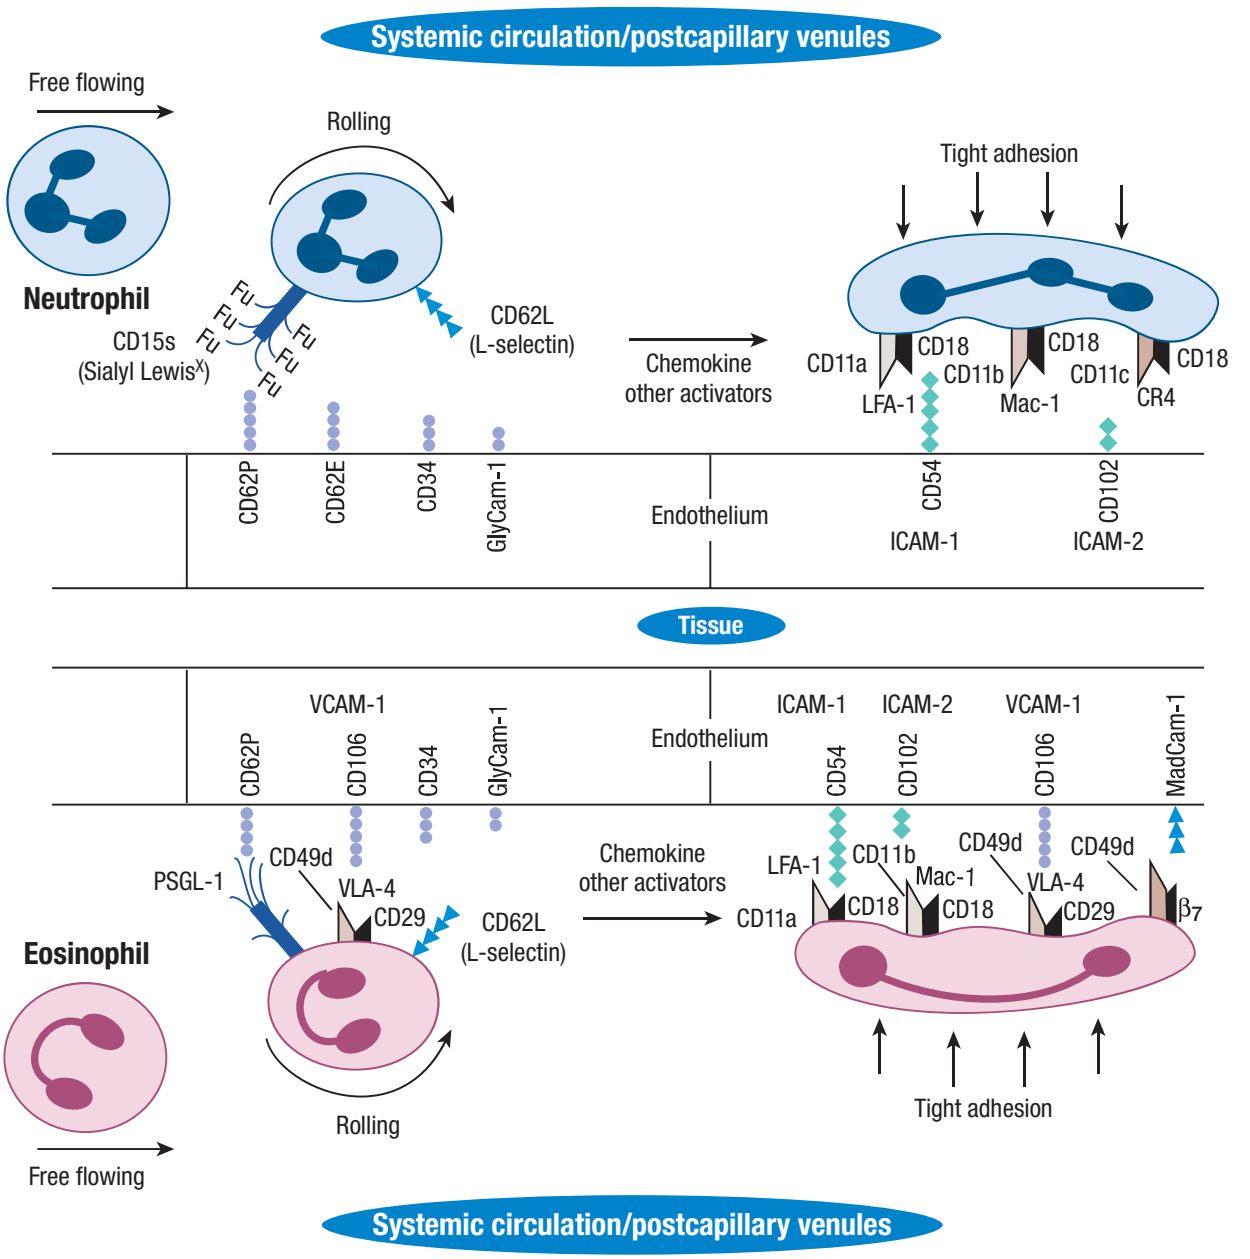
ADHESION Neutrophils exist as free-flowing (those which are sampled on blood drawing) and marginated cells (those which are attached to the endothelium or are traversing the lung, skin, or other tissues). Neutrophils rolling along the endothelium recognize sites of activation (e.g., chemokine expression), adhere to those sites, and traverse the endothelium to enter the tissue and fight infection. Leukocyte physical interaction with endothelium and other leukocytes is mediated by integrins, selectins, and intercellular adhesion molecules (ICAMs; Fig. 30-1).

Elaboration of chemoattractants or display of activation markers on endothelium triggers leukocyte high affinity binding by β_2 integrins, heterodimeric surface molecules largely stored in the secondary granules of neutrophils that are displayed on the cell surface upon leukocyte activation. There are three β_2 integrin heterodimers comprised of different α chains, CD11a, -b, and -c, and a common β chain, CD18. Each CD11/CD18 complex has separate and overlapping activities. CD11a/CD18 [leukocyte function–associated molecule 1 (LFA-1)] binds to other leukocytes and mediates tight adhesion to the endothelium through ICAM-1 and ICAM-2. CD11b/CD18 (Mac-1, Mo-1, or CR3) binds to the inactivated form of the third component of complement (C3bi) and thereby facilitates complement-mediated phagocytosis. CD11b/CD18 also binds to bacteria directly, to fibrinogen, and to endothelium through ICAM-1. The divalent cations Ca^{2+} and Mg^{2+}/Mn^{2+} mediate adhesion through β_2 integrin "A" domains containing a metal ion-dependent adhesion site. CD11b/CD18 may also induce the expression of the β_1 integrin very late antigen 6 [VLA-6 (CD49f/CD29)], derived from neutrophilic granules, to aid in tissue infiltration. The integrin-associated protein (CD47), expressed on neutrophils and endothelial and epithelial cells, is also involved in the transendothelial and transepithelial migration of neutrophils.[4] Metalloproteinases may be involved in cleavage of L-selectin, allowing neutrophil migration through the basement membrane.

Absence of CD18 causes lack of the CD18/CD11 heterodimers and is called *leukocyte adhesion deficiency type 1* (LAD1). Neutrophils lacking CD18 roll normally along the endothelium but are unable to stick to the vessel wall or exit the circulation after chemotactic stimulation. Absence of LFA-1 (CD11a/CD18) makes neutrophils unable to bind tightly to and traverse activated endothelium to infected areas. Therefore, affected patients have chronic neutrophil leukocytosis, presumably from inability of neutrophils to bind tightly to endothelium and exit the circulation, thus leading to a reduction in the marginated pool and an increase in the circulating pool. Poor neutrophil penetration to sites of bacterial invasion leads to necrotic ulcers that lack neutrophils on biopsy. Absence of Mac-1 (CD18/CD11b or CR3) leads to inability to perform complement-mediated phagocytosis, although antibody-mediated phagocytosis remains intact.

Severe LAD-1 (< 0.5 percent of normal protein expression) is a disorder manifested by delayed umbilical stump separation, umbilical stump infection, persistent leukocytosis in the absence of active infection (> 15,000/μL), and severe, destructive periodontitis with loss of teeth and alveolar bone. Recurrent infections of the skin, upper and lower airway, bowel, perirectal area, and septicemia are common and usually due to *Staphylococcus aureus* or Gram-negative rods. Severe LAD-1 patients should receive bone marrow transplantation in early childhood. Moderate LAD-1 (2.5 percent to 10.0 percent of normal protein expression) tends to be diagnosed later in life and is less commonly associated with life-threatening infections. Leukocytosis, delayed wound healing, and periodontal disease are still common. Fluorescent-activated cell sorting shows reduction or absence of CD18 and the co-expressed molecules CD11a, CD11b, and CD11c.

Neutrophil "rolling" along the endothelium is mediated through selectins, surface glycoproteins on the endothelium, and sialyl-Lewis X (CD15s), a surface glycoprotein on neutrophils (see Fig. 30-1). Endothelial cells express E-selectin (CD62E) and P-selectin (CD62P), whereas leukocytes express L-selectin (CD62L). Although endothelial E-selectin and P-selectin bind to the sialyl-Lewis X (CD15s) antigen on neutrophils, the neutrophil molecule L-selectin probably binds to distinct antigens on endothelium, including CD34, and is highly sensitive to glycosylation. L-selectin is shed by neutrophils on activation, thereby allowing neutrophil migration into sites of inflammation. Cross-linking of L-selectin on neutrophils results in superoxide generation and may result in upregulation of TNF-α, IL-8, and tyrosine phosphorylation and activation of MAP kinase. LAD2 occurs in the absence of properly fucosylated CD15s, leading to neutrophilia, recurrent pulmonary, periodontal, and cutaneous infections, and abnormal chemotaxis. The defect is in the gene FUCT1, which is a fucosyl transferase. Because the product of FUCT1 is a GDP-fucose transporter, this disease is now classified as a congenital disorder of glycosylation (CDG), and known as *CDG-IIc*. Interestingly, although infections are common early in life, LAD-2 (CDG-IIc) patients appear to improve with age. Administration of oral fucose to some patients with LAD-2 has



▲ **FIGURE 30-1** Tissue trafficking of neutrophils and eosinophils. The interaction of selectins and integrins on the leukocyte surface with their endothelial addressins is depicted (neutrophils on the top and eosinophils on the bottom). The majority of leukocytes are in a laminar flow pattern. Following tissue signals that activate endothelial selectins and glycoproteins, a subset of leukocytes begin to roll along the vascular wall. For the neutrophil, this typically involves the interaction of CD15s with CD62P (P-selectin) and CD62E (E-selectin) on the endothelial cell or CD62L (L-selectin) with CD34 or glycosylation-dependent cell adhesion molecule 1 (GlyCAM-1) on the endothelial cell. Eosinophil rolling primarily uses P-selectin glycoprotein ligand 1 (PSGL-1) and its counter-ligand on the endothelium, P-selectin, with a more minor role played by CD62L [very late antigen 4 (VLA-4)] and their endothelial addressins, CD34/GlyCAM-1 and vascular cellular adhesion molecule-1 (VCAM-1), respectively. Abnormalities in fucosylation of CD15s cause leukocyte adhesion deficiency 2. Activation of leukocytes by the requisite chemoattractant leads to the expression of integrins with higher avidity conformations. In the case of the neutrophil, the relevant integrins are the β_2 family members [lymphocyte function–associated antigen 1 (LFA-1), Mac-1, and CR4]; whereas eosinophils express a more limited number of β_2 family members (LFA-1 and Mac-1), but also express a β_1 integrin VLA-4 and β_7 integrin ($\alpha_4\beta_7$). The β_2 integrins bind to endothelial intercellular adhesion molecule 1 (ICAM-1) and ICAM-2, whereas the β_1 and β_7 integrins bind VCAM-1 and mucosal addressin cell adhesion molecule-1 (MadCAM-1), respectively. Defects in CD18, the β chain of the β_2 integrins, lead to the inability of neutrophils to exit the circulation at sites of infection and is called *leukocyte adhesion deficiency 1*. Interestingly, eosinophils, monocytes, and lymphocytes are observed at sites of infection in these patients, as these cells can use β_1 integrins to mediate the firm adhesion step required for leukocyte transendothelial migration.

been reported to be therapeutic, but this has not been consistent. Most patients also have mental retardation, short stature, distinctive facies, and the Bombay (hh) blood phenotype, indicating the multiple systems in which fucosylation is critical.

The CD18 integrin pathway is critical for inflammation in the skin, but not necessary for accumulation of neutrophils in the lung or peritoneum. Therefore, although CD18-dependent pathways are critical for cutaneous inflammation, CD18-independent pathways exist for pulmonary and peritoneal inflammation. Further, in the setting of congenital absence of CD18, compensatory pathways exist in the mouse to respond to peritoneal inflammation.

PHAGOCYTOSIS Phagocytosis is the culmination of object recognition, binding, signaling, adherence, cytoskeletal remodeling, engulfment, and membrane fusion. Two mechanisms are well characterized, one mediated by immunoglobulin and one mediated by complement.

Receptors for the Fc portions of immunoglobulin G [IgG (FcγR)] are present on many components of the cellular immune response, including neutrophils, monocytes, macrophages, eosinophils, and basophils. FcγRI (CD64) is a receptor for IgG1 and IgG3 on monocytes, macrophages, and eosinophils and is upregulated on neutrophils after interferon-γ (IFN-γ) stimulation. FcγRII (CD32) binds IgG with rather low affinity, and prefers IgG1 and IgG3. FcγRIII (CD16) binds IgG1 and IgG3 with intermediate affinity. Neutrophil FcγRIIIB, is bound to the membrane through a glycan phosphatidyl inositol linkage, which is largely cleavable by phosphatidyl inositol-specific phospholipase C. As FcγRIIIB has no cytoplasmic domain, its role in signal transduction may be through association with FcγRII. Cross-linking of these receptors by antibody leads to rapid engulfment of targets with release of granule contents and oxygen metabolites into the phagolysosome. If the target is too large, degranulation occurs against the antibody-coated surface.

The complement receptors CR1 and CR3 are expressed on the surfaces of neutrophils, eosinophils, and basophils. Complement receptor 1 is designated *CD35* and is found on many cell types. It binds C3b and enhances its degradation to C3dg by factor I, thereby removing that molecule from further activation of the alternative pathway. CR3, CD11b/CD18, binds iC3b and fibrinogen as well as certain bacteria, parasites, and fungi. CR1 and CR3 are not per se able to stimulate phagocytosis, but in the presence of a second signal, such as one given through FcγR or by cytokines, phagocytosis proceeds.

MECHANISMS OF KILLING Neutrophil granules contain enzymes and proteins for killing ingested bacteria and fungi. Some of these bactericidal mechanisms are dependent on the generation of oxygen metabolites for microbicidal activity, but others are not. In addition to mobilizing their own resources, neutrophils produce a multitude of cytokines that stimulate and attract other phagocytes as well as lymphocytes.

OXYGEN-INDEPENDENT PATHWAYS Bactericidal/permeability-increasing protein (BPI) is a highly potent antibacterial granule protein synthesized and stored in the primary granules. It is a highly basic (isoelectric point > 9.6) protein of 452 amino acids and approximately 58 kd. Sequence homology to lipopolysaccharide (LPS)-binding protein, a critical endotoxin binding acute-phase reactant, suggests that it acts by directly binding to LPS. BPI is cytotoxic to Gram-negative bacteria at concentrations as low as 10^{-9} *M*, but much less effective against Gram-positive organisms. Binding to LPS leads to insertion of BPI into the outer membrane of the organism and eventual insertion into the inner membrane. Arrest of bacterial growth is solely dependent on the N-terminal half of the molecule. The C-terminal fragment serves as an anchor to the membrane. BPI appears to act inside the phagolysosome. Not all Gram-negative rods are sensitive to BPI, especially *Burkholderia (Pseudomonas) cepacia* and *Serratia marcescens*, pathogens in patients who lack oxidative killing.

Defensins are small (< 4 kd) cationic proteins in the primary granules of neutrophils involved in killing ingested Gram-positive and Gram-negative bacteria. Defensins are synthesized during the promyelocyte/myelocyte stage as prepropeptides, stored predominantly in a dense subset of the primary granules as propeptides, and released during neutrophil degranulation. Defensins prefer an actively metabolizing target and can kill transformed mammalian cells as well as prokaryotes and yeasts. Defensins and BPI act synergistically against Gram-negative bacteria. Defensins are reduced in the CHS but absent in specific granule deficiency.

Proteinase 3 is the antigen against which the antineutrophil cytoplasmic antibody is directed in Wegener granulomatosis (see Chap. 165). It is found predominantly in primary granules but is also in secondary and secretory granules. Synthesis and surface display are upregulated by cytokines such as TNF-α. Elastase is a myeloid serine protease in primary granules that has remarkable roles in host defense. Mice with elastase defects have decreased resistance to Gram-negative bacteria. However, human neutrophil elastase deficiency causes severe congenital neutropenia and cyclic neutropenia. Phospholipase A2 is also found in neutrophil granules, where its various isoforms act both directly and synergistically with BPI to kill intracellular bacteria.

Lactoferrin is an iron-binding protein present in specific granules and in mucosal secretions. When released into the phagolysosome, lactoferrin binds iron and inhibits the growth of phagocytosed bacteria and some fungi. The mechanisms through which lactoferrin exerts its antimicrobial action probably include the depletion of iron from an organism's environment, but iron-binding–independent antimicrobial activities and direct immunomodulatory effects are also reported. Lactoferrin is readily released into the circulation after burns and experimental endotoxemia, presumably from neutrophil degranulation.

OXYGEN-DEPENDENT PATHWAYS Neutrophils can produce toxic oxygen metabolites through the reduced nicotinamide dehydrogenase phosphate (NADPH) oxidase complex, which typically is assembled in the wall of the phagolysosome. The NADPH oxidase catalyses the addition of an electron to molecular oxygen, leading to the formation of superoxide anion. Superoxide in turn is converted to hydrogen peroxide by superoxide dismutase. Inside the phagolysosome, the primary granule component myeloperoxidase converts the hydrogen peroxide to hypohalous acid by the addition of a halogen (bleach when the halide is chloride in neutrophils, bromide in eosinophils). The NADPH oxidase is a multiprotein complex, which is maintained in separate membrane-bound and cytosolic compartments. On cell activation, the cytosolic components translocate to the phagolysosome membrane, resulting in an active NADPH oxidase, which can produce the respiratory burst.

The components of the NADPH oxidase are named *phox* (*ph*agocyte *ox*idase) proteins. $p22^{phox}$ and $gp91^{phox}$ are the α and β chains, respectively, of the cytochrome b558 complex, which resides in the wall of the secondary granule. The cytosolic compartment contains three factors, $p47^{phox}$, $p67^{phox}$, $p40^{phox}$ and the small guanine nucleotide (guanine triphosphate) binding protein *rac*. Assembly of the NADPH complex is caused by diverse stimuli. $p47^{phox}$ and $p67^{phox}$ contain *src*-homology type 3 domains (SH3 boxes), which bind to proline-rich targets in themselves and other members of the NADPH complex. Stimulation leads to structural changes in $p47^{phox}$ that promote its interaction with $p22^{phox}$ through $p47^{phox}$ SH3 domains and $p22^{phox}$ C-terminal proline-rich sequences.

Pathologic mutations in the four required components impair the generation of phagocyte superoxide and cause

CGD, a disease characterized by recurrent life-threatening infections with bacteria and fungi and exuberant granuloma formation (see Chap. 144).[5]

Pharmacologic Manipulation

When neutrophils are over-recruited into neutrophilic dermatoses, they can produce reactive oxygen intermediates, activate proteinases, and release chemotactic cytokines, which can contribute to tissue injury and inflammation. Therefore, it makes sense to aim treatment to suppress the generation of reactive oxygen intermediates, to inhibit neutrophil adhesion and chemotaxis, and to suppress the release of lysosomal enzymes and chemotactic factors.

Dapsone is often used for chronic neutrophilic dermatoses such as dermatitis herpetiformis, sub-corneal pustular dermatosis, or erythema elevatum diutinum (see Chap. 226). Dapsone suppresses neutrophil adherence and subsequent migration, is a successful scavenger of reactive oxygen intermediates, and interferes with the myeloperoxidase-halide system and leukocyte-mediated cytotoxicity. Thalidomide reduces inflammation through inhibition of TNF-α and subsequent neutrophil-endothelial adhesion and reactive oxidant generation (see Chap. 236). Dapsone and thalidomide both inhibit the pro-inflammatory cytokine TNF-α, which activates neutrophils through upregulation of complement receptors (CR3, CR4) and endothelial adhesion molecules, ICAM-1, and E-selectin. Colchicine inhibits neutrophil chemotaxis, release of lysosomal enzymes, and production of reactive oxidants and is therefore considered for Sweet syndrome and neutrophilic bullous dermatoses. Antibiotics such as tetracyclines, macrolides, and metronidazole also have antioxidant properties and interfere with neutrophil chemotaxis. In addition to its antioxidant activity, sulfasalazine induces neutrophil apoptosis and enhances adenosine release at sites of inflammation, making it especially useful in pyoderma gangrenosum.

EOSINOPHILS

Ontogeny and Development

Eosinophils develop and mature in the bone marrow from $CD34^+$ hematopoietic progenitor cells and are released into the circulation as mature cells. Eosinophils share this progenitor with basophils, defined as the eosinophil/basophil colony forming unit. This hybrid cell, which has been found in the circulation of subjects with atopic dermatitis, is characterized by granule contents that have features of both cell types as well as by the expression of the IL-5 receptor and the CC chemokine receptor, CCR3.[6] Several investigators have also found eosinophil/basophil colony forming unit in inflamed tissues of subjects with allergic diseases.[7] Because these tissues produce many of the eosinophilopoietins, it has been proposed that extramedullary hematopoiesis may occur at sites of inflammation. IL-5, the most selective eosinophil-active cytokine, induces the differentiation and proliferation of eosinophil precursors in the bone marrow. Allergen challenge induces production of eosinophil precursors in the bone marrow and release of mature eosinophils, which is due to the endocrinologic actions of tissue-derived IL-5 with a modest contribution by the CCR3 ligand, CCL11 (eotaxin). IL-3 and GM-CSF have also been shown to stimulate eosinophil production by the bone marrow and, interestingly, bind to receptors that share a common β chain (with IL-5) but have unique α chains.[8]

Mouse studies have corroborated the primary importance of the cytokines, IL-5, and the CC chemokine, CCL11.[9] For example, IL-5 transgenic mice develop peripheral blood and tissue eosinophilia, whereas the administration of neutralizing anti–IL-5 antibodies in wild-type mice leads to a significant reduction in baseline levels of circulating eosinophils and diminished tissue eosinophilia in response to infection with various parasites or allergen challenge.[10] It is important to note that despite the massive eosinophilia observed in IL-5 transgenic mice, these mice do not develop the tissue damage observed in eosinophilic diseases. This is probably because eosinophils must also be activated to degranulate and/or release their inflammatory mediators. Not surprisingly, mice deficient in both CCL11 and IL-5 have the greatest reduction in tissue eosinophils in asthma models.[10] The human correlate to this would be the recently recognized variant of idiopathic hypereosinophilic syndrome (IHES) referred to as the *lymphocytic variant* (see Chap. 35), where a clonal population of T cells producing IL-5 is responsible for the profound eosinophilia as demonstrated by the dramatic clinical response to an anti–IL-5 (mepolizumab) therapy.[11]

EOSINOPHILS AT A GLANCE

- Eosinophils are bone marrow–derived cells that normally account for 1 percent to 3 percent of peripheral blood leukocytes or less than 350 cells/mm^3 of blood.
- As pro-inflammatory cells, their presence within tissue sites is usually associated with diseased states that can be divided into: Parasitic infections, atopic diseases, fibrotic disorders, reactive eosinophilias, and hypereosinophilic syndromes.
- They play a role in innate and adaptive immune responses, which may explain why they are present in normal, noninflamed tissues such as the gastrointestinal tract and lymphoid tissues.
- This section reviews the biologic actions of eosinophils with particular focus on what controls eosinophil production, activation, and tissue trafficking.
- Pharmacologic manipulation of eosinophilic inflammation is possible but mostly non-specific; however, new, more specific strategies are emerging.

Biologic Functions

Both intact and degranulated eosinophils are a significant component of the inflammatory infiltrate in many cutaneous diseases such as urticaria, bullous pemphigoid, herpes gestationis, drug eruptions, incontinentia pigmenti, arthropod bite in this location, Wells syndrome, and atopic dermatitis.[12–16] Furthermore, evaluations of a variety of tissue samples have demonstrated that eosinophils can be found in lymph nodes and spleen and are especially prominent after allergen or microbial insults.[10] This observation, coupled with evidence that eosinophils can process and present a variety of antigens, has led to the speculation that eosinophils are recruited to secondary lymphoid structures to promote the proliferation of effector T cells. Under more unique situations, eosinophils also home to the thymus, mammary glands, and uterus. It has been suggested based on the localization of eosinophils within the thymus

and the timing of their migration, namely during the neonatal period, that they may be important for thymocyte deletion. Murine models also suggest that eosinophils are important for postnatal mammary gland development and their recruitment into the uterus heralds estrus.[17] Interestingly, eosinophils are resident cells in the lamina propria of much of the gastrointestinal tract and it is thought that reactions play a role in host defense. The recruitment of eosinophils to the gastrointestinal, thymic, and mammary areas appears to be under the control of the CC chemokine, CCL11. There are many pathologic states in the gastrointestinal tract where eosinophil numbers are substantially increased such as drug reactions, helminthic infections, inflammatory bowel disease, gastroesophageal reflux, eosinophilic gastroenteritis, and eosinophilic esophagitis; in the latter condition, there is a report suggesting that tissue eosinophilia and disease manifestations can be treated with an anti–IL-5 therapy (mepolizumab).[10,18–20] The skin, in contrast to these other tissues, is devoid of eosinophils except during pathologic conditions.

EOSINOPHIL ULTRASTRUCTURE AND GRANULE CONTENT (See Table 30-1) Eosinophils are approximately 8 μm in diameter and have a bilobed nucleus and distinctive cytoplasmic granules. Each cell contains approximately 20 membrane-bound, core-containing, secondary granules, which contain the basic proteins.[21] These granules avidly take up acidic dyes such as eosin to give the eosinophils their characteristic microscopic appearance. Four highly basic proteins are found within these granules: major basic protein (MBP), eosinophil cationic protein (ECP), eosinophil peroxidase (EPO), and eosinophil-derived neurotoxin (EDN). Other proteins have been found in the secondary granules, including enzymes, cytokines, growth factors, and chemokines. In addition, the cells contain a number of primary granules, which lack a core and are of variable size. These granules contain Charcot-Leyden crystal protein (also known as *galectin-10*) that is a characteristic feature of asthmatic sputum and can be found in both eosinophils and neutrophils. Normal eosinophils contain five non-membrane–bound lipid bodies, which are the principal stores of arachidonic acid. They also contain the enzymes cyclooxygenase and 5- and 15-lipoxygenase, which are required to synthesize prostaglandins and leukotrienes.[22,23]

FUNCTION OF GRANULE PROTEINS AND RELEASED PRODUCTS Eosinophils contain many substances (cationic granule proteins, arachidonic acid–derived lipids, hydrolytic enzymes, neuropeptides, reactive oxygen species, and cytokines/chemokines) that mediate inflammation (see Table 30-1), probably the best characterized of these are the cationic proteins.[21] All of these proteins have been shown to induce direct tissue damage to both host cells (myocytes, endothelial cells, neurons, epithelial cells, and smooth muscles cells) and microbes (parasites and some bacteria).[18,24] For example, MBP, ECP, or EPO application to airway epithelium in primates produces ciliostasis, desquamation, and hyperreactivity of respiratory smooth muscle.[25] The damage to the endothelium in IHES is thought to be the initiating factor in the cardiomyopathy observed in these subjects.

All four of the cationic granule proteins likely contribute to the edema observed in many eosinophilic diseases, in part due to the release of histamine from mast cells and basophils. This is further supported by the observation that MBP injected into the skin of humans causes a dose-dependent wheal-and-flare response.[21] NERDS (nodules, eosinophilia, rheumatism, dermatitis and swelling), bullous pemphigoid, herpes gestationis, episodic angioedema with eosinophilia (Gleich syndrome), urticaria, eosinophilic cellulitis (Wells syndrome), and even insect bite reactions demonstrate variable degrees of edema that are probably explained at least in part by this mechanism (see Chap. 35).[26]

There is evidence to show that eosinophils from both healthy and diseased subjects produce several neuro-active mediators, including MBP, EDN, nerve growth factor, vasoactive intestinal peptide, and substance P. This, coupled with the fact that eosinophils (both intact and degranulated) are often observed in close proximity to nerve endings, suggests some cross-talk.[27] Eosinophil-induced nerve dysfunction is thought to be responsible for the gastric dysmotility observed in subjects with food allergies or the dysfunction of vagal muscarinic M2 receptors observed in asthmatics.[10]

ECP and EDN are ribonucleases and as such have been thought to play a role in viral host defense. Coupling this finding with the evidence that eosinophils express Toll-like receptors 7 and 8 (which bind single-stranded RNA from viral replication) makes it credible that these cells are important in viral host defense.[28]

MBP and ECP are thought to have procoagulant activity due in part to their ability to neutralize heparin and their effects on platelet activation.[21] Thrombosis has been noted in IHES, including several case reports of hepatic vein obstruction (Budd-Chiari syndrome). The etiology of this thrombosis is not completely clear. It could be the result of direct endothelial damage or due to the procoagulant activity of MBP and ECP.[29] Additionally, MBP and ECP neutralize heparin and MBP is a strong platelet agonist. Last, PAF, which is released by eosinophils, can cause platelet aggregation.

Eosinophils produce several arachidonic acid metabolites, and the best characterized of those are from the 5-lipoxygenase pathway [leukotriene C_4 (LTC_4), LTD_4, and LTE_4] and the cyclooxygenase pathway (thromboxane B_2, prostaglandin E_2, and prostaglandin $F_1\alpha$).[22,23] LTC_4 is the only leukotriene produced intracellularly by eosinophils. LTD_4 and LTE_4 are metabolites of LTC_4 produced by extracellular cleavage. LTC_4, LTD_4, and LTE_4 are called *cysteinyl leukotrienes* and have several biologic effects, including bronchoconstriction, increased airway reactivity, increased vascular permeability, and leukocyte recruitment. The cysteinyl leukotrienes elaborated at least in part by eosinophils are major mediators of asthma and allergic rhinitis, and this is further demonstrated by the clinical improvement observed with the leukotriene antagonists (montelukast, zafirlukast, and zileuton). Whether leukotrienes play a role in eosinophilic disorders of the skin is less clear. The predominant cyclooxygenase product of eosinophils is thromboxane B_2, but this and the other mediators produced through this pathway are minor compared to those produced by the 5- and 15-lipoxygenase pathways.

Many hydrolytic enzymes have been identified in human eosinophils, but their role in disease remains largely speculative (see Table 30-1). Arylsulfatase B, β-glucuronidase, acid phosphatase, catalase, and histaminase are present in the eosinophil. On stimulation with IL-5 or PAF, eosinophils have been shown to release matrix metalloproteinase 9 (MMP-9), which is thought to be important for their migration through basement membranes. Collagenase, which degrades type I and type III collagen, may play a role in tissue remodeling.

Reactive oxygen species are important in tissue injury induced by eosinophils. The reactive oxygen species produced include superoxide and hydrogen peroxide. These are produced by NADPH oxi-

dase during the respiratory burst initiated on eosinophil activation. Hydrogen peroxide can generate hypohalous acids through the action of EPO, which are also cytotoxic. Reactive oxygen species can also propagate the inflammatory response by inducing gene expression and T-cell proliferation.

A variety of cytokines and chemokines are produced by eosinophils.[21] Tumor growth factor (TGF)-α, TGF-β, fibroblast growth factor-2, vascular endothelial growth factor, nerve growth factor, platelet-derived growth factor-β, TNF-α, IL-1α, IL-2 through -6, IL-10, IL-12, IL-16, GM-CSF, IL-8, CCL3 (MIP-1α), lymphocyte chemoattractant factor, CCL5 (RANTES), and CCL11.

The release of TGF-α, TGF-β, fibroblast growth factor-2, vascular endothelial growth factor, MMP-9 and inhibitors of MMPs from eosinophils and the ability of eosinophil mediators to induce platelet release of TGF-β, suggests that they are important inducers of fibroblast proliferation and extracellular matrix proteins.[30] After intradermal eosinophilic infiltration, there is production of the extracellular proteins tenascin and procollagen 1 and myofibroblast formation.[28] Eosinophil-induced fibrosis is observed in the lungs and heart of IHES patients and in the skin of subjects with eosinophilic fasciitis (Shulman syndrome), eosinophilia myalgia syndrome, or toxic oil syndrome (see Chaps. 35 and 158).

Products released by eosinophils (chemoattractants, colony-stimulating factors, and endothelial-activating cytokines) facilitate further leukocyte recruitment to sites of inflammation. Additionally, some investigators have suggested that eosinophils present antigen to T cells.[31] For example, eosinophils have been shown to express some of the requisite co-stimulatory molecules characteristic of the T-cell–antigen presenting cells synapse, such as the IL-2 receptor (CD25), B7 homologs, and HLA-DR (major histocompatibility complex class II). GM-CSF stimulated eosinophils induce T-cell proliferation in response to staphylococcal superantigens (*Staphylococcus* enterotoxins A, B, and E).

Eosinophils have also been found in a variety of cancers, particularly in lymphomas, leukemias, and colon cancer. Numerous clinical studies suggest that tumors associated with tissue and/or peripheral eosinophilia have a more favorable prognosis.[6] Whereas in other tumors, they are thought to confer a poor prognosis, such as nodular sclerosing Hodgkin disease, Sézary syndrome, and gastric carcinomas, in Sézary syndrome (see Chap. 146), the tumor cells produce IL-5 and are therefore responsible for the eosinophilia. Therefore, in this tumor, the eosinophilia is a reflection of tumor burden.[32] In the case where eosinophilia is a good prognostic factor, the eosinophils may be a host response to the tumor.[33,34] The specific nature of eosinophil-dependent antitumor activity has not been sufficiently explored but may include direct cytotoxic effects on tumor cells by ECPs, antigen presentation, vascular compromise via microthrombi formation (secondary to release of heparinases and PAF), or synergism with the antitumor response of other leukocytes.

Thus, the actions of these granule proteins and released cytokines/chemokines derived from activated eosinophils are numerous and include direct cytotoxic effects on structural cells and microbes, increased vascular permeability, procoagulant effects, immediate host response to some parasites, viruses, and tumor cells, enhanced leukocyte migration, amplification of effector T-cell responses and possibly even mammary gland development. Collectively, these varied biologic actions provide the explanation for most of the signs and symptoms observed in eosinophilic skin diseases (see Chap. 35).

ACTIVATION OF EOSINOPHILS A variety of inflammatory mediators have been shown to activate eosinophils. These include cytokines (TNF-α, GM-CSF, and IL-3 and -5), complement components (C3a and C5a), lipid mediators (LTC_4 and PAF), chemokines as well as engagement of IgA and IgG Fc receptors. Several members of the CC chemokine subfamily [CCL5, CCL7 (MCP-3), CCL11, CCL14 (MCP-4), CCL24 (eotaxin-2)] that bind to the chemokine receptor CCR3 are also potent activators of eosinophils.[35] Activated eosinophils develop a number of phenotypic changes, including a reduction in granules, vacuolization, and an expansion of their cytoplasm, leading to a reduction in cell density and are referred to as *hypodense*. The number of hypodense cells predicts allergic disease severity. A cell surface marker that can distinguish hypodense from normodense eosinophils has not been identified, but there are several surface markers with enhanced expression on in vitro or in vivo activated or hypodense cells: αM integrin (CD11b), αX integrin (CD11c), FcγR111 (CD16), hyaluronic acid receptor (CD44), ICAM-1 (CD54), CD69, and HLA-DR.[36]

SURFACE RECEPTORS There is a large variety of receptors present on the surface of eosinophils but no single surface protein is uniquely expressed on eosinophils. These receptors have either been identified by flow cytometry or by functional assays, and can be grouped as follows: chemotactic factor receptors (chemokine, complement, and others), immunoglobulin and other immunoglobulin supergene family members, cytokine receptors, adhesion molecule receptors, and a variety of receptors involved in apoptosis.

Chemotactic Factor Receptors. Chemotactic factors are thought to be important in orchestrating cellular trafficking to sites of inflammation as well as physiologic homing (e.g., gastrointestinal tract). Many chemotactic agents [leukotriene B_4, PAF, bacterial products (fMLP), and C5a] have quite potent effects on eosinophils but are non-selective in that they recruit most leukocytes. Because many eosinophilic diseases are characterized by tissue eosinophilia with little to no neutrophilia, the identification of more selective chemotaxins, such as CCR3 ligands, was an important breakthrough.

As with neutrophils, specific members of the chemokine family are thought to be essential for the cellular trafficking of eosinophils. The binding of chemokines to their respective receptors on the eosinophil mediates many biologic effects in addition to cell shape change and migration such as cell activation, receptor internalization, induction of the respiratory burst, and transient activation of integrin adhesiveness.

It has become increasingly clear that the chemokine receptor CCR3 and its major ligands (CCL5, CCL11, CCL13, CCL24, CCL26) play a critical role in both the homeostatic and inflammation-induced recruitment of eosinophils to tissue sites.[10,35] Not surprisingly, the most highly expressed chemokine receptor on human eosinophils is CCR3.

Immunoglobulin Receptors and Members of the Immunoglobulin Supergene Family. In the immunoglobulin family, the receptor most highly expressed on eosinophils is FcγR11 (CD32), which binds aggregated IgG, particularly of the subclass IgG_1 and IgG_3. The binding of IgG to this receptor can alter eosinophil survival. There is conflicting evidence

concerning the presence of the high affinity IgE receptor FcεR1 on the surface of eosinophils. FcαRI (CD89), the IgA receptor, is present on the surface of eosinophils and the binding of IgA opsonized particles to this receptor triggers a variety of immune effector functions. This, coupled with the fact that there are many eosinophils found in the gastrointestinal tract, suggest that eosinophils play an important role in mucosal immunity.

Members of the immunoglobulin superfamily are type I transmembrane molecules that share common structural characteristics of the globular domains found in immunoglobulins. ICAM-1 (CD54) and ICAM-3 (CD50) are expressed on eosinophils and are thought to be important in leukocyte-leukocyte and leukocyte-tissue cell adhesion using LFA-1(αLβ2; CD11a) as its counterligand (see Fig. 30-1).

Cytokine Receptors. Cytokine receptors are present at low levels on the surface of eosinophils. Receptors for IL-3 (CD123), IL-5 (CD125), and GM-CSF (CD116) are most readily detectable and all share a common β chain (CD132). Eosinophil activation has been noted by a variety of other cytokines despite the fact that their receptors are not readily detected by flow cytometry. These include: stem cell factor (c-kit receptor; CD117), IFN-γ (CD119), TNF-α (CD120), IL-4 (CD124), IL-9 (CD129 and CD132), IL-13β (gp65), IL-2 (CD25), and TGF-β receptors.

Receptors Involved in Apoptosis. Apoptosis plays a role in many biologic processes. Diseases characterized by eosinophilia are thought to result in part from a delayed or defective apoptotic pathway. Eosinophils from atopic dermatitis patients have markedly reduced death kinetics compared to those isolated from non-atopic and even airway allergic donors.[10] Eosinophils express several "death receptors," such as Fas receptor (CD95), Siglec-8, CD30, CD45, Campath (CD52), and CD69 and important intracellular regulators of eosinophil apoptosis such as the members of the B-cell leukemia/lymphoma (Bcl)-2 and inhibitor of apoptosis families.[37] Eosinophil apoptosis is one mechanism by which glucocorticoids lower eosinophil counts and this effect can be overcome by the actions of IL-3, IL-5, and GM-CSF.[38] Interestingly, lidocaine and sulfonylureas (such as glyburide) can also inhibit this cytokine-induced eosinophil survival and may have some anti-eosinophilic effects clinically.[28]

Adhesion Molecule Receptors. Adhesion molecule receptors are expressed on the eosinophil cell surface to mediate trafficking to tissues and within tissues, and for general cell-cell interactions (see Fig. 30-1).[39] These receptors fall into three groups: IgSF, selectins and their glycoprotein counterligands, and integrins. L-selectin (CD62L) and P-selectin glycoprotein ligand-1 (PSGL-1, CD162) are expressed at high levels, whereas E-selectin ligands [e.g., sialyl-Lewis X (CD15s)] are expressed at very low levels. P-selectin and PSGL-1 are the most important selectin pair in eosinophil migration into tissues.[8]

Eosinophils express a variety of integrins (β_1, β_2, and β_7) on their surface, which facilitate their adhesion to extracellular matrix proteins, vascular cellular adhesion molecule 1 (VCAM-1) (CD106) on activated endothelium or ICAM-1 present on resting or activated epithelium and activated endothelium. Integrins are composed of two subunits that exist as noncovalently associated heterodimers, with an α and a β subunit. The β_1 integrins expressed on eosinophils include α4β1 (VLA-4), which binds to VCAM-1 found on activated endothelium and the extracellular matrix protein, fibronectin. Eosinophil adhesion to fibronectin induces the autocrine production of eosinophil survival cytokines (IL-3, IL-5, and GM-CSF). The only other β_1 integrin expressed on eosinophils is $\alpha_6\beta_1$, which mediates the binding to another matrix protein, laminin. Four β_2 integrins are found on eosinophils: αLβ2 (LFA-1), αMβ2 (Mac-1), αXβ2, and αDβ2. These integrins bind to ICAM-1, -2, and -3; VCAM-1; fibrinogen; and the complement fragment, C3bi. Last, eosinophils also express α4β7, which is the ligand for the gut mucosal addressin cell adhesion molecule-1 thought to be important in homing of eosinophils to gastrointestinal mucosa. $\alpha_4\beta_7$ also mediates adhesion to fibronectin and VCAM-1.

Tissue Trafficking

The selective recruitment of eosinophils into sites of inflammation is largely a function of eosinophil-activating cytokines, endothelial-activating cytokines, and chemokines (see Fig. 30-1).

EOSINOPHIL-ACTIVATING CYTOKINES The eosinophil-activating cytokines (IL-3, IL-5, and GM-CSF) enhance cell survival, eosinophil maturation, chemotactic responses, and leukotriene production. Eosinophils from subjects with atopic dermatitis have increased migratory responses in vitro to several common chemotaxins (*N*-formylmethionyl-leucyl-phenylalanine, IL-4, and PAF) in comparison to eosinophils from unaffected individuals, suggesting that they were exposed to one of these activating cytokines in vivo.[3] In fact, IL-5 treatment of eosinophils from normal donors induced the migratory responses observed in eosinophils from atopic dermatitis subjects.[40] Similarly, we have observed that the kinetics of eosinophil recruitment in response to intradermal RANTES challenge are profoundly faster in allergic subjects.[41] Eosinophils from atopic dermatitis donors also have prolonged cell survival ex vivo compared with normal controls providing further evidence that they have been primed by activating cytokines like IL-5 in vivo.[42] Although eosinophil-activating cytokines can be produced by many cell types (keratinocytes, endothelial cells, monocytes, and T cells) there is some evidence that eosinophils themselves may be a major source and therefore suggests that there may be an autocrine feedback loop.[42] Interestingly, the local reactions observed in response to subcutaneous GM-CSF administration given as an adjunct to chemotherapy demonstrate both intact and degranulated eosinophils, suggesting that eosinophil activation by GM-CSF coupled with cutaneous trauma may be sufficient to get tissue recruitment.[43]

ENDOTHELIAL-ACTIVATING CYTOKINES (See Chap. 163) There are at least three types of endothelial activations that occur. The first is the expression of P-selectin, which occurs when endothelial cell Weibel-Palade bodies are transported to the cell surface extremely quickly after exposure of endothelial cells to histamine, leukotrienes, and a host of other inflammatory mediators. Expression of P-selectin on the endothelial surface initiates leukocyte rolling (via PSGL-1), which is an important initial step before firm adhesion and transendothelial migration. A second type of endothelial activation is that induced by nonspecific activators such as IL-1 and TNF-α. These cytokines stimulate endothelial expression of E-selectin, ICAM-1, and VCAM-1. They also induce production of chemokines by endothelial cells. The third type of endothelial activation is that induced by IL-4 and IL-13. These cytokines selectively

induce VCAM-1, which is centrally involved in the recruitment of VLA-4–positive cells, including eosinophils, basophils, and lymphocytes into sites of allergic inflammation.

The initial step of eosinophil recruitment involves rolling on endothelial selectins (and perhaps the L-selectin counterligand or VCAM-1). This is followed by a firm adhesion, or "tethering," of the eosinophil. Recent in vitro studies have shown that tethering or firm adhesion of eosinophils to VCAM-1 or ICAM-1 is a process which is substantially increased by CCR3 ligands (CCL5, CCL7, and CCL11).

CHEMOKINES The transition from rolling on the endothelial surface to firm adherence is mediated by chemokines on the endothelial surface. Induction of the expression of chemokines by activated endothelial cells results in higher levels of chemokines on or near the endothelial surface, which transiently affect β_1 and β_2 integrin avidity, resulting in firm adhesion of the eosinophil to the endothelial cell. Chemokines produced by structural cells such as fibroblasts, smooth muscle cells, and epithelium are probably more important in directing migration and activation of eosinophils within tissues.[44]

Pharmacologic Manipulation

Many available therapies (glucocorticoids, calcineurin antagonists, myelosuppressive drugs, IFN-α, IFN-γ, leukotriene antagonists, and possibly even antihistamines) inhibit eosinophilic inflammation; however, none is specific for eosinophils. Glucocorticoids are the most effective. They are thought to affect tissue eosinophil infiltration by three mechanisms: induction of eosinophil apoptosis, reduction of eosinophil production by bone marrow, and inhibition of the production of the cytokines and chemokines important in eosinophil trafficking.[38,45] Steroids also suppress the production of several cytokines important for the induction of adhesion molecules on endothelial cells (IL-1, TNF-α, IL-4, and IL-13) and the release of eosinophil-active chemokines (CCL5, CCL7, and CCL11). The immediate (within 3 hours) reduction in circulating eosinophils observed after systemic administration of steroids is thought to occur as a consequence of sequestration into extramedullary organs (liver, spleen, and lymph node) as has been shown in rodents.

Several myelosuppressive drugs [hydroxyurea, interferons (IFN) and calcineurin antagonists] are beneficial in eosinophilic disorders alone or as steroid-sparing agents.[2] IFNs are thought to act by inhibiting eosinophil degranulation and inflammatory mediator release. IFN-α is primarily used as a steroid-sparing agent in subjects with the myeloproliferative variant of hypereosinophilic syndrome (see Chap. 35). Calcineurin antagonists (cyclosporin, FK506, and pimecrolimus) are thought to act by inhibiting T-cell cytokine release including cytokines that induce eosinophilic inflammation (IL-4, IL-5, and GM-CSF). Topical tacrolimus has been shown to decrease the expression of CCL5, CCL11, and IL-5 in atopic dermatitis, which was observed in conjunction with a decrease in tissue eosinophil counts.[46] Leukotriene antagonists, including 5-lipoxygenase inhibitors (zileuton) and cysLT$_1$ receptor antagonists (zafirlukast and montelukast) have been shown to decrease tissue eosinophils in allergic subjects and may diminish the biologic actions of eosinophil-derived leukotrienes. Lastly, there have been conflicting reports regarding the ability of the newer generation antihistamines (cetirizine and fexofenadine) to inhibit eosinophil recruitment in allergen challenge models of the skin or airways.

New, more specific strategies have emerged: for example, mepolizumab (a humanized monoclonal antibody to IL-5) decreases peripheral eosinophil counts in the majority of hypereosinophilic subjects and demonstrated a moderate improvement in small trial in subjects with atopic dermatitis.[8,47] Imatinib mesylate, a tyrosine kinase inhibitor U.S. Food and Drug Administration–approved for the treatment of chronic myelogenous leukemia, has produced complete or near complete remissions for hypereosinophilic cases associated with platelet-derived growth factor receptor rearrangement which has kinase activity (see Chap. 35). In these subjects, the clinical responses are rapid, with normalization of eosinophil counts generally occurring within 1 week of initiation of treatment and reversal of signs and symptoms within 1 month.[11] There is limited evidence that alemtuzumab, a monoclonal antibody to CD52, which is U.S. Food and Drug Administration–approved for B-cell lymphocytic leukemia may also be useful for this group of hypereosinophilic disorders.[11] CCR3-blocking antibodies have been shown to inhibit allergen-induced eosinophil recruitment in human skin xenografts from allergic subjects. Two companies (Glaxo-SmithKline and Bristol-Myers Squibb) have CCR3 antagonists in phase I or II studies for use in atopic airway diseases.[48]

The eosinophil is clearly a multifunctional cell whose original function was primarily to fight parasitic infections. As this function is largely unnecessary in developed countries, the eosinophil has likely evolved to respond to other environmental insults, leading to the rise of eosinophilic diseases such as atopy.[24] It has become clear that eosinophils play a role in allergic diseases, fibrotic diseases, and antitumor host response.[30] Only recently has it been recognized that it is present under "normal" conditions in parts of the gastrointestinal tract and lymphoid organs, suggesting that it may have a homeostatic function as well. A better understanding of the relevant inflammatory versus homeostatic functions of this leukocyte will likely yield therapies for eosinophilic diseases with improved risk/benefit ratios.

CHAPTER 31

Acute Febrile Neutrophilic Dermatosis (Sweet Syndrome)

Philip R. Cohen
Herbert Hönigsmann
Razelle Kurzrock

HISTORY

EPIDEMIOLOGY

The distribution of Sweet syndrome cases is worldwide, and there is no racial predilection.[1,2,12,16–20,30,31] The dermatosis presents in three clinical settings (Table 31-1).[13,15] Classic or idiopathic Sweet syndrome may be associated with infection (upper respiratory tract or gastrointestinal tract), inflammatory bowel disease, or pregnancy.[13,15] It most commonly occurs in women between the ages of 30 years to 60 years. However, classic Sweet syndrome also occurs in younger adults and children.[32–48] The youngest Sweet syndrome patients are brothers who developed the dermatosis at 10 and 15 days of age.[46]

Several investigators consider it appropriate to distinguish between the classic form and the malignancy-associated form of this disease because the onset or recurrence of many of the cases of Sweet syndrome are temporally associated with the discovery or relapse of cancer.[15,49–60] Malignancy-associated Sweet syndrome does not have a female predominance and is most often associated with acute myelogenous leukemia.[61,62] In Sweet syndrome patients with dermatosis-related solid tumors, carcinomas of the genitourinary organs, breast, and gastrointestinal tract are the most frequently occurring cancers.[1,2,63–66]

A drug-induced variant of the dermatosis has also been described.[13,67,68] It has most frequently been observed to occur in association with the administration of granulocyte-colony stimulating factor (G-CSF).[1,2] However, several other medications have also been implicated in eliciting drug-induced Sweet syndrome.[11,13,17,39,41,69–124]

ETIOLOGY AND PATHOGENESIS

The pathogenesis of Sweet syndrome may be multifactorial and remains to be definitively determined. A septic process is suggested by the accompanying fever and peripheral leukocytosis. Indeed, a bacterial infection may have a causative role because most patients with classic Sweet syndrome have a febrile upper respiratory tract infection or tonsillitis that precedes their skin lesions by 1 to 3 weeks. Also, Sweet syndrome patients with culture-confirmed and serology-confirmed *Yersinia enterolitica* intestinal infection improve with systemic antibiotics.[2,77,125–127]

Sweet syndrome may result from a hypersensitivity reaction to an eliciting bacterial, viral, or tumor antigen. The appearance, histopathology, and course of the skin lesions suggest this concept. In addition, the prompt response of both the symptoms and the lesions to corticosteroids supports this hypothesis.[2,127]

Leukotactic mechanisms, dermal dendrocytes, circulating autoantibodies, immune complexes, HLA serotypes, and cytokines have all been postulated to contribute to the pathogenesis of Sweet syndrome. Complement does not appear to be essential to the disease process. In some patients antibodies to neutrophilic cytoplasmic antigens have been demonstrated; however, these are likely to represent an epiphenomenon.[2]

On the other hand, cytokines—directly and/or indirectly—may have an etiologic role in the development of Sweet syndrome symptoms and lesions.[2,21–23]

G-CSF, granulocyte macrophage–colony-stimulating factor, interferon-γ, interleukin 1, interleukin 3, interleukin 6, and interleukin 8 are potential cytokine candidates in the pathogenesis.[2,13,21–23,44,128–132]

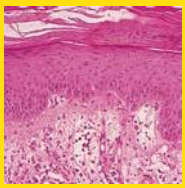
CLINICAL FINDINGS

History

Sweet syndrome patients may appear dramatically ill. The skin eruption is usually accompanied by fever and leukocytosis. However, the skin disease can follow the fever by several days to weeks or be concurrently present with the fever for the entire episode of the dermatosis. Arthralgia, general malaise, headache, and myalgia are other Sweet syndrome–associated symptoms.[1,2,23]

ACUTE FEBRILE NEUTROPHILIC DERMATOSIS (SWEET SYNDROME)

AT A GLANCE



- A constellation of symptoms and findings: the acute onset of fever, neutrophilia, erythematous, and tender skin lesions that typically show an upper dermal infiltrate of mature neutrophils.
- Cardiovascular, central nervous system, gastrointestinal, hepatic, musculoskeletal, ocular, oral, otic, pulmonary, renal, and splenic organs can be involved.
- Classic Sweet syndrome may be associated with infection of the upper respiratory and/or gastrointestinal tract, inflammatory bowel disease, and pregnancy.
- Malignancy-associated Sweet syndrome occurs in individuals with previously undiagnosed or relapsing hematologic malignancies and solid tumors; in these patients, Sweet syndrome appears as a cutaneous paraneoplastic syndrome.
- Drug-induced Sweet syndrome describes the onset of the dermatosis in patients after the initiation of certain medications—most commonly granulocyte-colony stimulating factor.
- Cytokines may have an important role in the pathogenesis.
- The first-line oral systemic agents for treating Sweet syndrome are corticosteroids, potassium iodide, and colchicine.
- Topical application of high potency corticosteroids or intralesional corticosteroids may be efficacious for treating localized lesions.

Cutaneous Lesions

Skin lesions of Sweet syndrome typically appear as tender, red, or purple-red papules or nodules. The eruption may present as a single lesion or multiple lesions which are often distributed asymmetrically (Fig. 31-1). The pronounced

[c]Recurrence after oral rechallenge testing in the patients with drug-induced Sweet syndrome.
[d]Temperature > 38°C (100°F).
[e]Neutrophil count > 6000 cells/μL.
[f]Erythrocyte sedimentation rate > 20 mm/h.
[g]Hemoglobin < 13 g/dL in men and < 12 g/dL in women.
[h]Platelet count < 150,000/μL or > 500,000/μL.
[i]This includes hematuria, proteinuria, and renal insufficiency.

▲ **FIGURE 31-1** Unilateral lesions of Sweet syndrome around the eye and upper lip consisting of plaques and pseudovesicular papules suggesting herpes simplex.

▲ **FIGURE 31-2** Multiple confluent papules and plaques of Sweet syndrome that at first sight give the illusion of vesiculation, but are solid on palpation. (From Hönigsmann et al: Akute febrile neurtophile Dermatose. *Wien Klin Wochenschr* **91**:842, 1979, with permission.)

edema in the upper dermis of the lesions results in their transparent, vesicle-like appearance and has been described as an *illusion of vesiculation* (Fig. 31-2). In later stages, central clearing may lead to annular or arcuate patterns. The lesions may appear bullous, become ulcerated, and/or mimic the morphologic features of pyoderma gangrenosum in patients with malignancy-associated Sweet syndrome.[133,134] The lesions enlarge over a period of days to weeks. Subsequently, they may coalesce and form irregular sharply bordered plaques (Fig. 31-3). They usually resolve, spontaneously or after treatment, without scarring. Lesions associated with recurrent episodes of Sweet syndrome occur in one-third to two-thirds of patients.[1,2,135,136]

Cutaneous pathergy, also referred to as *skin hypersensitivity*, is a dermatosis-associated feature.[1,2] It occurs when Sweet syndrome skin lesions appear at sites of cutaneous trauma. These include the locations where procedures have been performed such as biopsies,[20] intravenous catheter placement,[20] and venipuncture.[12,17,20,37,137,138] They also include sites of insect bites and cat scratches,[20] areas that have received radiation therapy,[139–141] and places that have been contacted by sensitizing antigens.[137,142] In addition, in some Sweet syndrome patients, lesions have been photodistributed or localized to the site of a prior phototoxic reaction (sunburn).[13,20,98,143–145] Sweet syndrome lesions have also rarely been located on the arm affected by postmastectomy lymphedema.[100,146]

Sweet syndrome can present as a pustular dermatosis.[147] The lesions appear as tiny pustules on the tops of the red papules or erythematous-based pustules. Some of the patients previously described as having the "pustular eruption of ulcerative colitis" are perhaps more appropriately included in this clinical variant of Sweet syndrome.[1,148]

Neutrophilic dermatosis of the dorsal hands or *pustular vasculitis of the dorsal hands* refers to a localized, pustular variant of Sweet syndrome when the clinical lesions are predominantly restricted to the dorsal hands.[3,149–154] The lesions from this latter group of individuals are similar to those of Sweet syndrome in morphology and rapidly resolve after systemic corticosteroids and/or dapsone therapy is initiated. In addition, many of the individuals with this form of the disease also had concurrent lesions located on either their oral mucosa, arm, leg, back, and/or face.[3,155–163]

The cutaneous lesions of subcutaneous Sweet syndrome usually present as erythematous, tender dermal nodules

▲ **FIGURE 31-3** Acute febrile neutrophilic dermatosis. Typical lesion consisting of coalescing, plaque-forming papules. **A.** Bright-red lesions on the neck. **B.** Lesion on the dorsum of the right hand exhibiting the "relief of a mountain range" feature. [From Hönigsmann H, Wolff K: Acute febrile neutrophilic dermatosis (Sweet syndrome), in *Major Problems in Dermatology*, vol. 10, edited by Wolff K, Winkelmann RK. London, Lloyd-Luke, 1980, p 307, with permission.]

on the extremities.[4,8,12,17,99,119,164–185] When the lesions are located on the legs, they often mimic erythema nodosum (see Chap. 69).[170] Because Sweet syndrome can present concurrently[21,125,187–189] or sequentially[170] with erythema nodosum,[17,21,187,190] tissue evaluation of one or more new dermal nodules may be necessary to establish the correct diagnosis—even in a patient whose Sweet syndrome has previously been biopsy confirmed.[1,2,4] Diagnostic criteria are summarized in Table 31-2.

Related Physicial Findings

EXTRACUTANEOUS MANIFESTATIONS (Table 31-3) Extracutaneous manifestations of Sweet syndrome can affect bones, central nervous system, ears, eyes, kidneys, intestines, liver, heart, lung, mouth, muscles, and spleen.[12,16,17,20,25,26,32,33,44,73,75,101,117,138,139,165,202,203,205,212–257]

In children, dermatosis-related sterile osteomyelitis has been reported. Ocular manifestations of Sweet syndrome may be the presenting feature of the condition. However, the incidence of ocular involvement (such as conjunctivitis) is variable in classic Sweet syndrome and uncommon in the malignancy-associated and drug-induced forms of the dermatosis. In contrast, mucosal involvement of the mouth, presenting as oral ulcers, occurs more frequently in Sweet syndrome patients with hematologic disorders and is uncommon in patients with classic Sweet syndrome.[23,26,102,117,203,252] The oral lesions typically resolve after initiation of treatment with systemic corticosteroids, similar to extracutaneous manifestations of Sweet syndrome occurring at other sites.[1,2]

ASSOCIATED DISEASES Several conditions have been observed to occur either before, concurrent with, or after the diagnosis of Sweet syndrome. Hence, the appearance of Sweet syndrome may be etiologically related to the development of some of these conditions. Specifically, the association between Sweet syndrome and the other condition is probably bona fide, possibly bona fide, or remains to be established.[1,2,5,11–20,30,36–43,69–126,158–161,164,166,186–190,195,214,231,236,259–339]

ASSOCIATED NEUTROPHILIC DERMATOSES The unifying characteristic of neutrophilic dermatoses of the skin and mucosa is their inflammatory infiltrate: mature polymorphonuclear leukocytes. Several of these conditions can display similar clinical and pathologic features. However, the location of the neutrophilic infiltrate helps to differentiate these dermatoses.[6,120] Concurrent or sequential occurrence of Sweet syndrome and the following additional neutrophilic dermatoses have been observed: erythema elevatum diutinum (see Chap. 166),[340] neutrophilic eccrine hidradenitis

TABLE 31-2
Diagnostic Criteria for Classic Sweet Syndrome versus Drug-Induced Sweet Syndrome

Classic[a]	Drug-Induced[b]
Major	• Abrupt onset of painful erythematous plaques or nodules
• Abrupt onset of painful erythematous plaques or nodules	• Histopathologic evidence of a dense neutrophilic infiltrate without evidence of leukocytoclastic vasculitis
• Histopathologic evidence of a dense neutrophilic infiltrate without evidence of leukocytoclastic vasculitis	• Pyrexia > 38°C (100°F)
Minor	• Temporal relationship between drug ingestion and clinical presentation, or temporally related recurrence after oral challenge
• Pyrexia > 38°C (100°F)	• Temporally related resolution of lesions after drug withdrawal or treatment with systemic corticosteroids
• Association with an underlying hematologic or visceral malignancy, inflammatory disease, or pregnancy, or preceded by an upper respiratory or gastrointestinal infection or vaccination	
• Excellent response to treatment with systemic corticosteroids or potassium iodide	
• Abnormal laboratory values at presentation (three of four): Erythrocyte sedimentation rate > 20 mm/h, positive C-reactive protein, > 8000 leukocytes, > 70% neutrophils	

[a]The presence of both major criteria and two of the four minor criteria is required to establish the diagnosis of classic Sweet syndrome; the patients with malignancy-associated Sweet syndrome are included with the patients with classic Sweet syndrome in this list of diagnostic criteria.
[b]All five criteria are required for the diagnosis of drug-induced Sweet syndrome.
Adapted with permission from Walker DC, Cohen PR: Trimethoprim-sulfamethoxazole-associated acute febrile neutrophilic dermatosis: Case report and review of drug induced Sweet syndrome. *J Am Acad Dermatol* **34**:918, 1996.

TABLE 31-3
Extracutaneous Manifestations of Sweet Syndrome

- Bone: Acute sterile arthritis, arthralgias, focal aseptic osteitis, pigmented villonodular synovitis, sterile osteomyelitis (chronic recurrent multifocal osteomyelitis)[12,32,44,164,212–215]
- Central nervous system: Acute benign encephalitis, aseptic meningitis, brain single-photon emission computed tomography abnormalities, brainstem lesions, cerebrospinal fluid abnormalities, computed axial tomography abnormalities, electroencephalogram abnormalities, encephalitis, Guillain-Barré syndrome, idiopathic hypertrophic cranial pachymeningitis, idiopathic progressive bilateral sensorineural hearing loss, magnetic resonance imaging abnormalities, neurologic symptoms, "neuro-Sweet disease," pareses of central origin, polyneuropathy, psychiatric symptoms[33,68,212–229]
- Ears: Tender red nodules and pustules that coalesce to form plaques in the external auditory canal and the tympanic membrane[230]
- Eyes: Blepharitis, conjunctival erythematous lesions with tissue biopsy showing neutrophilic inflammation, conjunctival hemorrhage, conjunctivitis, dacryoadenitis, episcleritis, glaucoma, iridocyclitis, iritis, limbal nodules, ocular congestion, periocular swelling, peripheral ulcerative keratitis, retinal vasculitis, scleritis, uveitis[12,20,26,101,185,202,214,229,231–239]
- Kidneys: Mesangiocapillary glomerulonephritis, urinalysis abnormalities (hematuria and proteinuria)[16,17,25,26,73]
- Intestines: Intestine with extensive and diffuse neutrophilic inflammation, neutrophilic ileal infiltrate, pancolitis (culture-negative)[36,203,240,241]
- Liver: Hepatic portal triad with neutrophilic inflammation, hepatic serum enzyme abnormalities, hepatomegaly[12,16,17,20,25,26,212,224,242]
- Heart: Aortic stenosis (segmental), aortitis (neutrophilic and segmental), cardiomegaly, coronary artery occlusion, heart failure, myocardial infiltration by neutrophils, vascular (aorta, brachiocephalic trunk and coronary arteries) dilatation[243–247]
- Lung: Bronchi (main stem) with red-bordered pustules, bronchi with neutrophilic inflammation, pleural effusion showing abundant neutrophils without microorganisms, chest roentgenogram abnormalities: corticosteroid-responsive culture-negative infiltratives, pulmonary tissue with neutrophilic inflammation[17,20,73,101,138,139,165,205,212,246–251]
- Mouth: Aphthous-like superficial lesions (buccal mucosa, tongue), bullae and vesicles (hemorrhagic: labial and gingival mucosa), gingival hyperplasia, necrotizing ulcerative periodontitis, nodules (necrotic: labial mucosa), papules (macerated: palate and tongue), pustules (individual and grouped: palate and pharynx), swelling (tongue), ulcers (buccal mucosa and palate)[26,75,102,117,203,249,252–254]
- Muscles: Magnetic resonance imaging (T1-weighted and T2-weighted) abnormalities: high signal intensities due to myositis and fasciitis, myalgias (in up to one-half of the patients with idiopathic Sweet syndrome), myositis (neutrophilic), tendinitis, tenosynovitis[73,75,244,255–257]
- Spleen: Splenomegaly[212]

From Cohen PR, Kurzrock R: Sweet's syndrome revisited: A review of disease concepts. *Int J Dermatol* **42**:761, 2003, with permission.

(see Chap. 82),[6] pyoderma gangrenosum (see Chap. 32),[231,269,341,342] sub-corneal pustular dermatosis (see Chap. 34),[6] and vasculitis (see Chap. 164).[3,192,231]

CONCURRENT LEUKEMIA CUTIS In patients with hematologic disorders, such as leukemia, Sweet syndrome may present as either a paraneoplastic syndrome (signaling the initial discovery of an unsuspected malignancy), a drug-induced dermatosis (after treatment with either all-*trans* retinoic acid, bortezomib, G-CSF, or imatinib mesylate), or a condition whose skin lesions concurrently demonstrate leukemia cutis.[1] In the third setting of hematologic dyscrasia-associated Sweet syndrome, there is the coincident presence of leukemia cutis (characterized by abnormal neutrophils) and Sweet syndrome (consisting of mature polymorphonuclear leukocytes) within the same skin lesion.[1,70,71,93,109,165,205–211] Acute leukemia (myelocytic and promyelocytic) is the most frequent hematologic malignancy associated with this unique presentation of Sweet syndrome. Myelodysplastic syndrome and myelogenous leukemia (either chronic or not otherwise specified) are the other associated hematologic disorders that have been associated with concurrent Sweet syndrome and leukemia cutis.[109] "Secondary" leukemia cutis, in which the circulating immature myeloid precursor cells are innocent bystanders that have been recruited to the skin as the result of an inflammatory oncotactic phenomenon stimulated by the Sweet syndrome lesions has been suggested as one of the hypotheses to explain concurrent Sweet syndrome and leukemia cutis in the same lesion.[165,206,207] Alternatively, "primary" leukemia cutis, in which the leukemic cells within the skin constitutes the bonified incipient presence of a specific leukemic infiltrate is another possibility.[207] Finally, it is possible that the atypical cells of leukemia cutis developed into mature neutrophils of Sweet syndrome as a result of G-CSF therapy–induced differentiation of the sequestered leukemia cells in patients with "primary" leukemia cutis who were being treated with this agent.[205]

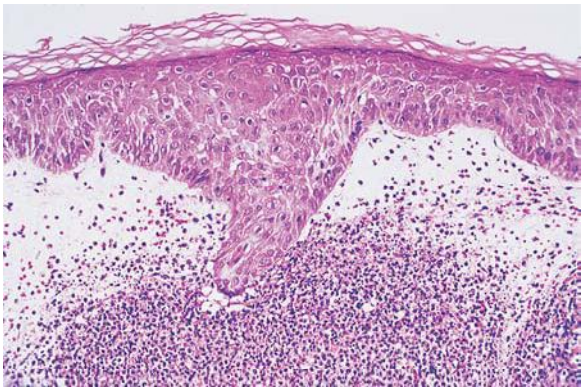
LABORATORY TESTS

Histopathology

Evaluation of a lesional skin biopsy is helpful when the diagnosis of Sweet syndrome is suspected. Lesional tissue should also be submitted for bacterial, fungal, mycobacterial, and possibly viral cultures because the pathologic findings of Sweet syndrome are similar to those observed in cutaneous lesions caused by infectious agents.[1,2]

A diffuse infiltrate of mature neutrophils and edema are characteristically present in the upper dermis (Fig. 31-4). Swollen endothelial cells, dilated small blood vessels, and fragmented neutrophil nuclei (referred to as *karyorrhexis* or *leukocytoclasia*) may also be present (Fig. 31-5). Fibrin deposition or neutrophils within the vessel walls (changes of "primary" leukocytoclastic vasculitis) are usually absent and the overlying epidermis is normal.[1,2,23,167,168] However, the spectrum of pathologic changes described in cutaneous lesions of Sweet syndrome has expanded to include concurrent leukemia cutis, vasculitis, and variability of the composition or the location of the inflammatory infiltrate.[3,191]

The inflammatory infiltrate in Sweet syndrome is typically located in the papillary and upper reticular dermis; however, it can also involve the epidermis or adipose tissue. Although the dermal inflammation is usually dense and diffuse, it can also be perivascular or demonstrate "secondary" changes of leukocytoclastic vasculitis believed to be occurring as an epiphenomenon and not representative of a "primary" vasculitis.[3,192,193] Neutrophilic spongiotic vesicles[194] or sub-corneal pustules[12,80,167,195,196] result from exocytosis of neutrophils into the epidermis.[12,17,80,167,194,195,197] When the neutrophils are located either entirely or only partially in the subcutaneous fat, the condition is referred to as *subcutaneous Sweet syndrome*.[4,8,12,17,99,119,164–184]



▲ **FIGURE 31-4** Histopathologic presentation of acute febrile neutrophilic dermatosis (Sweet syndrome) demonstrates massive edema of the papillary dermis and a dense diffuse infiltrate of mature neutrophils throughout the upper dermis (hematoxylin and eosin stain). (From Cohen PR et al: Sweet's syndrome in patients with solid tumors. *Cancer* **72**:2723, 1993, with permission.)

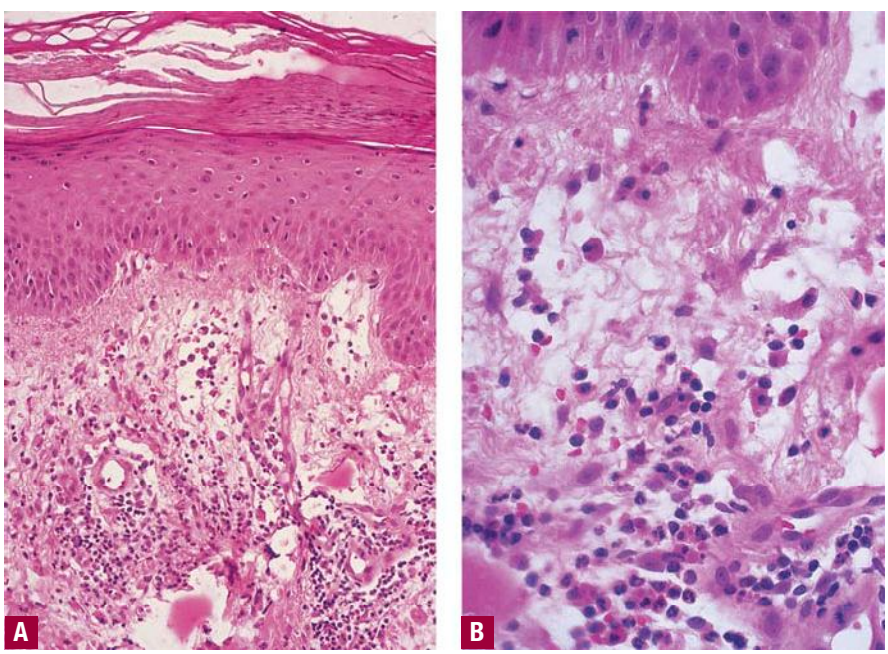
Other Laboratory Tests

Peripheral leukocytosis with neutrophilia and an elevated erythrocyte sedimentation rate are the most consistent laboratory findings in Sweet syndrome.[23] However, leukocytosis is not always present in patients with biopsy-confirmed Sweet syndrome.[26] For example, anemia, neutropenia, and/or abnormal platelet counts may be observed in some of the patients with malignancy-associated Sweet syndrome. Therefore, a complete blood cell count with leukocyte differential and platelet count, evaluation of acute phase reactants (such as the erythrocyte sedimentation rate or C-reactive protein), serum chemistries (evaluating hepatic function and renal function), and a urinalysis should be performed. It is also reasonable to perform a serologic evaluation of thyroid function because there appears to be a bona fide association between thyroid disease and Sweet syndrome.[1,2]

Special Tests

EVALUATION FOR EXTRACUTANEOUS MANIFESTATIONS Extracutaneous manifestations of Sweet syndrome may result in other laboratory abnormalities. Patients with central nervous system involvement may have abnormalities on brain single photon emission computed tomography, computerized axial tomography, electroencephalograms, magnetic resonance imaging, and cerebrospinal fluid analysis. Patients with kidney and liver involvement may demonstrate urinalysis abnormalities (hematuria and proteinuria) and hepatic serum enzyme elevation. In addition, patients with pulmonary involvement may have pleural effusions and corticosteroid-responsive culture-negative infiltrates on their chest roentgenograms.[2,343]

MALIGNANCY WORKUP



▲ **FIGURE 31-5** Characteristic histopathologic features of Sweet syndrome are observed at low (**A**) and high (**B**) magnification: papillary dermal edema, swollen endothelial cells, and a diffuse infiltrate of predominantly neutrophils with leukocytoclasia, yet no evidence of vasculitis (hematoxylin and eosin stain). (From Cohen PR, Holder WR, Rapini RP: Concurrent Sweet's syndrome and erythema nodosum: A report, world literature review and mechanism of pathogenesis. *J Rheumatol* **19**:814, 1992, with permission.)

DIFFERENTIAL DIAGNOSIS

Clinical Differential Diagnosis (Box 31-1)

Sweet syndrome skin and mucosal lesions mimic those of other conditions. Therefore, infectious and inflammatory disorders, neoplastic conditions, reactive erythemas, vasculitis, other cutaneous conditions, and other systemic diseases are included in the clinical differential diagnosis of Sweet syndrome (see Box 31-1).[2,15,23,148,165,202,220,344,345]

Histologic Differential Diagnosis (Box 31-2)

The histologic differential diagnosis of Sweet syndrome includes conditions microscopically characterized by either neutrophilic dermatosis or neutrophilic panniculitis.[2–4,6,12,193,346–353] The pathologic changes associated with Sweet syndrome are similar to those observed in an abscess or cellulitis; therefore, culture of lesional tissue for bacteria, fungi, and mycobacteria should be considered to rule out infection.[23] Leukemia cutis not only mimics the dermal changes of Sweet syndrome, but can potentially occur within the same skin lesion as Sweet syndrome; however, in contrast to the mature polymorphonuclear neutrophils found in Sweet syndrome, the dermal infiltrate in leukemia cutis consists of malignant immature leukocytes.[354] The pathologic changes in the adipose tissue of subcutaneous Sweet syndrome lesions can be found in either the lobules, the septae, or both; therefore, conditions characterized by a neutrophilic lobular panniculitis (see Chap. 68) also need to always be considered and ruled out.[2,4]

Box 31-1

Clinical Differential Diagnosis of Sweet Syndrome

Most Likely

- Drug eruptions
- Cellulitis
- Chloroma
- Erysipelas
- Erythema nodosum
- Leukemia cutis
- Leukocytoclastic vasculitis
- Panniculitis
- Pyoderma gangrenosum

Consider

- Acral erythema
- Erythema elevatum diutinum
- Erythema multiforme
- Halogenoderma
- Lymphoma
- Neutrophilic eccrine hidradenitis
- Periarteritis nodosa
- Urticaria
- Viral exanthema

Always Rule Out

- Bacterial sepsis
- Behçet disease
- Bowel bypass syndrome
- Dermatomyositis
- Familial Mediterranean fever
- Granuloma faciale
- Leprosy
- Lupus erythematosus
- Lymphangitis
- Metastatic tumor
- Rheumatoid neutrophilic dermatitis
- Syphilis
- Systemic mycosis
- Thrombophlebitis
- Tuberculosis

COMPLICATIONS

Complications in patients with Sweet syndrome can be directly related to the mucocutaneous lesions or indirectly related to the Sweet syndrome–associated conditions. Skin lesions may become secondarily infected and antimicrobial therapy may be necessary. In patients with malignancy-associated Sweet syndrome, reappearance of the dermatosis may herald the unsuspected discovery that the cancer has recurred. Systemic manifestations of Sweet syndrome–related conditions—such as inflammatory bowel disease, sarcoidosis, and thyroid diseases—may warrant disease-specific treatment.

PROGNOSIS AND CLINICAL COURSE

The symptoms and lesions of Sweet syndrome eventually resolve without any therapeutic intervention in some patients with classic Sweet syndrome. However, the lesions may persist for weeks to months.[10,23,254,355] In patients with malignancy-associated Sweet syndrome, successful management of the cancer occasionally results in clearing of the related dermatosis.[13,15,23] Similarly, discontinuation of the associated medication in patients with drug-induced Sweet syndrome is typically followed by spontaneous improvement and subsequent resolution of the syndrome.[13,15,23] Surgical intervention has also resulted in the resolution of Sweet syndrome in some of the patients who had associated tonsillitis, solid tumors, or renal failure.[1,2,19,315,356,357]

Sweet syndrome may recur after either spontaneous remission or therapy-induced clinical resolution.[10] The duration of remission between recurrent episodes of the dermatosis is variable. Sweet syndrome recurrences are more common in cancer patients; in this patient population, the reappearance of dermatosis-associated symptoms and lesions may represent a paraneoplastic syndrome which is signaling the return of the previously treated malignancy.[1,2,15,135]

TREATMENT

Systemic corticosteroids are the therapeutic mainstay for Sweet syndrome.[7,8,10,12,16,17,19,20,23,36,49,50,70,184,223,233,240,250,284,358–361] Initiation of therapy promptly results in improvement of the symptoms and resolution of the mucocutaneous lesions. Daily pulse methylprednisolone administered intravenously may be necessary in patients with refractory disease. Topical (such as 0.05 percent clobetasol propionate)[13,19–21,30,234,362–365] or intralesional (such as triamcinolone acetonide at a dose between 3.0 mg/cc to 10.0 mg/cc)[362,366,367] corticosteroids may be effective for treating localized Sweet syndrome lesions.[1,2,7]

Other first-line (potassium iodide and colchicine) and second-line (indomethacin, clofazimine, cyclosporine, and dapsone) systemic treatments for Sweet syndrome are summarized in Box 31-3.[10,12,17,20,23,30,49,70,143,184,198,203,221,223,231,240,245,250,259,261,281,284,294,296,329,359–363,368–384]

Vasculitis and hypothyroidism are potential drug-induced side effects of potassium iodide.[385] Gastrointestinal symptoms, such as diarrhea, abdominal pain, and nau-

Box 31-2

Histologic Differential Diagnosis of Sweet Syndrome

Most Likely

- Abscess/cellulitis: Positive culture for infectious agent
- Leukemia cutis: Dermal infiltrate consists of immature neutrophils
- Leukocytoclastic vasculitis: Vessel wall destruction—extravasated erythrocytes, fibrinoid necrosis of vessel walls, karyorrhexis, and neutrophils in the vessel wall
- Pyoderma gangrenosum: Ulcer with overhanging, undermined violaceous edges

Consider

- Erythema elevatum diutinum: Erythematous asymptomatic plaques often located on the dorsal hands and elbows; younger lesions have microscopic features of leukocytoclastic vasculitis, whereas older lesions have dermal fibrosis and mucin
- Granuloma faciale: Yellow to red to brown indurated asymptomatic facial plaques; there is a grenz zone of normal papillary dermis beneath which there is a dense diffuse inflammatory infiltrate of predominantly neutrophils (with microscopic features of leukocytoclastic vasculitis) and numerous eosinophils
- Neutrophilic eccrine hidradenitis: Neutrophils around eccrine glands, often in patients with acute myelogenous leukemia receiving induction chemotherapy

Always Rule Out

- Bowel (intestinal) bypass syndrome: History of jejunal-ileal bypass surgery for morbid obesity
- Halogenoderma: Neutrophilic dermal infiltrate with necrosis and pseudoepitheliomatous hyperplasia with intraepidermal abscesses; history of ingestion of bromides (leg lesions), iodides (facial lesions), or topical fluoride gel to teeth during tumor radiation therapy to face
- Lobular neutrophilic panniculitides: In addition to subcutaneous Sweet syndrome, these include α_1-antitrypsin deficiency syndrome, factitial panniculitis (secondary to the presence of iatrogenic or self-induced foreign bodies), infectious panniculitis (secondary to either a bacterial, fungal, mycobacterial, or protozoan organism), pancreatic panniculitis, rheumatoid arthritis–associated panniculitis
- Rheumatoid neutrophilic dermatitis: History of rheumatoid arthritis, nodules, and plaques

Box 31-3

Systemic Treatments for Sweet Syndrome

LINE	MEDICATION	DOSE
First	Prednisone	1 mg/kg/day (usually ranging from 30–60 mg) as a single oral morning dose. Within 4–6 wk, taper dose to 10 mg/day; however, some patients may require 2–3 mo of treatment or intravenous therapy.
	Methylprednisolone sodium succinate	Intravenously administered (up to 1000 mg/day) over 1 or more hours daily for 3–5 days. This is followed by a tapering oral dose of corticosteroid or another immunosuppressant agent.
	Potassium iodide	Administered orally as 300-mg enteric-coated tablets, three times each day (for a daily dose of 900 mg) or as a saturated solution (1 g/mL of water) of potassium iodide (saturated solution of potassium iodide, also referred to as *Lugol's solution*), beginning at a dose of 3 drops three times each day (9 drops/day = 450 mg/day) and increasing by 1 drop three times/day, typically to a final dose of 21 drops/day (1050 mg) to 30 drops/day (1500 mg).[a]
	Colchicine	Administered orally at a dose of 0.5 mg three times each day (for a daily dose of 1.5 mg).
Second	Indomethacin	Administered at an oral daily dose of 150 mg for 7 days, and then 100 mg/day for 14 days.
	Clofazimine	Administered orally at a daily dose of 200 mg for 4 wk, and then 100 mg/day for 4 wk.
	Cyclosporine	As monotherapy or as a second-line agent (after failure of first-line therapy or as a corticosteroid-sparing agent). Initial oral daily dose ranged from 2 mg/kg/day[380] to 4 mg/kg/day[231] to 10 mg/kg/day; in the latter patient, from the eleventh day the dose was reduced by 2 mg/kg/day every 2 days and discontinued on day 21.
	Dapsone	As either monotherapy or in combination therapy. Initial oral dose ranged from 100 mg/day to 200 mg/day; the latter dose was either administered as a single dose or divided into two equal doses.

[a]One drop = 0.05 mL (or 50 mg when the concentration of potassium iodide is 1000 mg/mL) when a "standard" medicine dropper (which dispenses 20 drops/mL) is used.
From Cohen PR, Kurzrock R: Sweet's syndrome revisited: A review of disease concepts. *Int J Dermatol* **42**:761, 2003.

sea and vomiting, are potential adverse effects from colchicine that may improve after lowering the daily dose of the drug.[2]

Second-line systemic agents for Sweet syndrome have all been used as monotherapy either in the initial management of the patient or after first-line therapies have failed. In addition, cyclosporine and dapsone have been used in combination therapy either as a corticosteroid-sparing agent or with other drugs.[1,2,7,303]

There are certain patients whose Sweet syndrome lesions have improved after receiving systemic antibiotics.[7] For example, these include individuals with *Staphylococcus aureus* secondarily impetiginized lesions (treated with an antimicrobial agent to which their bacterial strain is susceptible),[23] patients with inflammatory bowel disease (treated with metronidazole),[267,387] and persons with dermatosis-related yersinia[125,126] or chlamydia[306,307] infection (treated with either doxycycline,[125,389] minocycline,[30,126] or tetracycline[306,307,388]). In addition, effective treatment of Sweet syndrome has also been described, predominantly in case reports, with other drugs: cytotoxic chemotherapies and antimetabolites (chlorambucil and cyclophosphamide),[30,39,148,200,251,360,390] immunoglobulin,[303] interferon alpha,[202,366] etretinate,[361] and tumor necrosis factor antagonists (etanercept,[392] infliximab,[264,265,278,266] and thalidomide[5,393]). Pentoxifylline was hypothesized to be beneficial for treating Sweet syndrome[394,395]; however, when used as monotherapy, it was not found to be efficacious.[1,2,7,295,362]

CHAPTER 32

Pyoderma Gangrenosum

Frank C. Powell
Bridget C. Hackett

EPIDEMIOLOGY

The prevalence of pyoderma gangrenosum (PG) is unknown. Estimates have suggested that approximately three cases of PG per million of the population occur per year, with most large referral centers seeing one to two cases per year.[1] It has been reported in all age groups but mainly affects adults between the ages of 40 and 60 years.[2] Most reported series of patients with PG indicate a moderate preponderance of females. PG often occurs in patients who have other diseases (arthritis, inflammatory bowel disease, hematologic dyscrasias, etc.) but is not a manifestation or complication of these diseases and its clinical course is usually unrelated to their severity or activity.[3]

ETIOLOGY AND PATHOGENESIS

The etiology of PG is unknown, and its pathogenesis poorly understood. Because a lymphocytic infiltrate is prominent at the advancing border of active lesions, it has been postulated that lymphocyte antigenic stimulation takes place in the skin with subsequent clonal proliferation in lymph nodes and recirculation to the skin with cytokine release and neutrophil recruitment. The predominance of neutrophils in the infiltrate of established lesions of PG (both in the skin and sometimes other organs) has suggested to others that a defect in neutrophil chemotaxis or reactivity is the basic pathologic problem in PG. Abnormal immune reactivity and cross-reacting autoantibodies directed at antigens common to the skin and intestine or joints are other proposed pathogenic mechanisms. Several studies have shown positive direct immunofluorescent findings in the vessels adjacent to active PG lesions.[4]

CLINICAL FINDINGS

The approach to an individual suspected of having PG is outlined in the patient algorithm (Fig. 32-1). The clinical presentation of PG may be diverse and there is neither a diagnostic laboratory test nor pathognomonic histopathologic findings. It is therefore important to avoid misdiagnosing other diseases as PG.[5] The most important considerations are the exclusion of vascular disease (stasis, occlusion, and vasculitis), infection (bacterial and deep fungal infection), and malignancy (primary or secondary cutaneous malignancy) in every patient. Close follow-up and re-evaluation (with repeated skin biopsies, tissue and swab cultures, and blood tests as indicated) is an important part of the ongoing evaluation of patients with suspected PG, particularly those who show a poor response to therapy.

History

A patient with PG usually complains of severe pain related to the cutaneous lesion but out of proportion to its clinical appearance. Approximately 25 percent of patients note the onset of PG at sites of minor cutaneous trauma (needle stick, inoculation site, insect bites), called the *pathergic phenomenon* (Fig. 32-2). Lesions progress rapidly (with the exception of vegetative PG), and cutaneous destruction evolves over days rather than weeks. Special inquiry regarding drug intake (especially iodides/bromides, hydroxyurea); exposure to and symptoms of infectious diseases (Box 32-1); symptoms relating to the musculoskeletal system (joint pains, swelling etc), the gastrointestinal tract (abdominal pain, diarrhea, constipation, etc.), hematologic disease (tiredness, anemia, bruising, blood clotting disorders, etc.), and non-specific but potential malignancy-related symptoms, such as weight loss and fatigue, should be made.

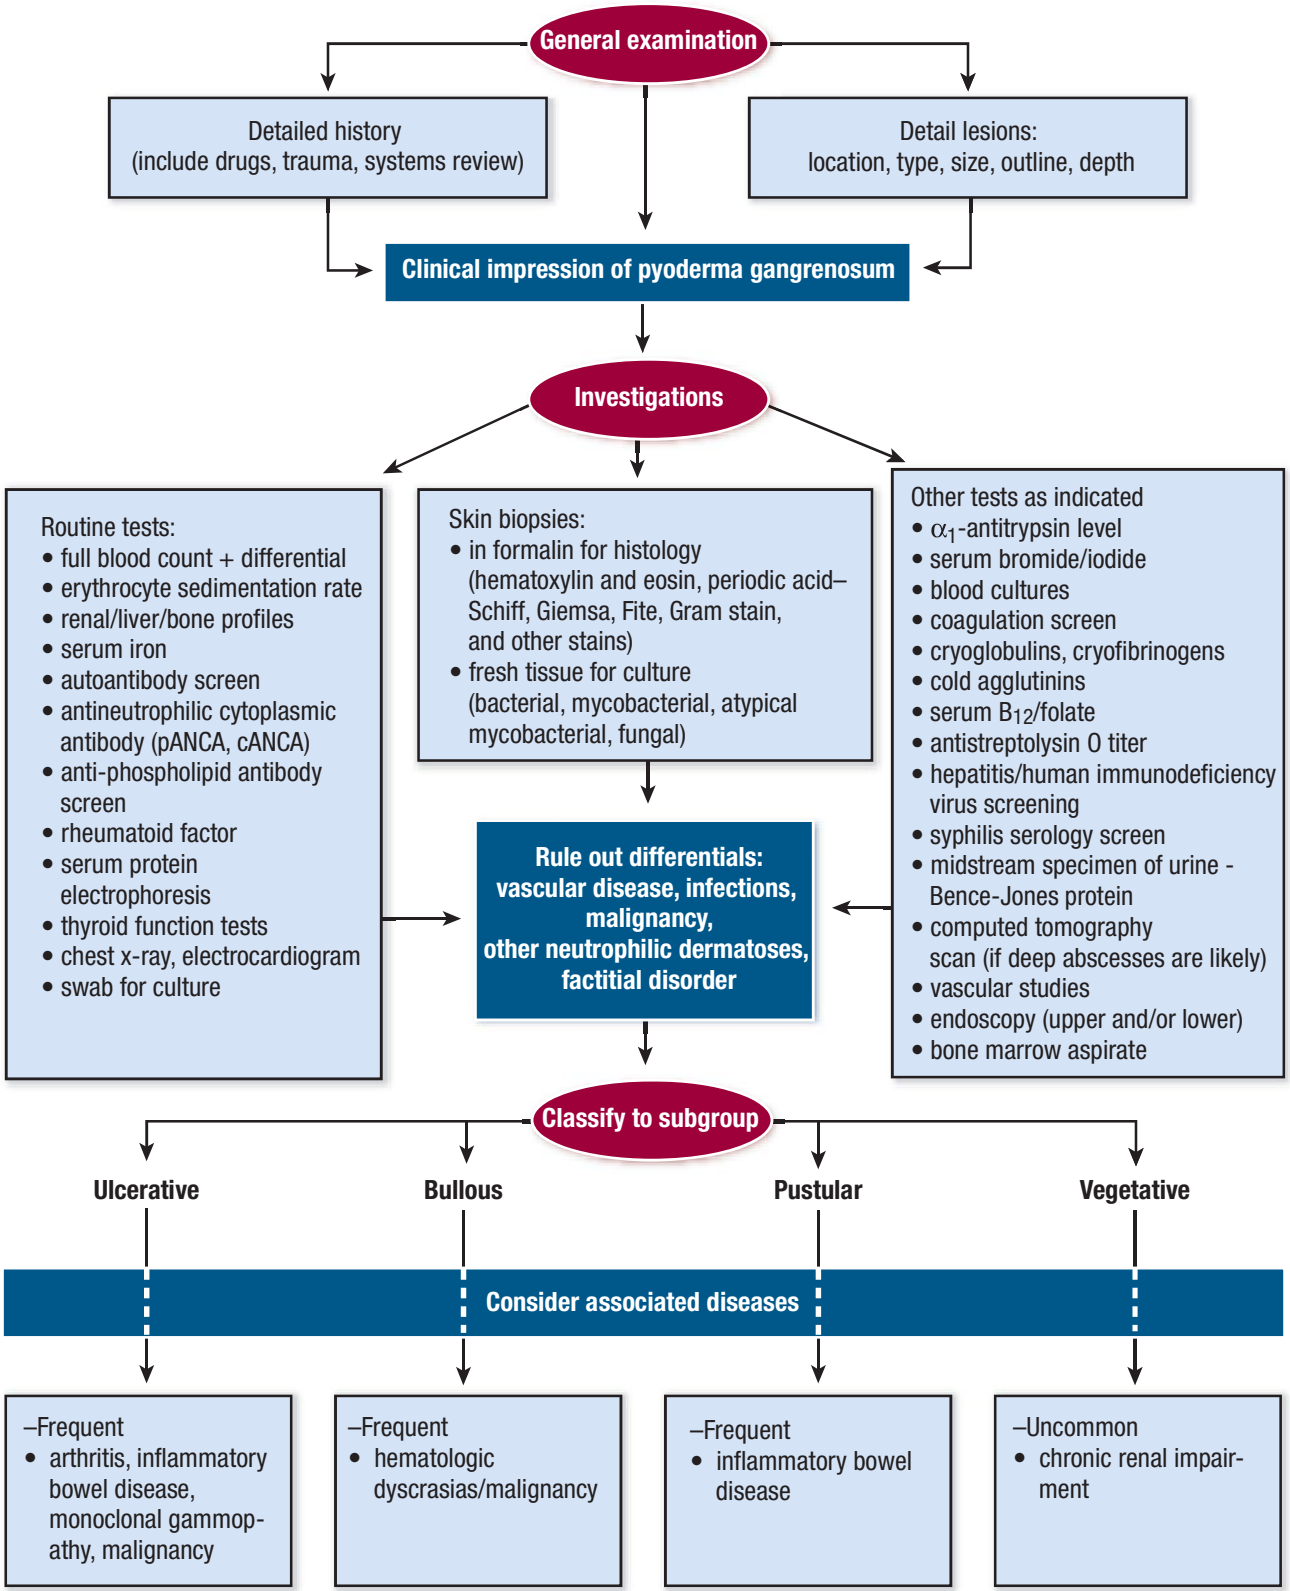
Cutaneous Lesions

PG is protean in its clinical expression with extreme variability according to the type and stage of disease. Lesions can be classified morphologically as being ulcerative, bullous, pustular, or vegetative. Usually one variant of PG dominates the clinical picture, but some patients show more than one type (isolated pustular lesions frequently occur in patients with ulcerative PG).

The most common initial lesion in a patient with ulcerative PG is an inflammatory pustule or furuncle (usually single but sometimes multiple) which appears on normal appearing skin (most commonly the leg), sometimes at the site of minor trauma. This develops a surrounding areola or zone of erythema that broadens into the normal skin ahead of the enlarging inflammatory lesion (Fig. 32-3). As it enlarges, the center degenerates, crusts, and erodes, converting it into an eroding ulcer the development of which is accompanied by an alarming increase in the severity of the pain. The ulcer has a bluish edge (due to undermining by the necrotizing inflammatory process) and the base is covered with purulent material. Exposure of muscle or tendon occurs in some cases. Control of

PYODERMA GANGRENOSUM AT A GLANCE

- Pyoderma gangrenosum (PG) is a rare inflammatory disease of unknown etiology characterized by neutrophilic infiltration of the dermis and destruction of tissue.
- PG is more frequent in female patients and occurs at any age, usually between 40 and 60 years.
- The majority of patients with PG have other systemic diseases (such as arthritis, inflammatory bowel disease, hematologic dyscrasias, malignant disease, etc.), but PG also occurs independently of these disorders.
- PG may present as ulceration, bullous lesions, or pustular or vegetative lesions. Clinical features sometimes overlap in individual patients.
- There is no laboratory test or investigation that establishes the diagnosis of PG.
- Specified criteria suggest the diagnosis of PG, but other conditions (particularly infection, vascular disease, and malignancy) must be excluded.
- The mainstays of management are systemic immunosuppressive agents together with appropriate local and topical therapy.
- The disease in most patients is chronic. Remission usually requires months of therapy; maintenance therapy is necessary in many and relapses occur in many patients. Significant morbidity and mortality are experienced by patients with ulcerative and bullous PG.



▲ **FIGURE 32-1** Approach to the patient with pyoderma gangrenosum.

ulcerative PG usually requires systemic immunosuppressive therapy.

Bullous PG (or atypical PG) usually presents as a painful, rapidly expanding superficial inflammatory erosion. In the early acute stage the bullous nature of the lesion is evident, but because the roof of the blister necroses rapidly, close inspection of the border of established lesions is necessary to reveal its bullous nature (Fig. 32-4). Bullous PG is commonly associated with hematologic disease and most often appears on the upper limbs.[2] It usually requires systemic immunosuppressive therapy for control.

Pustular PG (also called the *pustular eruption of inflammatory bowel disease*) is a generalized eruption that occurs almost exclusively in the setting of acute inflammatory bowel disease. Its onset is dramatic, with the rapid development

▲ **FIGURE 32-2** Several pathergic pyoderma gangrenosum lesions occurring along a thoracotomy scar site. Note central ulceration, violaceous borders, and peripheral rim of erythema.

of multiple, large, circular-to-oval, painful pustules on the trunk and, to a lesser extent, the face and limbs (Fig. 32-5). Control of this eruption is difficult without controlling the bowel disease. Vegetative PG (or superficial granulomatous pyoderma) usually presents as a single furunculoid nodule, abscess, plaque, or ulcer, typically on the trunk (Fig. 32-6). In contrast to other variants, it is gradual in its onset, mild in the discomfort it generates, and not usually associated with the presence of systemic disease. This form of PG is usually more responsive to localized or mild forms of systemic therapy than the other variants.[6]

Related Physical Findings

Because PG involvement of internal organs (especially the lungs, liver, and spleen) with sterile neutrophilic abscesses can occur and because many patients with PG have diseases of other systems, a thorough physical examination is mandatory with particular search for clinical manifestations of inflammatory bowel disease, arthritis, vasculitis (leukocytoclastic/granulomatous/cryoglobulinemic/Takayasu arteritis), hematologic disease and internal malignancy.

LABORATORY TESTS

Routine Investigations (See Fig. 32-1)

All patients with PG should have the following tests carried out: Full blood cell count with differential white cell count and erythrocyte sedimentation rate (anemia, leukocytosis, and elevated erythrocyte sedimentation rate may be seen); renal, liver, and bone profiles; autoantibody screen (including anti-Ro/La antibodies, antineutrophilic cytoplasmic antibodies, anti-phospholipid antibodies, rheumatoid factor); serum protein electrophoresis (monoclonal gammopathy occurs in 10 percent of patients); thyroid function studies; chest x-ray, electrocardiogram, and midstream specimen of urine; and swabs from lesions sent for bacterial, fungal, and viral cultures. An incisional, wedge skin biopsy should be taken from the edge of the lesion sampling a portion of normal skin progressing through the border into the area of active inflammation to allow the various histologic patterns to be discerned. The excised tissue should then be divided with one section (fresh tissue) sent for bacterial, mycobacterial, and fungal culture, and another portion sent in formalin for histologic evaluation requesting hematoxylin and eosin and periodic acid-Schiff, Giemsa, Fite, Gram, and other stains considered relevant. Although immunofluorescent studies may show positive vascular staining in perilesional skin, this is not essential for diagnostic purposes and can be omitted unless vasculitis is suspected.

Histopathology

The histopathology is non-specific. The histopathologic changes seen in the skin depend on the clinical type of PG (ulcerative, bullous, pustular, or vegetative) and the timing and site of the biopsy relative to the inflammatory process.[7] In general, biopsies taken from the center of established PG lesions show marked neutrophilic infiltration with abscess formation, whereas those taken from peripheral areas show a mixed or predominantly lymphocytic inflammatory infiltrate.

A marked perivascular lymphocytic infiltration is seen in biopsies taken from the "zone" or area of erythema which surrounds active lesions of ulcerative PG. Lymphocytes may be seen to infiltrate vessel walls with intramural and intravascular fibrin deposition indicative of vascular damage (lymphocytic vasculitis).[8] Biopsies taken from the edge of an ulcer show a transition in the cellular infiltrate from lymphocytes and some histiocytes to a predominance of polymorphonuclear leukocytes and early abscess formation. Abscess formation with intense dermal neutrophilic infiltration extending to the panniculus and areas of tissue necrosis dominates the histologic findings in biopsies taken from central areas of ulcerative PG lesions. Leukocytoclasis is not a prominent finding and although occasionally evidence of leukocytoclastic vasculitis is seen close to the abscess center, this is a minor feature and considered secondary to the intense inflammatory changes. Histologic examination of lesional skin from a patient with bullous PG shows a poorly defined sub-epidermal or intra-epidermal bulla with epidermal necrosis and marked upper dermal edema with prominence of neutrophils. Biopsy of pustular PG shows a dense dermal neutrophilic infiltration (often centered about a follicle) with sub-epidermal edema and infiltration of neutrophils into the epidermis with sub-corneal aggregations, whereas vegetative PG is characterized histologically by the presence of pseudoepitheliomatous hyperplasia, sinus tract formation, and the presence of palisading granulomas in the setting of focal dermal neutrophilic abscesses.

The predominance of the neutrophilic infiltrate in established lesions of PG have led to its classification as one of the neutrophilic dermatoses. Clinical (and to an extent histologic) overlap occurs with the other dermatoses in this category, especially atypical or bullous forms of Sweet syndrome (see Chap. 31). Several of the neutrophilic dermatoses (Sweet syndrome, erythema elevatum diutinum, sub-corneal pustular dermatosis, and PG) share an association with immunoglobulin A mono-

Differential Diagnosis of Pyoderma Gangrenosum (PG)

VARIANT SPECIFIC

Ulcerative PG

Most Likely

- Vascular
  - Venous stasis ulceration
  - Occlusive disease/Arteritis
  - Vasculitis
  - Anti-phospholipid-antibody syndrome
- Malignancy
  - Primary or secondary
- Infection
  - Bacterial
  - Mycobacterial/Atypical mycobacterial
  - Viral (herpes simplex)
  - Deep fungal infection (*Sporotrichosis*, *Aspergillus*, *Cryptococcus*)
- Other
  - Drugs (halogenoderma/hydroxyurea, etc.)

Consider

- Infection
  - Necrotizing fasciitis
  - Syphilis/Amebiasis/Mucormycosis
  - Histoplasmosis/Rhizopus
- Other
  - Dermatitis artefacta
  - Calciphylaxis/Insect bite (spider)

Bullous PG

Most Likely

- Infection
  - Bacterial (cellulitis/impetigo)
  - Viral (in immunocompromised)
  - Fungal (mucormycosis in diabetics)
- Other
  - Sweet syndrome/Behçet disease

Consider

- Bullous dermatoses
  - Erythema multiforme/Bullous pemphigoid
- Other
  - Insect/Arthropod bite/Malignancy

Pustular PG

Most Likely

- Infection
  - Bacterial/Viral/Fungal
- Vasculitis
  - Pustular vasculitis

Consider

- Other
  - Pustular psoriasis
  - Sneddon-Wilkinson disease
  - Pustular drug eruption
  - Bowel bypass syndrome
  - Pyostomatitis vegetans

Vegetative PG

Most Likely

- Infection
  - Bacterial/Viral/Fungal
  - Mycobacterial/Atypical mycobacterial
  - Leishmaniasis

Consider

- Blastomycosis-like pyoderma
- Dermatitis artefacta/Malignancy
- Pyoderma vegetans

SITE-SPECIFIC[a]

Parastomal

Most Likely

- Dermatoses
  - Irritant/Allergic contact dermatitis
  - Other (e.g., psoriasis)
- Infection
  - Bacterial (*Staphylococcus*/*Streptococcus*)/Cellulitis
  - Fungal (*Candida*)
- Other
  - Extra-intestinal inflammatory bowel disease
  - Malignancy

In wounds

Most Likely

- Infection
  - Bacterial/Cellulitis
  - Fungal (e.g., mucormycosis)
- Breakdown
  - Suture allergy
  - Mechanical

Consider

- Malignancy

Genital

Most Likely

- Infection
  - Bacterial/Viral infection (herpes simplex virus, Epstein-Barr virus, cytomegalovirus)
  - Tuberculosis/Tuberculide
  - Fournier gangrene
- Malignancy
  - Squamous cell/Extramammary
  - Paget disease

Consider

- Infection
  - Syphilis/Lymphogranuloma venereum/Histoplasmosis
  - Leishmaniasis/Granuloma inguinale
- Other
  - Dermatitis artefacta
  - Behçet disease

Head and neck

Most Likely

- Infection
  - Bacterial/Viral/Fungal
  - Dissecting cellulitis of the scalp
- Malignancy
  - Squamous cell carcinoma
  - Basal cell carcinoma

Consider

- Vasculitis
  - Wegener granulomatosis
  - Malignant pyoderma
- Other
  - Dermatitis artefacta

[a]The differential diagnosis of lower limb PG is essentially that delineated for variant-specific ulcerative PG.

clonal gammopathy, and diseases such as inflammatory bowel disease and hematologic disorders occur more frequently than expected in these patients.

Special Investigations

In patients in whom the clinical history or examination indicates further testing is necessary, the following additional tests should be considered: endoscopy (upper and/or lower gastrointestinal); vascular studies; bone marrow aspirate examination; ultrasound of abdomen (including liver/spleen/aorta); computed tomography of the thorax, abdomen, or brain; and other directed investigations as indicated in Fig 32-1.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis to be considered in a patient with PG is extensive.[5] Different variants of PG (ulcerative, bullous, vegetative, pustular) suggest alternative diagnoses and the occurrence of PG at certain cutaneous sites raises further diagnostic issues for the clinician, as shown in Box 32-1.

Because there is no confirmatory diagnostic test for PG, the following major criteria are proposed. The diagnosis of PG is likely in a patient with:

- Sudden onset of a painful lesion fitting the morphologic criteria (ulcerative, bullous, pustular, or vegetative) in a (usually middle-aged) patient without significant toxemia or relevant drug intake, *and*
- Histologic evidence of marked tissue neutrophilia in the absence of leukocytoclastic vasculitis and exclusion of malignancy and infective organisms by special studies and negative tissue culture, *and*
- Exclusion of vascular stasis/occlusion/vasculitis by appropriate studies.

The following minor criteria provide supportive evidence of the diagnosis or raise suspicion of PG in patients who do not fulfil all the major criteria above:

- Localization at a characteristic site (ulcerative PG on the legs, vegetative on the trunk, bullous PG on the upper limb, pustular PG on the trunk or face) or at a site of cutaneous trauma (ulcerative PG) or in a peristomal site.
- Rapid progression of the inflammatory lesion with escalating pain severity (except vegetative PG).
- Occurrence in an individual with systemic disease, such as arthritis, inflam-

▲ **FIGURE 32-3** Established lesion of ulcerative pyoderma gangrenosum showing well-defined ulceration with surrounding zone of erythema.

matory bowel disease, or hematologic dyscrasias (except vegetative PG).
- Rapid reduction of pain and inflammation on initiation of systemic steroid therapy.

COMPLICATIONS

Active or poorly controlled PG causes significant morbidity (loss of mobility, pain, exposure to secondary infection, anemia of chronic disease, etc.). Many of the treatments for PG have significant side effects and have to be administered for many months. Frequent monitoring and follow-up of patients are necessary.

PROGNOSIS AND CLINICAL COURSE

The prognosis depends on the PG variant; the age and sex of the patient; presence of other systemic disease; and the type, dosage, and duration of therapy required to bring the disease under control. Patients with vegetative PG generally have a good prognosis and the skin lesions often heal within 6 months of the initiation of relatively mild forms of treatment.[6] Patients with pustular PG often have complete remission of their cutaneous lesions if they gain control of the severe inflammatory bowel disease that usually accompanies this variant. Ulcerative PG is a chronic recurrent disease with a significant morbidity and mortality.[2,4] Patients older than 65 years of age and male patients seem to have a worse prognosis. Patients with bullous PG who have an associated hematologic disorder also have a poor prognosis. The onset of bullous PG in a patient with stable polycythemia rubra vera appears to herald the onset of leukemic change in some patients.[9]

▲ **FIGURE 32-5** Pustular pyoderma gangrenosum lesions of the penis in a patient who also had ulcerative pyoderma gangrenosum.

TREATMENT

General Measures

The age, mobility, social support networks, pain threshold, extent and severity of disease, and ability to comply with

▲ **FIGURE 32-4** Bullous pyoderma gangrenosum lesion showing collapsed roof of blister and superficial erosive quality of the subsequent ulceration.

▲ **FIGURE 32-6** Vegetative pyoderma gangrenosum—an indolent area of chronic inflammation and ulceration that was present for months.

therapeutic measures should be evaluated for each patient and the treatment adapted accordingly. The patient should be given realistic expectations of the speed of recovery likely in this disease. Thus, although lesions develop and evolve within days, the healing process usually takes weeks or months. Adequate bed rest, efficient pain relief, correction of anemia, and appropriate therapy of any associated disease are pivotal in the overall management strategy of a patient with PG.[10] If other systemic illnesses are present, cooperation with a general physician is important, and if surgery is anticipated appropriate measures (such as the use of subcuticular sutures and systemic steroid cover) adopted to avoid precipitating new PG lesions.

The location, morphology, size, and outline of each lesion should be recorded (by photography and by using a calibrated transparent plastic sheet placed over lesions on which the outline is traced) on presentation and subsequent review.

Wound Care

The cutaneous lesions of PG are usually extremely tender so cleansing should be carried out daily with tepid sterile saline or a mild antiseptic solution. Potassium permanganate solution diluted 1:2000 is helpful if there is marked exudation. Silver sulphadiazine 1 percent cream is usually soothing when applied to the ulcerated lesions of PG and may facilitate granulation tissue formation as well as inhibiting bacterial growth. A non-adhesive dressing should be applied over the lesion and held in place with a crêpe elasticized bandage wound firmly, but not tightly, over it. Some patients, particularly those with superficial lesions, obtain significant easing of discomfort with the use of hydrocolloid dressings, which can be left on for 2 to 3 days and "melt" into the lesion. Careful instruction is important to ensure compliance and to avoid the use of irritants such as chemical de-sloughing agents, caustics (such as silver nitrate), or dressings (such as gauze impregnated with soft paraffin and/or antibacterial agents), which may adhere to the ulcer base.

Topical Treatments

Topical treatments are important adjuncts to the systemic treatment needed for the management of most PG patients, and may be sufficient to bring the condition under control in those who have vegetative or mild ulcerative PG. Fluorinated topical corticosteroid ointment applied to the periphery of an active PG lesion can reduce inflammation and may be sufficient as a monotherapy to heal vegetative or superficial peristomal PG.[11] Topical disodium cromoglycate (with or without occlusion), benzoyl peroxide, nicotine cream or patches, hyperbaric oxygen, and radiotherapy have all been reported as being effective in individual patients with PG. Topical tacrolimus (with or without occlusion) seems to be particularly effective for isolated pustular lesions and for peristomal PG.

Box 32-2

Systemic Treatments for Pyoderma Gangrenosum

MEDICATION	DOSAGE
Prednisone	0.5–1.5 mg/kg/day PO
Methylprednisolone (pulsed dose)	500 mg–1 g IV
Dapsone	50–200 mg/day PO
Clofazimine	200–400 mg/day PO
Minocycline	50–100 mg twice daily PO
Cyclosporine	3–6 mg/kg/day PO
Tacrolimus	0.1–0.3 mg/kg PO
Mycophenolate mofetil	500 mg–1 g bid PO
Infliximab	5 mg/kg IV

Intralesional Treatments

Intralesional triamcinolone acetonide (5 to 10 mg/mL) injected twice weekly into the border of a vegetative PG lesion may lead to healing and can be useful in a patient with ulcerative PG if one section of the ulcer is proving recalcitrant to other therapies. Intralesional cyclosporine and tacrolimus have also been reported to be effective in some PG patients.

Systemic Treatments

Because PG is a rare disease, most treatment recommendations are based on experience gained from small series of patients studied.[12] The treatments of PG with suggested doses are listed in Box 32-2. As experience with newer agents is gained, it is likely these recommendations will change. Systemic steroid treatment is probably the initial treatment of choice for most patients with PG. It is important to initiate systemic steroids at a sufficiently high dose to control the disease. Rapid diminution of pain is often recorded by the patient after initiation of therapy and steroids should be continued at this dosage until lesions show evidence of healing, after which gradual tapering of the dose can be undertaken. A steroid-sparing agent should be added as soon as possible as prolonged therapy is anticipated in most patients, as well as bone protective measures to diminish the risk of osteoporosis. Intravenous corticosteroids in pulsed doses have also been used to induce remission, but serious potential adverse effects limit their use to exceptional circumstances. Dapsone has been traditionally used in the treatment of PG and remains a useful drug, particularly when used in conjunction with systemic corticosteroids. Dapsone is generally well tolerated, but hematologic complications (including agranulocytosis, hemolysis and hemolytic anemia, and methhemoglobulinemia) as well as other potentially serious side effects may occur. Other antimicrobial agents reported as successful in the treatment of PG patients include rifampicin, tetracyclines, vancomycin, mezlocillin, clofazimine, and minocycline. These have usually been prescribed in combination with other systemic therapies and seem to work in PG patients by mechanisms other than their antibacterial properties. Most experience has been with clofazimine and minocycline (100 to 200 mg daily). The latter is well tolerated and often allows for a reduction in systemic corticosteroid dosage and appears to prolong remission in some patients.

Cyclosporine is an alternative first-line therapy of PG[13] or may be used in combination with systemic corticosteroids to achieve rapid control of disease. Doses of 3 to 6 mg/kg/day have shown efficacy and continued treatment is usually required for 3 to 4 months. Less risk of serious side effects (such as impairment of renal function and hypertension) is seen at these low doses, but careful monitoring of patients is required and attention should paid to the possibility of other drugs interacting with this medication.

Tacrolimus (FK-506) and mycophenolate mofetil have also been used successfully in the treatment of PG either as monotherapies or in combination with systemic corticosteroids or cyclosporine.[14]

Both drugs cause significant immunosuppression with resultant susceptibility of the patient to infection and malignant disease and can have other potentially serious side effects. Infliximab, an antitumor necrosis factor antibody, has been used successfully to treat patients with inflammatory bowel disease and has been reported to be effective in some patients with PG.[15] Other similar drugs that have been reported to be efficacious in the treatment of patients with PG include etanercept and adalimumab. The role of these agents in the management of PG has yet to be fully defined and susceptibility to reactivation of tuberculosis infection and other significant side effects remain a concern in patients treated with these agents. The use of thalidomide in the treatment of PG has probably been superseded by the development of these agents. Other drugs which have been reported to be helpful in the treatment of PG include azathioprine (thiopurine methyl transferase levels should be checked pre-treatment), colchicine,[16] cyclophosphamide, chlorambucil, and melphalan. These agents can have toxic effects and experience of their efficacy is limited.

Other modalities which have been reported to be useful in the treatment of individual patients or small series of patients with PG include human intravenous immunoglobulin,[17] interferon-α, nicotine,[18] potassium iodide, leukocytapheresis,[19] and plasma exchange. Skin grafting should be avoided if possible because of the risk of inducing new PG lesions at the donor sites, but cultured tissue allografts/autografts and the use of bovine collagen matrix have been reported to be useful in patients in whom the disease is controlled but re-epithelialization incomplete.[20]

The unpredictable nature of PG and its variable aggressiveness in individual patients mean that a flexible approach to treatment is required and the use of therapeutic agents have to be adapted to the patient's physiologic state (childhood, pregnancy, old age). By whichever modality control of PG is achieved, maintenance therapy should be continued until there is complete wound healing. Patients with ulcerative PG have a significant risk of relapse, so long-term follow up is required.

PREVENTION

A patient who has had a history of PG should be advised to avoid trauma to the skin as there is the possibility of precipitating a new lesion (the pathergic phenomenon). If such patients have to undergo surgery, they should have close supervision by a dermatologist of their postoperative course. Patients with a history of aggressive PG may warrant a course of systemic steroids during and for a period (2 weeks or longer) postoperatively to prevent the development of new PG lesions and subcuticular sutures should be used where possible. Patients with a history of PG and Crohn disease who are to have an ileostomy should be warned about the possible development of peristomal PG lesions.

CHAPTER 33

Granuloma Faciale

Darius R. Mehregan
David A. Mehregan

HISTORICAL ASPECTS

EPIDEMIOLOGY

Granuloma faciale[3] occurs predominantly in adult men and women. There is a slight male predominance, and mean age at presentation is 52 years.[4,5] Granuloma faciale can occur in individuals of any race; however, it is more common in Caucasians. The disease presents most commonly with a single lesion on the face, but extra-facial lesions have been described.[6] Patients with multiple lesions have also been reported.[7] A rare mucosal variant has been described as eosinophilic angiocentric fibrosis, which typically involves the upper respiratory tract.[8]

ETIOLOGY AND PATHOGENESIS

The etiology of granuloma faciale is unknown. The disease can be considered a localized chronic fibrosing vasculitis.[9] Immunofluorescence studies have revealed deposition of immunoglobulins and complement factors in the vessel walls consistent with a type III immunologic response, marked by deposition of circulating immune complexes in vascular lumina.[10] However, other authors have described negative results with immunofluorescence.[11]

CLINICAL FINDINGS

Granuloma faciale is characterized by solitary papules, plaques, or nodules. The lesions are typically asymptomatic red, brown, or violaceous plaques that are soft

GRANULOMA FACIALE AT A GLANCE

- Granuloma faciale is an uncommon inflammatory dermatosis characterized clinically by reddish brown papules and plaques primarily involving the face.
- The pathology shows changes of a chronic leukocytoclastic vasculitis with a mixed infiltrate containing eosinophils, extensive perivascular fibrin deposition, and dermal fibrosis.
- Etiology is unknown.

◀ **FIGURE 33-1** Granuloma faciale. Raised edematous plaques on cheek showing prominent follicular ostia.

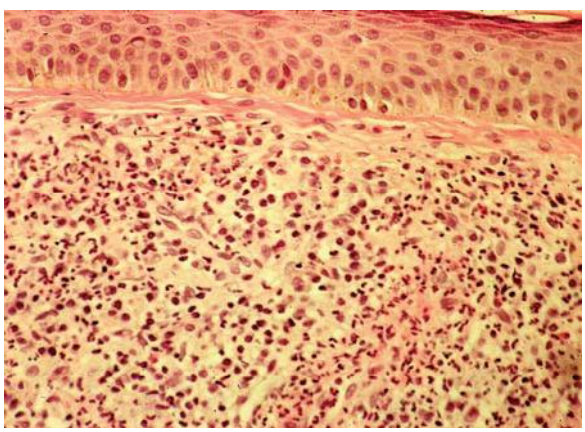
and well circumscribed (Figs. 33-1 and 33-2). Lesions are most common on the face. Sites of predilection include the nose, preauricular area, cheeks, forehead, eyelids, and ears.[4,11] Rarely, patients may present with multiple lesions or lesions on the trunk or extremities. Extra-facial lesions have been reported both as isolated findings and in conjunction with facial lesions. Lesions may be present for weeks or months and tend to follow a chronic course. The plaques typically have a smooth surface and show dilated follicular ostia (see Fig. 33-1). Ulceration is rare. Lesions are typically asymptomatic; however, patients may complain of tenderness, burning, or pruritus.[4] Photo-exacerbation of lesions has been reported.[12]

LABORATORY FINDINGS

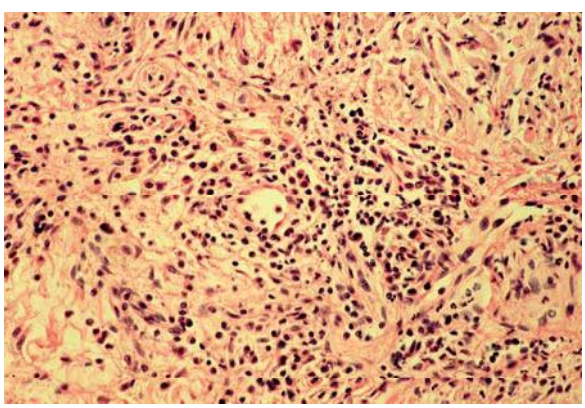
An extensive laboratory evaluation is not required. Peripheral blood eosinophilia is occasionally detected.

▲ **FIGURE 33-2** Granuloma faciale. Single plaque on the nose showing prominent follicular ostia and central dell.

The diagnosis may be established by a combination of clinical findings and confirmatory tissue biopsy results. A punch biopsy that includes the full thickness of the dermis is recommended. Histologic examination shows a normal-appearing epidermis, which may be separated from the underlying inflammatory infiltrate by a narrow grenz zone (Fig. 33-3). Within the dermis is a dense and diffuse infiltrate of lymphocytes, plasma cells, eosinophils, and neutrophils with evidence of leukocytoclasis (Fig. 33-4). The inflammatory infiltrate surrounds the blood vessels, which show evidence of fibrin deposition. In later stages, the perivascular fibrin deposition becomes extensive and dominates the histologic picture. Deposition of hemosiderin may contribute to the brown color seen clinically. Electron microscopic studies confirm the presence of an extensive eosinophilic infiltrate with Charcot-Leyden crystals and numerous histiocytes filled with lysosomal vesicles; however, cases with few eosinophils in the infiltrate have also been described.[13] Immunoglobulins, fibrin, and complement can be found deposited along the dermo-epidermal junction in a granular pattern and around blood vessels by direct immunofluorescence.[10]



▲ **FIGURE 33-3** Granuloma faciale. This low-power histologic section shows a mixed infiltrate of lymphocytes, histiocytes, neutrophils, plasma cells, and eosinophils. There is sparing of a narrow grenz zone between the inflammatory infiltrate and the overlying epidermis.



▲ **FIGURE 33-4** Granuloma faciale. This histologic section shows perivascular deposition of fibrin and a mixed infiltrate of lymphocytes, neutrophils, and eosinophils. There are scattered macrophages containing hemosiderin.

Differential Diagnosis of Granuloma Faciale

Most Likely

- Face
  - Sarcoidosis
  - Granuloma annulare
  - Lymphocytic infiltration of Jessner
  - Rosacea
- Extrafacial
  - Erythema elevatum diutinum

Consider

- Face
  - Discoid lupus erythematosus
  - Lymphoma cutis
  - Angiolymphoid hyperplasia with eosinophilia
  - Tinea faciei
  - Basal cell carcinoma
  - Xanthogranuloma
  - Mastocytoma
- Extrafacial
  - Granuloma annulare
  - Benign lymphocytic infiltrate of Jessner
  - Fixed drug eruption

Always Rule Out

- Face
  - Discoid lupus erythematosus
- Trunk
  - Erythema elevatum diutinum

Box 33-2

Treatments for Granuloma Faciale

	TOPICAL	PHYSICAL	SYSTEMIC
First-line therapy	Topical corticosteroids	Cryotherapy Intralesional steroids Pulsed dye laser	Dapsone, 50–100 mg/day
Second-line therapy	Topical tacrolimus ointment	Surgical excision	

DIFFERENTIAL DIAGNOSIS

The clinical differential diagnosis for granuloma faciale includes discoid lupus erythematosus, polymorphous light eruption, fixed drug eruption, benign lymphocytic infiltrate of Jessner, lymphoma cutis, pseudo-lymphoma, sarcoidosis, granuloma annulare, tinea faciei, insect bite reaction, xanthogranuloma, mastocytoma, basal cell carcinoma, Langerhans cell histiocytosis, and rosacea (Box 33-1). The diagnosis can be reliably made by analysis of a punch biopsy specimen. Absence of serologic evidence of lupus erythematosus helps to differentiate these lesions from the lesions of discoid lupus erythematosus.

The primary histologic differential diagnosis is erythema elevatum diutinum (EED). Both diseases represent chronic forms of fibrosing small vessel vasculitis and may be related. However, there are several clinical and histologic differences. EED is characterized by multiple lesions, primarily located on extensor surfaces of the extremities in a symmetric acral distribution. The trunk and face are typically spared in EED. Histologically, both show a chronic fibrosing vasculitis.[14] However, a grenz zone of normal collagen beneath the epidermis is not typical of EED. EED may be associated with systemic conditions, primarily monoclonal gammopathies, and shows an excellent response to dapsone.[15,16] The histologic and clinical differential may also include angiolymphoid hyperplasia with eosinophilia. However, the lesions of angiolymphoid hyperplasia with eosinophilia contain blood vessels with prominent "hobnail" endothelial cells that protrude into the vascular lumina rather than perivascular fibrin deposition. One case of tinea faciei caused by *Trichophyton rubrum* has been described with clinical and histologic changes consistent with granuloma faciale.[17]

COMPLICATIONS

Granuloma faciale is rarely associated with systemic toxicity.[18]

PROGNOSIS AND CLINICAL COURSE

Lesions tend to be chronic and resistant to treatment.

TREATMENT

A variety of medical and surgical therapies have been used in the treatment of granuloma faciale (Box 33-2). Because of the small number of patients involved, randomized trials to evaluate these treatments are lacking. Resistance to therapy and cosmetic complications should be discussed with the patient before initiation of therapy. Topical and intralesional steroids have been administered with modest improvement.[4,19] Cryosurgery has been applied with effective results.[20,21] Because the disease is known to be a variant of chronic leukocytoclastic vasculitis, dapsone 25 to 100 mg/day has been used with benefit in a number of patients.[22,23] Topical tacrolimus ointment 0.1 percent also has been used with success.[24]

Surgical excision may be an option for small lesions. Lesions of granuloma faciale have been treated with a variety of medical lasers. In one study, the Candela Vbeam pulsed dye laser at 595 nm provided resolution in two of four patients.[25] A variety of pulsed dye lasers have been used with similar results.[26–29] A carbon dioxide laser has also been applied with varying success.[30] The use of an argon laser resulted in total resolution of the granuloma faciale with subsequent scarring. The lesions in two patients were reported to respond to the Laserscope potassium-titanyl-phosphate 532-nm laser in combination with tacrolimus ointment 0.1 percent.[31]

CHAPTER 34

Sub-Corneal Pustular Dermatosis (Sneddon-Wilkinson Disease)

Franz Trautinger
Herbert Hönigsmann

Sub-corneal pustular dermatosis (SPD) is a rare, chronic, recurrent, pustular eruption characterized histopathologically by sub-corneal pustules that contain abundant neutrophils. The condition was originally described in 1956 by Sneddon and Wilkinson,[1] who separated SPD from other previously unclassified pustular eruptions. Until 1966, when the first comprehensive review appeared, more than 130 cases had been reported, but not all fulfilled the clinical and histopathologic criteria required for this diagnosis.[2] A considerable number of additional cases have since appeared in the literature, and a sub-type with intraepidermal deposits of immunoglobulin A (IgA) directed against desmocollin 1 has been recognized.[3] Today, these cases are usually classified as SPD-type IgA pemphigus and it is a matter of debate whether the finding of epidermal IgA deposits define a subset of SPD or a new pemphigus variant that is otherwise indistinguishable from "classic" SPD.

EPIDEMIOLOGY

There is no racial predilection. Most of the reported cases have been in whites, but the disease has also been observed in Africans, Japanese, and Chinese. The condition is more common in women and in persons older than 40 years of age, but SPD may occur at any age.[2] A pustular eruption that is clinically and histologically similar to the human disease, which also responds to dapsone treatment, has been observed in dogs.[4]

ETIOLOGY AND PATHOGENESIS

The cause of SPD is unknown. Cultures of the pustules consistently do not reveal bacterial growth. The role of trigger mechanisms such as preceding or concomitant infections, though repeatedly discussed, has remained speculative. Immunologic mechanisms have been implicated in the pathogenesis, and in a subset of patients, whose disease clinically resembled SPD, intraepidermal IgA deposits have been detected. Some of these patients also had circulating IgA antibodies against the same sites within the epidermis. Desmocollin 1 has been described as an autoantigen in these cases and the disease has been classified as a rare pemphigus variant (SPD-type IgA pemphigus).[3,5,6] The pathogenetic role of these antibodies is still to be demonstrated.[7]

The occasional association of SPD with certain other diseases may represent more than a mere coincidence. Increased serum IgA has been detected in a number of patients, and the disease has been reported to occur in cases of IgA-paraproteinemia and IgA multiple myeloma.[8–11] In addition, SPD is associated with pyoderma gangrenosum,[12,13] ulcerative colitis,[14] and Crohn disease.[15] On the other hand, pyoderma gangrenosum is not uncommon in patients with inflammatory bowel disease, paraproteinemia, and myeloma (see Chap. 32). Whether or not the co-existence of these conditions reflects common pathogenetic mechanisms remains to be clarified, but an additional common denominator linking these disorders is their response to sulfone and sulfonamide therapy.

Further associations reported to date include IgG paraproteinemia,[16,17] CD30+ anaplastic large-cell lymphoma,[18] non-small cell lung cancer,[19] apudoma,[20] rheumatoid arthritis,[21,22] hyperthyroidism,[23] and mycoplasma pneumoniae infection.[24]

CLINICAL FINDINGS

The primary lesions are small, discrete, flaccid pustules or vesicles that rapidly turn pustular and usually arise in crops within a few hours on clinically normal or slightly erythematous skin (Fig. 34-1). In dependent regions, pus characteristically accumulates in the lower half of the pustule (see Fig. 34-1B); as the pustules usually have the tendency to coalesce, they often, but not always, form annular, circinate, or bizarre serpiginous patterns. After a few days, the pustules rupture and dry up to form thin, superficial scales and crusts, closely resembling impetigo. Peripheral spreading and central healing leave polycyclic, erythematous areas in which new pustules arise as others disappear (see Fig. 34-1A). There is no atrophy or scarring, but an occasional brownish hyperpigmentation may mark previously affected sites. Variable intervals of quiescence, lasting from a few days to several weeks, may be followed by the sudden development of new lesions. The eruptions tend to occur symmetrically, affecting mainly the axillae, groin, abdomen, submammary areas, and the flexor aspects of the limbs. In rare cases, the face,[25] palms, and soles[26] may be involved. Scalp and mucous membranes invariably remain free of lesions. Episodic itching and burning represent subjective symptoms in a small number of patients, but there are no systemic symptoms or abnormalities in routine laboratory parameters.

HISTOPATHOLOGY

The hallmark of the disease is a strictly sub-corneal pustule filled with polymorphonuclear leukocytes,[1] with only an occasional eosinophil.[2] Acantholysis is not involved in pustule formation, but a few acantholytic cells may be found in older lesions (secondary acantholysis). Surprisingly, the epidermal layers underlying the pustule exhibit little pathology, and, apart from a variable number of migrating leukocytes, there is little evidence of spongiosis or cytolytic damage to the epidermal cells. The dermis contains a perivascular infiltrate com-

SUB-CORNEAL PUSTULAR DERMATOSIS AT A GLANCE

- A rare condition with worldwide occurrence.
- A chronic recurrent disorder with a benign course, frequently associated with various forms of immune dysfunction [most commonly immunoglobulin A (IgA) monoclonal gammopathy]. Occurrence of intraepidermal deposits of IgA indicate a relationship with IgA pemphigus.
- Crops of flaccid, coalescing pustules; often in annular or serpiginous patterns.
- Usually distributed symmetrically in the axillae, groins, submammary, the flexor aspects of the limbs, and on the abdomen.
- Pathology: Sub-corneal pustules filled with polymorphonuclear leukocytes.

▲ **FIGURE 34-1** Sub-corneal pustular dermatosis. **A.** Typical distribution. Note accentuated involvement of groin and abdomen. Hyperpigmented macules mark previously affected areas. **B.** Close-up showing coalescence of pustules, which form annular and circinate patterns. Lesions of different developmental stages are seen side by side. At the lower right, newly formed pustule with characteristic hypopyon formation.

posed of neutrophils and rarely mononuclear cells and eosinophils (Fig. 34-2).

In a subset of patients, direct immunofluorescence reveals intraepidermal IgA deposits.[16] In these cases, IgA is usually present in a pemphigus-like intercellular pattern, either in the entire epidermis or confined to its upper layers. By indirect immunofluorescence, circulating IgA antibodies directed against the intercellular substance of the epidermis were detected in single cases. Today these cases are usually diagnosed as SPD-type IgA pemphigus (see Chap. 52).

Ultrastructural examination of paralesional skin has shown cytolysis of keratinocytes confined to the granular layer;[27] the formation of pustules has been regarded as a secondary event caused by invasion and sub-corneal accumulation of leukocytes.

DIFFERENTIAL DIAGNOSIS (Box 34-1)

An early localized eruption of SPD may be clinically and histologically indistinguishable from impetigo, but the distribution pattern of the lesions, the absence of bacteria in the pustules, the ineffectiveness of topical and systemic antibiotic therapy suggest the correct diagnosis. Dermatitis herpetiformis is also highly pruritic, affecting primarily the extensor surfaces and is sub-epidermal with IgA.

Pemphigus foliaceus has acantholysis and atypical immunofluorescence pattern. Generalized pustular psoriasis (von Zumbusch's type) presents with systemic symptoms (fever, malaise, leukocytosis), and spongiform pustules within the epidermis. The necrolytic migratory eruption of glucagonoma syndrome can be differentiated by its distribution, lack of actual pustule formation, erosions of the lips and oral mucosa, and, histologically, necrobiosis of the upper epidermis. Biochemically, excess levels of glucagon are diagnostic. Acute generalized pustulosis is widespread with predilection of the distal parts of the extremities, and histologically may exhibit leukocytoclastic vasculitis.

Box 34-1

Differential Diagnosis of Sub-Corneal Pustular Dermatosis

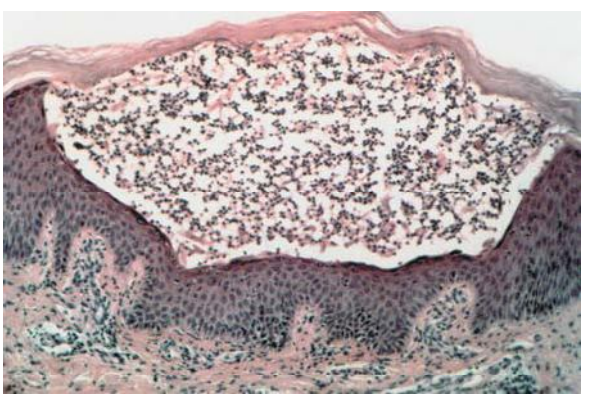
- Bacterial impetigo
- Dermatitis herpetiformis
- Pemphigus foliaceus
- Immunoglobulin A pemphigus/intraepidermal immunoglobulin A pustulosis
- Pustular psoriasis
- Necrolytic migratory erythema
- Acute generalized exanthematous pustulosis

PROGNOSIS AND CLINICAL COURSE

SPD is a benign condition. Without treatment, attacks recur over many years and remissions are variable, lasting from a few days to several weeks. Despite the protracted course the general health of the patient is usually not impaired. However, one of our own cases who had SPD, pyoderma gangrenosum, and IgA paraproteinemia of more than 20 years' duration died of septicemia with staphylococcal abscesses in the lungs, liver, and spleen.

TREATMENT

The drugs of choice are the sulfones (Box 34-2), such as dapsone in a dose of 50 to 150 mg daily. The response is slower and less dramatic than in dermatitis herpetiformis, but complete remission is most often obtained. In some patients, the treatment may be withdrawn after several months, although in others it may have to be continued for years; the minimal effective dose to suppress disease should be determined in these patients. Sulfapyridine (1.0 to 3.0 g daily) is also beneficial; systemic corticosteroids are less effective, although they can suppress generalized flares when given in high doses. Retinoids, phototherapy, and ultraviolet B have been reported to induce remissions, but this awaits confirmation.[28–30] Responses to colchicine, cyclosporine, and topical tacalcitol (1α-24R-dihydroxyvitamin D_3) have been anecdotally re-



▲ **FIGURE 34-2** Sub-corneal pustular dermatosis. Strictly sub-corneal pustule filled with polymorphonuclear leukocytes, with the underlying epidermal layers exhibiting only slight edema and some migrating leukocytes. There is a mild inflammatory infiltrate around dermal blood vessels.

CHAPTER 35

Eosinophils in Cutaneous Diseases

Kristin M. Leiferman
Margot S. Peters

Peripheral blood eosinophilia and/or infiltration of tissues by eosinophils occur in a variety of common and unusual diseases, including those of infectious, immunologic, and neoplastic etiology. Eosinophils are conspicuous in tissue sections stained with hematoxylin and eosin because of their intense avidity for eosin dye. Eosinophils have myriad phlogistic activities that implicate them in disease.[1–3] Common dermatoses associated with eosinophils in lesional tissues include arthropod bites and drug eruptions. Parasitic infections, especially those due to ectoparasites and helminths, typically have a marked eosinophilic host response.[4,5] Autoimmune blistering diseases, such as bullous pemphigoid and the various forms of pemphigus, often have prominent eosinophilic infiltrates, including histologic presentation as eosinophilic spongiosis.[6,7] Infiltration of eosinophils in the subcutaneous tissues (eosinophilic panniculitis) does not represent a specific diagnosis but rather is a manifestation of a diverse selection of entities, including erythema nodosum.[8,9] Eosinophils may be found in Langerhans cell histiocytosis, cutaneous neoplasms, and lymphoproliferative malignancies.[10] Although eosinophils constitute one of the histologic features in numerous cutaneous diseases, they represent a criterion for histologic diagnosis in relatively few entities (Table 35-1). They also play a role in certain categories of clinical reactions, particularly those characterized by edema.[11]

HYPEREOSINOPHILIC SYNDROMES

History

Epidemiology

The hypereosinophilic syndromes (HES) occur worldwide and span all age groups. Over 90 percent of patients with myeloproliferative HES and the mutant gene Fip1-like 1/platelet-derived growth factor receptor-α (*FIP1L1-PDGFRA*) are men, but lymphocytic HES shows equal gender distribution. The relative frequencies of the sub-types are unknown, although up to 25 percent of HES patients may have lymphocytic HES. Rare familial cases have been reported. A mini-epidemic has been observed over the last decade in eosinophilic esophagitis, a subset of overlap HES with organ-restricted disease, with prevalence estimates as high as 1:2500 among children and 1:4000 among adults.[25,26]

Etiology

Eosinophils are implicated as the cause of most end-organ damage in all HES subtypes. Clinical improvement usually parallels a decrease in eosinophil count. Patients with lymphocytic HES have abnormal T-cell clones with unusual surface phenotypes, including $CD3^+CD4^-CD8^-$ and $CD3^-CD4^+$. These T cells display activation markers, such as CD25, and secrete T helper 2 cytokines, including high levels of interleukin 5 (IL-5).[27] An 800-kilobase deletion on chromosome band 4q12 that codes for a tyrosine kinase has been found in myeloproliferative HES.[28] Patients with the *FIP1L1-PDGFRA* gene mutation, but without clinical manifestations of systemic mastocytosis, have elevated serum tryptase levels and increased atypical spindle-shaped mast cells in bone marrow.[29,30] Although they do not exhibit all its immunologic markers, these patients satisfy criteria for mastocytosis but are considered to form a distinct subset of HES, with cardiomyopathy and endomyocardial fibrosis, that responds to imatinib. The *FIP1L1-PDGFRA* gene is detected in mast cells, eosinophils, neutrophils, and mononuclear cells. Many HES patients have marked neutrophilia, likely due to the aberrant gene in the neutrophil lineage. Thus, alteration of several cell lines probably contributes to the pathogenesis of myeloproliferative HES. Multiple other chromosomal abnormalities have been identified in myeloproliferative HES, including translocations, partial and complete chromosomal deletions, and trisomies 8, 15, and 21.[31] The etiology of the other HES variants is not well understood, although patients with episodic angioedema and eosinophilia [Gleich syndrome[32]; see Episodic Angioedema Associated with Eosinophilia (Gleich Syndrome)] and the nodules, eosinophilia, rheumatism, dermatitis, and swelling (NERDS) syndrome[33] have developed T-cell clones.

Clinical Findings and Course

Patients satisfying HES diagnostic criteria (Table 35-2) present with signs and symptoms related to the organ systems infiltrated by eosinophils. HES may

EOSINOPHILS IN CUTANEOUS DISEASES

AT A GLANCE

- Eosinophils may be seen in skin biopsy specimens from a broad range of cutaneous diseases but are not pathognomonic for any dermatosis.
- Eosinophils are an important component of the characteristic histologic pattern in a limited number of diseases, including the following:
  - Hypereosinophilic syndromes
  - Wells syndrome (eosinophilic cellulitis)
  - Angiolymphoid hyperplasia with eosinophilia
  - Kimura disease
  - Eosinophilic pustular folliculitis
  - Granuloma faciale
  - Eosinophilic ulcer of the oral mucosa
- Clinical reaction patterns with eosinophil involvement include diseases in which eosinophils probably play a pathogenic role and are a component of the histologic pattern but are not important for diagnosis.
- Evidence for involvement of eosinophils in cutaneous diseases is provided by observation of intact eosinophils in lesional tissue sections and/or by immunostains for their toxic granule proteins, which are deposited in tissues.

present with cutaneous disease,[34] and pruritic erythematous macules, papules, plaques, wheals, or nodules[35] are present in over 50 percent of patients. Lesions may involve the trunk and extremities. Urticaria and angioedema occur in all HES sub-types and are characteristic of certain variant sub-types. Erythema annulare centrifugum,[36–38] purpuric papules,[39] livedo reticularis, and Wells syndrome (eosinophilic cellulitis)[40,41] also may be seen in patients with HES.

Lymphocytic HES commonly is associated with severe pruritus, eczema, erythroderma, urticaria, and angioedema, as well as lymphadenopathy and, rarely, endomyocardial fibrosis. In myeloproliferative HES, the usual presenting complex includes fever, weight loss, fatigue, malaise, skin lesions, and hepatosplenomegaly.[42] Mucosal ulcers of the oropharynx or anogenital region (Fig. 35-1) portend an aggressive clinical course; death is likely within 2 years of presentation if the disorder is untreated.[43,44] Cardiac disease occurs frequently. Eosinophils adhere to endocardium and release granule proteins onto endothelial cells, thrombus formation follows, and, finally, subendocardial fibrosis with restrictive cardiomyopathy occurs. Mitral or tricuspid valvular insufficiency results from tethering of chordae tendineae. Cardiac abnormalities that are essentially identical to those of HES but are confined to the in-

HYPER-EOSINOPHILIC SYNDROMES

AT A GLANCE

- Spectrum of entities defined by inclusive criteria (Table 35-2).
- Cutaneous lesions are common and may be the presenting sign.
- Two major hypereosinophilic syndromes (HES) sub-types and several variants.
  - Lymphocytic characterized by T-cell clones that produce interleukin 5.
  - Myeloproliferative associated with a deletion on chromosome 4 that produces a tyrosine kinase fusion gene Fip1-like 1/platelet-derived growth factor receptor-α.
    - Responsive to imatinib
    - Severely debilitating mucosal ulcers portend a grim prognosis unless HES is treated
    - Overlap with mastocytosis
  - Other variant HES sub-types may evolve into lymphocytic HES.
    - Familial
    - Organ-restricted
    - Associated with specific disorders such as Churg-Strauss syndrome
    - Undefined with benign, complex, and episodic presentations
- Associated embolic events constitute a medical emergency.
- Eosinophilic endomyocardial disease occurs in HES and in patients with prolonged peripheral blood eosinophilia from any cause.

TABLE 35-2
Diagnostic Criteria for Hypereosinophilic Syndromes

- Peripheral blood eosinophilia of at least 1500 eosinophils/μL
  - Longer than 6 mo or
  - Less than 6 mo with evidence of organ damage
- Signs and symptoms of multiorgan involvement
- No evidence of parasitic or allergic disease or other known causes of peripheral blood eosinophilia

tramural regions can occur without appreciable peripheral blood eosinophilia.[45,46] Splinter hemorrhages and/or nail fold infarcts may herald the onset of thromboembolic disease. The central and peripheral nervous system, lungs, and, rarely, kidneys may be affected. In contrast to myeloproliferative HES, lymphocytic HES generally follows a benign course, and T-cell clones can remain stable for years. Patients should be observed closely and regarded as having pre-malignant or malignant T-cell proliferation,[27] because the disease may evolve into lymphoma.

Patients with myeloproliferative HES frequently present with clinical features resembling those of chronic myelogenous leukemia and sometimes are regarded as having chronic eosinophilic leukemia. Although the disease may evolve into frank leukemia, the relatively mature nature of the eosinophils and lack of evidence for clonal expansion generally preclude such classification. During the decade or more after diagnosis, HES may evolve into acute leukemia and, less commonly, has been associated with B-cell lymphomas.

Churg-Strauss syndrome (see Chap. 165) is a variant HES sub-type. Other variant HES types include Gleich syndrome[32] [see Episodic Angioedema Associated with Eosinophilia (Gleich Syndrome)], in which eosinophil counts fluctuate with extreme angioedema. The overall 5-year survival rate for HES patients is 80 percent; congestive heart failure from the restrictive cardiomyopathy of eosinophilic endomyocardial disease is a major cause of death, followed by sepsis.

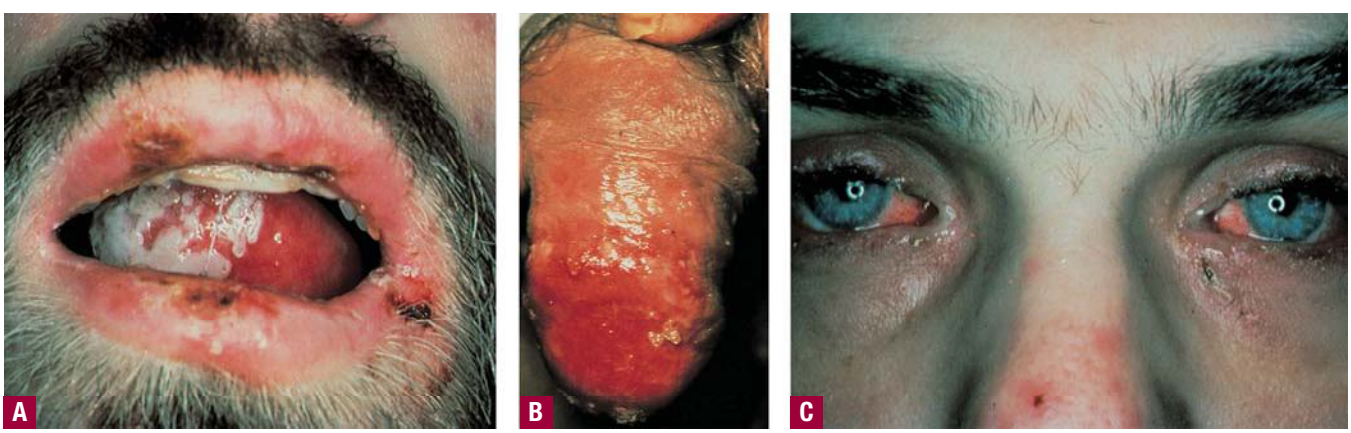
Laboratory Tests

A key criterion for diagnosis is marked, prolonged peripheral blood eosinophilia (see Table 35-2). Other causes of eosinophilia, including allergic and parasitic diseases, should be excluded. Tests to detect organ involvement, particularly measurement of liver enzyme levels, are important. Because eosinophilic endomyocardial disease can develop in any patient with prolonged peripheral blood eosinophilia, patients should undergo periodic echocardiography. Increased serum levels of immunoglobulin E (IgE) are often present in lymphoproliferative HES, and levels of vitamin B_{12} and tryptase are increased in myeloproliferative HES. The Chic2 fluorescent in situ hybridization assay detects the deletion that produces the *FIP1L1-PDGFRA* gene product and should be performed, because patients with this mutation respond to treatment with imatinib.[29,47] Alternatively, the mutant gene can be detected by a polymerase chain reaction assay. Both tests are available commercially. In patients who lack the fusion gene, testing for other clonal cytogenetic abnormalities or abnormal clonal T-cell populations is warranted. Cytoflow of peripheral blood lymphocytes and immunophenotyping of tissue lymphocytes should be performed for the diagnosis of lymphocytic HES and repeated periodically to look for transformation from a variant HES type to lymphocytic HES or to T-cell lymphoma.

The cutaneous histopathologic features of HES vary with the type of lesion. Skin biopsy specimens from urticarial lesions resemble idiopathic urticaria, with generally mild, non-specific perivascular and interstitial infiltration of lymphocytes, eosinophils, and, occasionally, neutrophils. Immunostaining reveals extensive deposition of eosinophil granule proteins in the absence of intact eosinophils in episodic angioedema with eosinophilia and HES with mucosal ulcers, and in synovial tissues in NERDS. Other than in Churg-Strauss syndrome, vasculitis is only rarely associated with HES.[39]

Differential Diagnosis

Clinically, parasitic infections and infestations may closely resemble HES. A history of travel to endemic areas or certain dietary exposure implicates helminthiasis. Along with eosinophilia, total serum IgE levels higher than 500 IU/mL commonly are found in helminthic infections. Examination of stool samples for ova and parasites and serologic testing for *Strongyloides* antibodies should be performed. In patients with isolated urticarial plaques with or without angioedema, the differential diagnosis includes urticaria, but demonstration of multiorgan involvement supports HES. HES with episodic angioedema may resemble hereditary angioedema clinically, although patients with hereditary angioedema often have a family history of the disease, rarely have the markedly elevated eosinophil counts that characterize HES, and may be distinguished by complement abnormalities. Pruritic eczematoid lesions of lymphocytic HES may resemble those of atopic dermatitis, contact dermatitis, drug reaction,



▲ **FIGURE 35-1** Hypereosinophilic syndrome. Mucosal erosions and ulcers of the mouth (**A**) and glans penis (**B**); conjunctival irritation (**C**).

fungal infection, and T-cell lymphoma. There are multiple diseases in the differential diagnosis of patients with orogenital ulcers,[44] including those associated with thrombosis, such as Behçet syndrome, Crohn disease, ulcerative colitis, and Reiter syndrome. Others considerations are recurrent aphthous stomatitis, immunobullous diseases, erythema multiforme, lichen planus, herpes simplex infection, and syphilis.

Treatment

The goal of treatment is to relieve symptoms and improve organ function while keeping peripheral blood eosinophils at 1000 to 2000/μL and minimizing treatment side effects (Fig. 35-2).[24] Myeloproliferative HES is very responsive to imatinib. In patients with the mutant gene *FIP1L1-PDGFRA*, administration of imatinib mesylate is indicated and usually induces hematologic remission, but endomyocardial disease may worsen during the first several days of treatment. Troponin levels should be monitored before and during imatinib therapy. To improve cardiac function, glucocorticoids should be given before and with initiation of imatinib therapy.[12,38] Imatinib resistance can develop.[48,49] In the absence of the gene mutation, after *Strongyloides* infection has been excluded,[50] first-line therapy is prednisone. Approximately 70 percent of patients will respond, with peripheral eosinophil counts returning to normal. Patients for whom glucocorticoid monotherapy fails have a worse prognosis generally; in such cases, or when long-term side effects become problematic, other treatments should be used. Patients who have features of myeloproliferative HES but who lack *FIP1L1-PDGFRA* still may respond to imatinib.[22] Interferon-α (IFN-α) has been beneficial in treating myeloid and lymphocytic HES.[51] In one patient, loss of the *FIP1L1–PDGFRA* mutation after several years of IFN-α therapy was associated with complete remission.[52] Other treatments with reported benefit include hydroxyurea, dapsone, vincristine sulfate, cyclophosphamide, methotrexate, 6-thioguanine, 2-chlorodeoxyadenosine and cytarabine combination therapy, pulsed chlorambucil, etoposide, cyclosporine, intravenous immunoglobulin, alemtuzumab, and psoralen plus ultraviolet A phototherapy.[53] Extracorporeal photopheresis alone or in combination with IFN-α or other therapies, as well as bone marrow and peripheral blood stem cell allogeneic transplantation,[54,55] represent additional options. Two monoclonal antibodies against human IL-5 have been associated with clinical improvement and reductions in peripheral blood and dermal eosinophils, particularly in patients with lymphocytic HES.[56]

WELLS SYNDROME

History

Epidemiology

Wells syndrome is primarily a disease of adults, but approximately 30 pediatric patients have been reported.[57,59–69] Familial eosinophilic cellulitis has been described.[70] The disease has no gender predilection.

Etiology

Whether Wells syndrome is a specific entity that is triggered by factors including underlying disease, infection, and drugs, or whether it is merely a reaction pattern may be difficult to discern from some of the reported cases and in practice.[71] Association of eosinophilic cellulitis with a range of disorders (Table 35-3), including arthropod bites,[60,66,72] myeloproliferative disease,[72] colon cancer,[73] reaction to thimerosal-containing vaccination,[74] Churg-Strauss syndrome,[65] hypereosinophilic syndromes,[40,41] dermographism,[75] onchocerciasis,[61] herpes simplex infection,[76] immunobullous disease,[60,77] and drug reactions[78,79] suggests that it is a reactive or allergic hypersensitivity phenomenon, although the pathogenesis is unknown.[80]

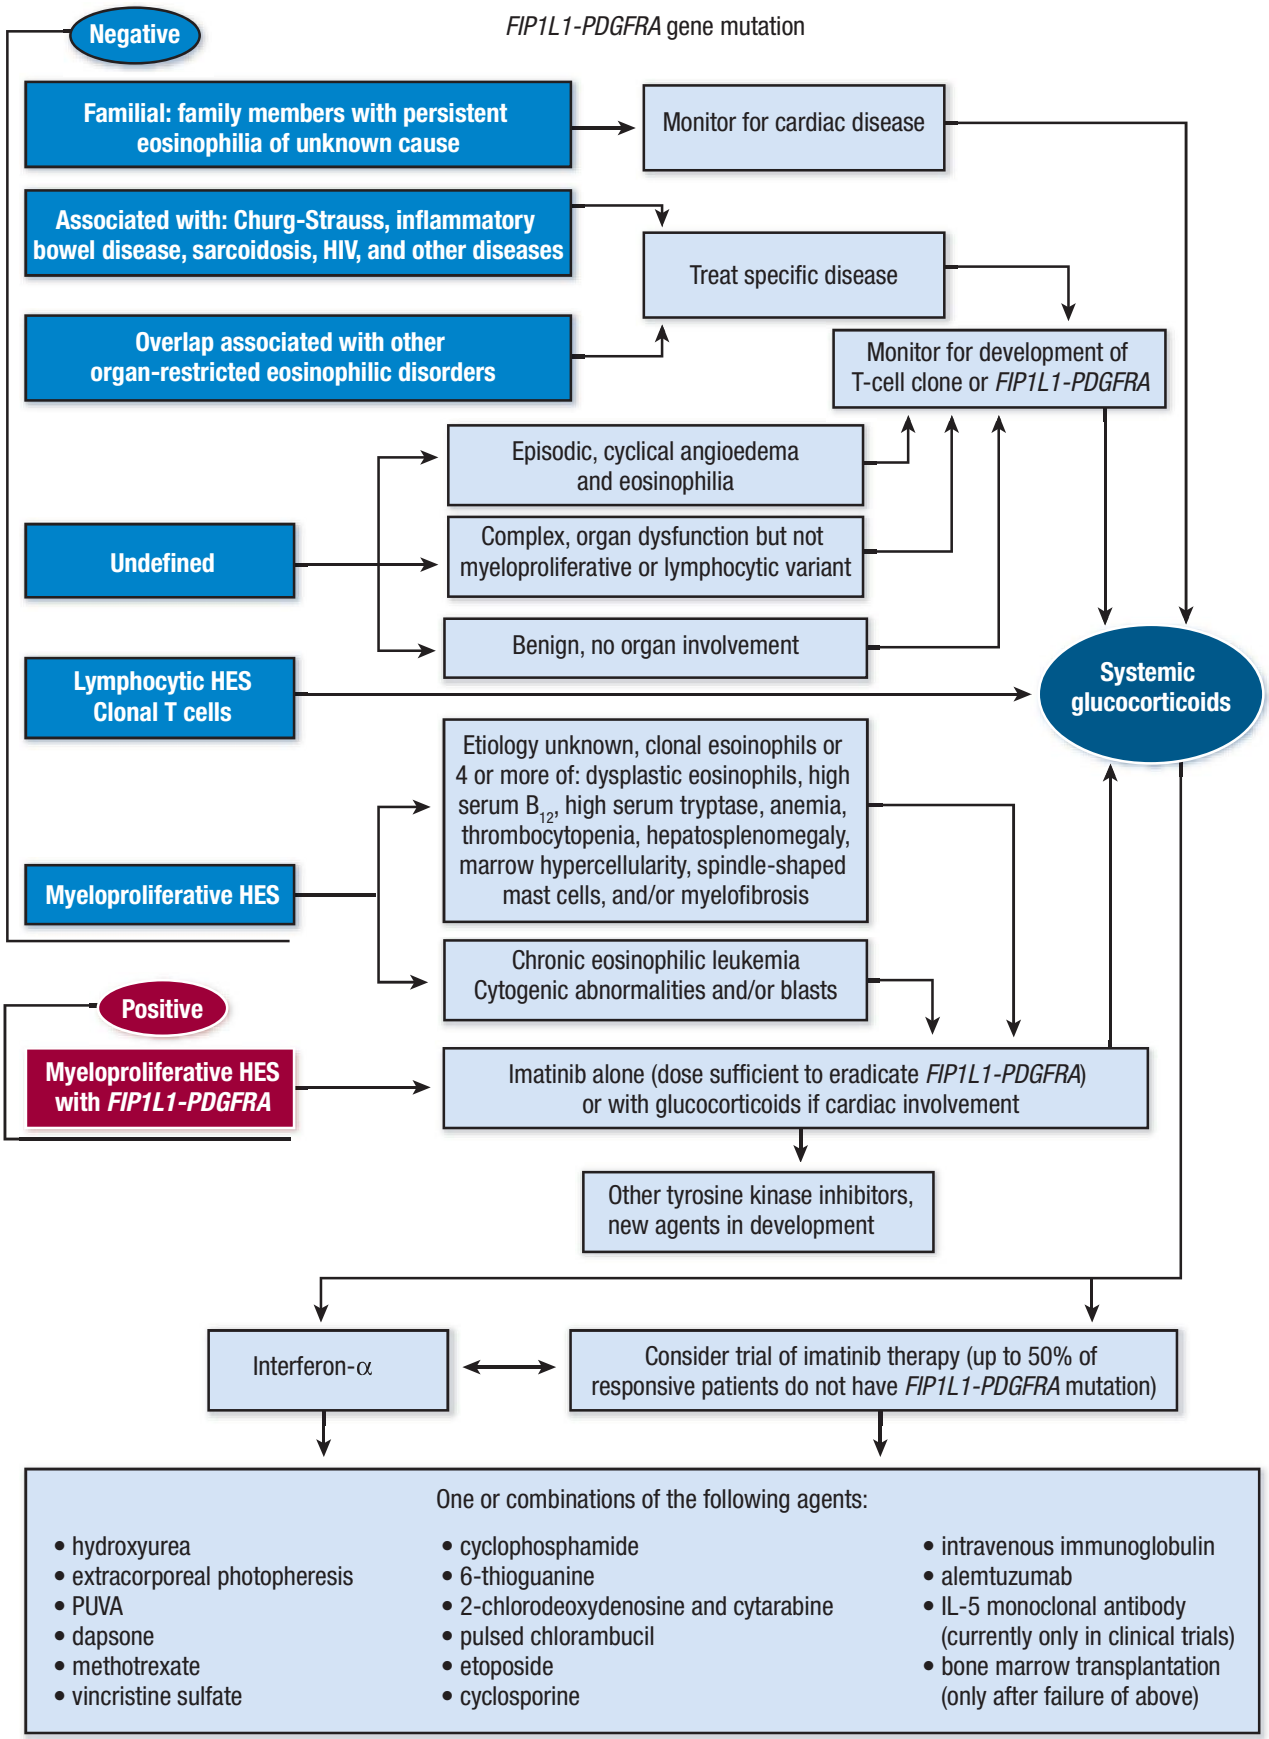
Deposition of toxic granule proteins in lesional tissues, revealed by immunofluorescence testing, provides evidence that eosinophil degranulation contributes to flame figure formation in Wells syndrome.[68] Indeed, Wells and Smith postulated that infiltration of phagocytic histiocytes between collagen bundles may be a response to collagen damage induced by eosinophil cytotoxicity.[60] The severity of Wells syndrome has been correlated with serum levels of IL-5 and eosinophil cationic protein,[81] and IL-5 is implicated in the development of hereditary eosinophilic cellulitis.[70]

Clinical Findings and Course

Cutaneous edema was the common clinical thread in the first four cases reported by Wells.[57] After prodromal burning or itching, lesions begin with erythema and edema (Fig. 35-3A), sometimes in the form of annular or arcuate plaques or nodules. Over a period of days, they evolve into large edematous plaques with violaceous borders. Bullae may develop. Individual lesions gradually change from bright red to brown-red and then to blue-gray or greenish gray, resembling morphea (Fig. 35-3B). Less common clinical presentations include papules, vesicles (Fig. 35-4), and hemorrhagic bullae. The cutaneous lesions may be single or multiple and may be located at any site, but typically involve the extremities and less often the trunk. The most frequent systemic complaint in patients with Wells syndrome is malaise; fever occurs in a minority of cases. Lesions resolve without scarring, usually within weeks to months, but multiple recurrences are common.

WELLS SYNDROME (EOSINOPHILIC CELLULITIS) AT A GLANCE

- Single or multiple lesions commonly located on the extremities or trunk.
- Lesions may be painful or pruritic.
- Sometimes associated with general malaise but only uncommonly with fever.
- Edematous and erythematous lesions evolve into plaques with violaceous borders.
- Blisters may be a prominent feature.
- Individual lesions persist for weeks and gradually change from red to blue-gray or greenish gray, resembling morphea.
- Multiple recurrences.
- Peripheral blood eosinophilia common.
- Histologic pattern characterized by dermal infiltration with eosinophils, and flame figures surrounded by histiocytes.
- Systemic glucocorticoids usually beneficial.



▲ **FIGURE 35-2** Hypereosinophilic syndromes (HES): classification and treatment. *FIP1L1-PDGFRA* = Fip1-like 1/platelet-derived growth factor receptor-α; HIV = human immunodeficiency virus; IL-5 = interleukin 5; PUVA = psoralen plus ultraviolet A phototherapy. - Hypereosinophilic syndromes
- Immunobullous diseases
- Mastocytoma
- Myeloproliferative disease
- Onchocerciasis
- Vaccination containing thimerosal
- Tinea
- Toxocariasis
- Urticaria

Laboratory Tests and Histopathology

Peripheral blood eosinophilia is observed in approximately 50 percent of patients.[77] Skin lesions are characterized histologically by diffuse dermal infiltration with eosinophils, histiocytes, and foci of amorphous and/or granular material associated with connective tissue fibers, which Wells termed *flame figures*.[57] In the early stages, there also is dermal edema. Later, histiocytes palisade around flame figures. In addition to eight patients with the syndrome, the 1979 report of Wells and Smith includes nine patients with the typical histologic features of eosinophilic cellulitis but in association with a variety of clinical diagnoses, including pemphigoid, eczema, and tinea.[60] This and subsequent reports of flame figures in lesions from patients with a wide spectrum of diseases (see Table 35-3),[60,66,72,78,82] indicate that the flame figure is characteristic for, but not diagnostic of, Wells syndrome.[71] When examined for eosinophil granule major basic protein by immunofluorescence, flame figures show bright extracellular staining (Fig. 35-5), indicating that extensive eosinophil degranulation has occurred.[68]

▲ **FIGURE 35-3** Wells syndrome. **A.** Early lesion with erythema and edema. **B.** Late lesion resembling morphea.

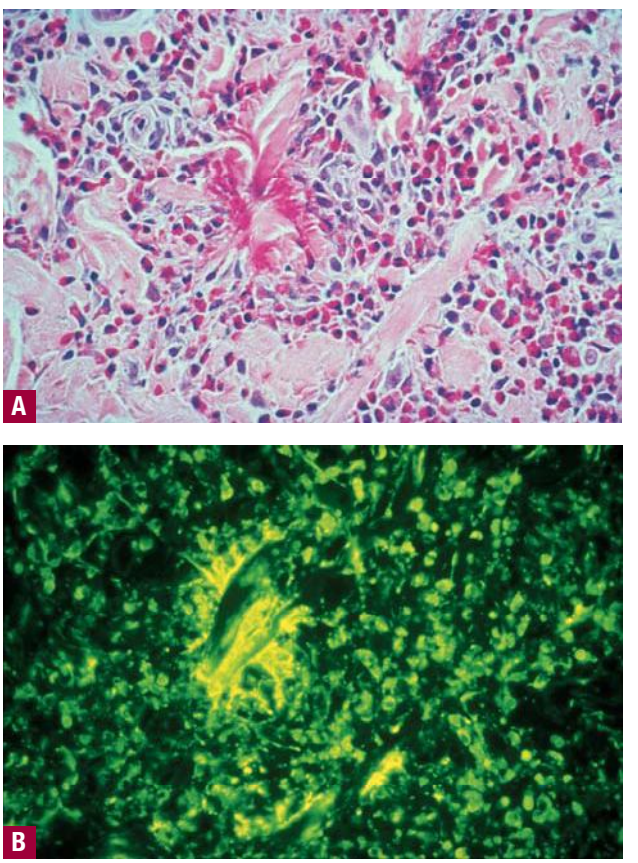
▲ **FIGURE 35-4** Familial Wells syndrome. Plaques with erythema, edema, vesicles, and bullae resembling acute dermatitis or pemphigoid. (From Davis MD et al: Familial eosinophilic cellulitis, dysmorphic habitus, and mental retardation. *J Am Acad Dermatol* **38**:919, 1998, with permission.)

Differential Diagnosis

Urticaria, erysipelas, and acute cellulitis should be considered in the differential diagnosis of the early stages of Wells syndrome (see Fig. 35-3A). Later, plaques may resemble morphea (see Fig. 35-3B). The presence of blisters may suggest pemphigoid (see Fig. 35-4). Flame figures are the hallmark of Wells syndrome, but because they have been identified in biopsy specimens from other dermatoses, they are not alone sufficient for the diagnosis. However, a diagnosis of Wells syndrome in the absence of flame figures should be met with skepticism, even in the presence of dermal infiltration with eosinophils and histiocytes.[71]

Treatment

Wells syndrome usually improves dramatically after administration of sys-



◀ **FIGURE 35-5** Flame figure in familial Wells syndrome. **A.** Hematoxylin and eosin–stained section. **B.** Eosinophil granule major basic protein immunostain (of serial section to **A**) shows extensive granule protein deposition localized to the flame figure. (Original magnification ×400.)

ANGIOLYMPHOID HYPERPLASIA WITH EOSINOPHILIA AND KIMURA DISEASE

AT A GLANCE

- Kimura disease (KD) occurs mainly in Asian males; angiolymphoid hyperplasia with eosinophilia (ALHE) occurs in all races with a female predominance.
- KD is found in a somewhat younger age group than ALHE.
- Characterized by recurrent dermal and/or subcutaneous lesions, primarily of the head and neck area.
  - ALHE lesions tend to be smaller, more superficial, and more numerous than those of KD.
  - KD tends to involve subcutaneous tissues, regional lymph nodes, and salivary glands.
- ALHE may be painful, pruritic, or pulsatile, whereas KD is generally asymptomatic.
- Peripheral blood eosinophilia is seen in both diseases.
- Increased immunoglobulin E levels are found only in KD.
- Renal disease is associated only with KD (reported incidence of 10 percent to 20 percent).
- Histopathologic features:
  - Dominant feature of KD is lymphoid proliferation, often with germinal centers, whereas ALHE is characterized by vascular proliferation with numerous large epithelioid or histiocytoid endothelial cells.
  - Fibrosis is characteristic of KD and is limited or absent in ALHE.
  - Inconspicuous to numerous eosinophils in ALHE.
  - Eosinophil abscesses may occur in KD.

temic glucocorticoids, and tapering of steroid dose over 1 month is well tolerated in most patients. Recurrences may be treated with additional courses of systemic glucocorticoids. For patients who fail to respond, or who experience relapse often enough to raise concerns about the long-term side effects of systemic glucocorticoid therapy, other options such as minocycline, dapsone, griseofulvin, and antihistamines may be beneficial. Cyclosporine and IFN-α also have been used with success. For treatment of mild disease, topical glucocorticoids may be sufficient.

ANGIOLYMPHOID HYPERPLASIA WITH EOSINOPHILIA

History

Epidemiology

Angiolymphoid hyperplasia with eosinophilia (ALHE) occurs in both males and females, but the literature indicates a slight female predominance. Patients are generally in the third to fifth decade of life. In contrast to Kimura disease (KD), which develops mainly in patients from Asia, ALHE has no racial predilection and is typically seen in Westerners.

Etiology

The pathogenesis of ALHE is unknown, but it is considered to be a reactive phenomenon, possibly arising in response to or in association with an underlying vascular malformation. There is a history of trauma in some cases. ALHE has been reported to occur in pregnancy, which suggests that sex hormones may be a factor in its development.[88]

Clinical Findings and Course

ALHE shows a predilection for the head and neck area and is characterized by solitary, few, or multiple, sometimes grouped, erythematous, violaceous or brown papules, plaques, or nodules of the dermis and/or subcutaneous tissues (Fig. 35-6; see also Fig. 147-11 in Chap. 147). Lesions may be associated with pruritus or pain, or may pulsate. Although they are confined to the skin in most patients, mucosal involvement may occur. ALHE tends to be chronic and nonremitting over months to years.

Laboratory Tests and Histopathology

Approximately 20 percent of patients have peripheral blood eosinophilia, but IgE levels are unremarkable. There is no association with renal disease. The dominant histologic feature is a well-defined area, in the dermis and/or subcutis, of prominent vascular proliferation with large epithelioid or histiocytoid endothelial cells that contain abundant eosinophilic cytoplasm, often with cytoplasmic vacuoles (see Fig. 147-11 in Chap. 147). There are variable numbers of eosinophils and lymphocytes,[89] with an occasional finding of lymphoid nodules. In their report of 116 patients with ALHE, Olsen and Helwig found 53 cases in which "an arterial structure" appeared to be associated with venules or "was the area of endothelial proliferation," which provided evidence that these lesions represent a form of arteriovenous shunt.[87] The stroma typically is myxoid, and fibrosis is minimal or ab-

▲ **FIGURE 35-6** Angiolymphoid hyperplasia with eosinophilia. **A.** Forehead nodule. **B.** Recurrence of lesions in skin graft and adjacent sites 6 years after surgical removal of lesion in **A**.

sent. Mast cells may be a component of the histologic picture.

Differential Diagnosis

Lesions of ALHE generally are smaller, more superficial, and more numerous than those of KD, and often are symptomatic. Although lymphoid follicles may occur in ALHE, they represent the dominant characteristic of KD (Table 35-4). Although KD may exhibit some vascularity, it lacks the large epithelioid endothelial cells that are a key feature of ALHE (see Table 35-4). ALHE should be distinguished from a variety of benign and malignant vascular proliferations, including pyogenic granuloma, epithelioid hemangioendothelioma, and Kaposi sarcoma—all of which lack a noticeable eosinophil infiltrate.

Treatment

Intervention is dictated in part by the number, location, and size of lesions. Patients with solitary or a few small lesions may benefit from excision or Mohs surgery.[90] There may be recurrence at the surgical site (see Fig. 35-6). A variety of other treatment modalities have been used with success, including systemic and intralesional steroid administration, IFN therapy,[91] cryotherapy,[92] laser therapy,[93] and topical application of tacrolimus.[94]

KIMURA DISEASE

History

Epidemiology

KD occurs predominantly in young adult Asian males. It also has been reported in children.

Etiology

KD is an idiopathic inflammatory disorder. The combination of peripheral blood eosinophilia, increased serum IgE levels, and histologic pattern of lymphoid nodules with germinal centers and numerous eosinophils suggests that KD represents an allergic hypersensitivity reaction. The pathogenic stimulus for the hypersensitivity response is unknown. Association with glomerulonephritis raises the possibility that KD has an autoimmune basis.

Clinical Findings and Course

Patients typically have one or a few asymptomatic, non-tender, slowly enlarging subcutaneous nodules. Lesions characteristically involve the head and neck region but may be localized to the extremities, axilla, groin, or trunk. There often is associated regional lymphadenopathy and sometimes more widespread lymph node enlargement.[96–98] The overlying skin appears normal. KD is typically chronic and recurrent.

TABLE 35-4
Comparison of Angiolymphoid Hyperplasia with Eosinophilia (ALHE) and Kimura Disease (KD)

	ALHE	KD
Gender	Typically middle-aged females	Predominantly young adult males
Symptoms	Pruritus, pain, pulsation	Asymptomatic
Lesion type and location	Small and superficial, with overlying erythema; head and neck region	Large, mainly subcutaneous; overlying skin normal; head and neck region; may involve regional lymph nodes and salivary glands
Lymphoid follicles	Uncommon	Prominent lymphoid follicles with germinal centers
Vascular proliferation	Prominent vascular proliferation with large epithelioid/histiocytoid endothelial cells; evidence of underlying vascular malformation may be evident	Some stromal vascularity with unremarkable endothelial cells
Fibrosis	Absent or limited	Prominent
Serum immunoglobulin E level	Normal	Increased
Nephropathy	Absent	Present in up to 20% of patients

Laboratory Tests and Histopathology

Peripheral blood eosinophil counts and serum IgE levels are elevated in most patients. Evaluation of renal function is indicated, because KD is associated with glomerulonephritis and nephrotic syndrome.[99,100] Histologically, lesions are characterized by lymphoid aggregates, usually in the form of lymphoid follicles with germinal centers, numerous eosinophils (see eFig. 35-6.1 in online edition), and fibrosis. Other features may include eosinophil abscesses and stromal vascularity, without the epithelioid or histiocytoid endothelial cells that are typical of ALHE.

Differential Diagnosis

Because lesions of KD are usually subcutaneous, with normal-appearing overlying skin and are associated with lymphadenopathy, the possibility of lymphoma or metastatic carcinoma should be considered in the clinical differential diagnosis. Historically, there has been debate about whether ALHE and KD represent separate entities or are part of a single disease spectrum, a confusion that may be furthered by a report of KD and ALHE occurring in the same patient.[101] Both ALHE and KD are characterized by persistent and recurrent lesions, primarily involving the head and neck areas. However, there are distinct clinical and histologic differences between the two disorders (see Table 35-4), particularly the lymphoid follicles with germinal centers that dominate KD in contrast to the vascular proliferation with large epithelioid endothelial cells that characterizes ALHE. Lesional tissue and peripheral blood eosinophilia are more pronounced in KD.

Treatment

Surgical excision is the treatment of choice when feasible in patients with a single or a limited number of nodules, but lesions may recur.[102] Other therapeutic options include systemic glucocorticoids, radiation therapy, and cyclosporine.[103] The presence of renal disease may influence or dictate the therapeutic regimen.

EOSINOPHILIC PUSTULAR FOLLICULITIS

History

Epidemiology

Predominantly a disease of males, eosinophilic pustular folliculitis (EPF) is now considered to encompass three clinical

EOSINOPHILIC PUSTULAR FOLLICULITIS

AT A GLANCE

- Three clinical types, characterized by follicular papules and pustules that may involve the head, trunk, and extremities
  - Classic eosinophilic pustular folliculitis (Ofuji disease)
    - Typically occurs in Japanese patients, who have chronic, recurrent follicular pustules, with a tendency to form circinate plaques, in a seborrheic distribution
  - Eosinophilic pustular folliculitis associated with immunosuppression
    - Most often occurs in patients with human immunodeficiency virus infection, who have severely pruritic papules of the face and upper trunk
  - Eosinophilic pustular folliculitis of infancy/neonatal period
    - Follicular pustules of the scalp
- Tendency for recurrences and chronicity (except eosinophilic pustular folliculitis of infancy)
- Characterized by follicular and perifollicular eosinophil infiltration
- Associated with peripheral blood eosinophilia

types.[108] Classic EPF is not racially restricted but typically occurs in Japanese adults in the third and fourth decades of life.[109] EPF associated with human immunodeficiency virus (HIV) infection is now the most common type and may develop in the setting of antiretroviral therapy.[107,110,111] EPF occurs infrequently in association with other types of immunosuppression.[112] EPF of infancy presents during the first year of life,[106,108] including the neonatal period. The number of patients reported to have HIV-associated EPF far exceeds those in the other two categories. EPF associated with immunosuppression has been observed in HIV-negative patients who have hematologic or lymphoproliferative disease, including lymphoma, leukemia, or polycythemia vera. Drug-induced EPF[112–114] and EPF associated with myelodysplastic syndrome[115] also have been described.

Etiology

Although a variety of theories concerning the pathogenesis of EPF have been proposed, the etiology is unknown. Immune dysfunction and allergic hypersensitivity are considered to play a role.

Clinical Findings and Course

Classic EPF presents as recurrent crops or clusters of follicular papules and pustules, which may form an annular pattern and usually resolve in 7 to 10 days. Lesions predominantly involve the face and trunk but also may affect the extremities, with involvement of the palms and soles in approximately 20 percent of patients.[109] In contrast, HIV-associated EPF tends to manifest as extremely pruritic discrete follicular papules, typically involving the head and neck and often the proximal extremities (see Fig. 198-3, Chap. 198). Rosenthal et al. emphasized the urticarial quality of such lesions.[110] In EPF of infancy, lesions typically are located on the scalp but also may be found on the face and extremities. In some neonates who have pustular eruptions that clinically resemble EPF and typically have peripheral blood eosinophilia, the disorder may be classified more appropriately under the term *eosinophilic pustulosis* because the cutaneous infiltrates are not folliculocentric (see Chap. 106).[116] EPF of infancy has a good prognosis, whereas classic and HIV-associated EPF are characterized by recurrences. Post-inflammatory pigmentation may be seen as lesions resolve, but scarring does not occur.

Laboratory Tests and Histopathology

Patients suspected of having EPF should be evaluated for underlying immune deficiency, particularly HIV infection. Peripheral blood eosinophilia is a component of all three types of EPF. Although patients with classic EPF usually have eosinophilia with leukocytosis, HIV-positive patients often exhibit eosinophilia with lymphopenia. Low CD4 cell counts and high IgE levels are typical of HIV-associated EPF.[110] Histologically, the most striking feature is the infiltration of eosinophils into hair follicles and perifollicular areas (see eFig. 35-6.2 in on-line edition), sometimes with follicular damage. The infiltrates also may contain lymphocytes and neutrophils, and may be perivascular as well as follicular. Follicular mucinosis (see Chap. 146) has been noted in association with EPF.

Differential Diagnosis

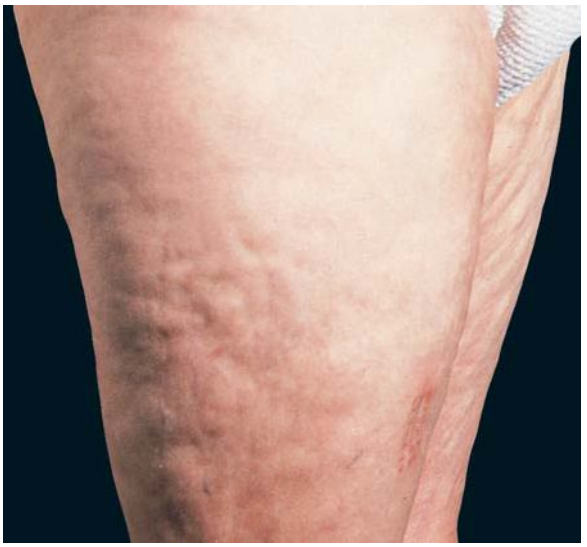
Folliculitis secondary to bacterial or fungal infection must be kept in mind, particularly in immunosuppressed patients. Because of the distribution of lesions, seborrheic dermatitis should be considered, as should lupus erythematosus, particularly when lesions are more maculopapular than pustular. Acneiform eruptions may resemble EPF. Erythema toxicum neonatorum, acropustulosis, and acne neonatorum also should be considered in infants.

Treatment

Topical glucocorticoids generally are the first approach to the treatment of all types of EPF. Nonsteroidal anti-inflammatory drugs, particularly indomethacin, also have been suggested as first-line therapy; clinical improvement may be observed within 2 weeks and is associated with a decrease in peripheral blood eosinophil counts.[117] Ultraviolet light therapy (ultraviolet B or psoralen and ultraviolet A) may be beneficial. Topical tacrolimus is a treatment option, particularly for facial lesions.[118] Topical permethrin, systemic retinoids, systemic glucocorticoids, cyclosporine, itraconazole, metronidazole, cetirizine, minocycline, dapsone, and IFNs have been tried with success.[119] Antiretroviral treatment that results in an increase in CD4 cell counts often is associated with improvement in HIV-associated EPF.

EOSINOPHILIC ULCER OF THE ORAL MUCOSA

Eosinophilic ulcer of the tongue, now referred to as *eosinophilic ulcer of the oral mucosa*, is a self-limited disease of the tongue, oral mucosa, or lips, manifested as a 1- to 2-cm ulcer with the histopathologic pattern of massive eosinophil infiltration extending into underlying muscle.[120–122] The infiltrate often contains lymphocytes, histiocytes, plasma cells, neutrophils and mast cells. The finding of large CD30$^+$ lymphocytes in eosinophilic ulcer of the oral mucosa suggests that it may be a lymphoproliferative disorder.[123]



◀ **FIGURE 35-7** Eosinophilic fasciitis. Puckered skin of the thighs.

CLINICAL REACTION PATTERNS WITH EOSINOPHIL INVOLVEMENT

There are a variety of diseases in which eosinophils may be present in cutaneous lesions, with or without associated peripheral blood eosinophilia, but either the histologic pattern is unremarkable or eosinophils are not critical for the histologic diagnosis of the given entity (see Table 35-1). In many of these dermatoses, the eosinophil loses its morphologic integrity after disruption through cytolysis and is not identifiable histologically.[124] However, toxic granule proteins and other eosinophil products are deposited in skin and persist for extended periods of time.[125]

Edema

Prominent among the eosinophil-associated skin reactions are those manifesting edema. In addition to the presence of cationic granule proteins in lesions, the ability of eosinophils to elaborate vasoactive mediators, induce histamine release from mast cells and basophils, and elicit a cutaneous wheal-and-flare reaction supports a role for the eosinophil as a primary participant in the edema associated with certain cutaneous diseases (see Chap. 37).[11]

EPISODIC ANGIOEDEMA ASSOCIATED WITH EOSINOPHILIA (GLEICH SYNDROME) Episodic angioedema associated with eosinophilia is characterized by recurrent angioedema (with up to 30 percent increase in body weight), urticaria, fever, increased serum IgM levels, and leukocytosis as high as 100,000 cells/mm^3 with up to 90 percent eosinophils; disease activity fluctuates with the peripheral eosinophil count.[32,131] Skin biopsy specimens from this disorder[32] and its localized variant, recurrent facial edema with eosinophilia,[132] show few eosinophils, but immunofluorescence staining reveals extracellular deposition of eosinophil granule proteins around collagen bundles and blood vessels. The syndrome is associated with a number of immunologic abnormalities, including increased activated T cells[132a] and increased serum IL-5 levels.[133] Capillary leak syndromes, due to administration of IL-2[134] and granulocyte-macrophage colony-stimulating factor,[135] also are associated with peripheral blood eosinophilia, increased serum IL-5 levels, and eosinophil degranulation.

Chronic Dermatitis/Pruritus

Although infestations typically are associated with eosinophils, the histologic pattern is non-diagnostic unless a specific organism is identified in tissue sections.[5,136]

Blisters

Autoimmune blistering diseases often are associated with prominent infiltration of eosinophils, including presentation as eosinophilic spongiosis (see Chaps. 52 and 54).

In addition to pemphigoid gestationis (which may exhibit eosinophilic spongiosis), several other pruritic dermatoses of pregnancy (see Chap. 107) may contain tissue eosinophilia.[156–159]

Fibrosis

Eosinophils are found in association with fibrotic reactions, including those resulting from parasitic infections, pulmonary and hepatic drug sensitivity reactions, and HES.[161] Eosinophils elaborate mediators that degrade collagen and stimulate dermal fibroblast DNA synthesis and matrix production.[162] Eosinophilic fasciitis usually presents with pain, erythema, swelling, and induration of the extremities, as well as peripheral blood eosinophilia and hypergammaglobulinemia.[163] Contractures and rippling of the skin may develop (Fig. 35-7). There is infiltration of lymphocytes, plasma cells, mast cells, and eosinophils, as well as increased thickness of the fascia.

Eosinophilia-myalgia syndrome (EMS), historically related to ingestion of certain lots of L-tryptophan, is characterized by marked peripheral eosinophilia, disabling generalized myalgias, pneumonitis, myocarditis, neuropathy, encephalopathy, and fibrosis,[164] a constellation of features that are similar to but distinguishable from eosinophilic fasciitis.[165,166] Cutaneous abnormalities of EMS include edema, pruritus, a faint erythematous rash, hair loss, and *peau d'orange* or morphea-like skin lesions.[167] Lungs, heart, and nervous system may be affected.[168] There is a prominent inflammatory infiltrate in the perimysium and fascia, and striking evidence of eosinophil granule protein deposition in skin and around muscle bundles.[169]

Toxic oil syndrome (TOS), which resembles EMS, was linked to consumption of adulterated rapeseed oil distributed in the industrial belt around Madrid.[170] Patients experienced acute respiratory symptoms followed by intense myalgias, thromboembolism, weight loss, sicca syndrome, and then a chronic phase characterized by eosinophilic fasciitis–like lesions, peripheral neuropathy, muscle atrophy, and pulmonary hypertension. The cutaneous manifestations of TOS were a non-specific pruritic, erythematous rash that persisted up to 4 weeks, followed over the next 2 months by subcutaneous edema, mainly of the extremities, accompanied by myalgias, arthralgias, contractures, and peripheral blood eosinophilia. Over many years, patients developed indurated plaques of the pretibial areas and occasionally the forearms and abdomen,[170] with marked fibrosis extending into subcutaneous fat. Eosinophil infiltration and degranulation were especially prominent in the acute phase of TOS, and serum eosinophil granule protein levels were elevated during all phases.[171]

Vasculitis

Eosinophils often are associated with cutaneous lesions that represent allergic

drug reactions. There is evidence that, when eosinophils are part of the histologic pattern in leukocytoclastic vasculitis, the eruption is probably drug induced[172] (see Chap. 164). In 1951, Churg and Strauss described the complex of systemic vasculitis, asthma, and eosinophilia as *allergic granulomatosis*.[173] Cutaneous lesions are characterized by eosinophil infiltration, necrotizing vasculitis, and extravascular granulomas (see Chap. 165).

Malignancy

Eosinophils may be observed in a variety of cutaneous and extracutaneous neoplasms. Their presence in tumors appears to be independent of immune surveillance and likely is part of an early inflammatory reaction at the site of tumorigenesis.[178]

SECTION 6

INFLAMMATORY DISEASES BASED ON ABNORMAL HUMORAL REACTIVITY AND OTHER INFLAMMATORY DISEASES

CHAPTER 36

Humoral Immunity and Complement

Lela A. Lee

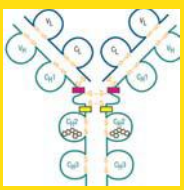
During evolution, jawed vertebrates developed the capacity to respond with exquisite specificity to foreign organisms.[1] Specific immunity is characterized by an enormous diversity of possible responses and by refinement in the immune response with successive exposures to the organism.[2] The cells that can discriminate with fine specificity through their vast repertoire of receptors are lymphocytes. Specific immunity, also called *adaptive immunity* because it develops as an adaptation to infection, can be segregated into humoral immunity, mediated by antibodies produced by B lymphocytes, and cellular immunity, mediated by T lymphocytes. These two forms of specific immunity developed to serve different functions. Humoral immunity is directed primarily toward extracellular antigens such as circulating bacteria and toxins. Cellular immunity is directed primarily toward antigens that infect or inhabit cells (for cellular immunity, see Chap. 10). To combat extracellular pathogens, the defending agent needs to be abundant and widely distributed in the body, particularly at its interfaces with the environment. Antibodies fulfill these characteristics by being capable of being secreted in great quantity from the cells that produce them and by being distributed in blood, mucosa, and interstitial fluid. In addition, antibodies can attach through Fc receptors (FcRs) to the surface of certain other cells of the immune system, such as mast cells, conferring antigen specificity to cells that do not have their own endogenously produced antigen-specific receptors.

ANTIBODY STRUCTURE

Antibodies, or immunoglobulins (Ig), are a family of glycoproteins that share a common structure.[2–4] The antibody molecule has a symmetric Y-shape consisting of two identical light chains, each about 24 kd, that are covalently linked to two identical heavy chains, each about 55 or 70 kd, that are covalently linked to one another (Fig. 36-1). Within the light and heavy chains are variable and constant regions. The major function of the variable region is to recognize antigen, whereas the constant region mediates effector functions. The light and heavy chains contain a series of repeating, homologous units of about 110 amino acids that assume a globular structure and are called *Ig domains*. The Ig domain motif is found not only in antibody molecules but also in a variety of other molecules of the Ig "superfamily," including the T cell receptor, the major histocompatibility complex (MHC), CD4, CD8, intercellular adhesion molecule 1, among other molecules. The light chain has two major domains, a variable (V_L) and a constant (C_L) domain. The heavy chains have four or five domains, a variable (V_H) and three (in IgA, IgD, and IgG) or four (in IgM and IgE) constant (C_H1-4) domains. In IgA, IgD, and IgG, there is a hinge region between C_H1 and C_H2 that confers additional flexibility to the molecule. The variable domains are at the N-terminus. At the C-terminus are the constant domains and, in the heavy chains of membrane-bound antibodies, the transmembrane and cytoplasmic domains.

Within the variable regions of the light and heavy chains are three areas of intense variability called *hypervariable regions*. These three regions, which are in proximity to one another in the three-dimensional structure of the antibody, are the areas most responsible for binding antigen. Because the hypervariable

HUMORAL IMMUNITY AND ANTIBODY STRUCTURE AT A GLANCE



- Humoral immunity, mediated by antibodies produced by B lymphocytes, is a form of specific immunity directed primarily toward extracellular antigens.
- Antibody molecules consist of two identical light chains covalently linked to two identical heavy chains. The variable region of the antibody molecule is responsible for antibody binding, and the constant region mediates most effector functions.
- The five antibody classes serve distinct functions. Immunoglobulin M (IgM) is involved in primary antibody responses, IgD is an antigen receptor on naive B cells, IgA is critical for mucosal immunity, IgG is the major Ig in the circulation and is important in secondary antibody responses, and IgE mediates immunity to parasites.
- An individual is capable of generating millions of distinct antibodies in millions of distinct B-cell clones through the processes of gene rearrangement and junctional diversity.

▲ **FIGURE 36-1** Schematic representation of an immunoglobulin G (IgG) molecule.

regions form a shape complementary to that of the antigen, the hypervariable regions are also called the *complementarity-determining regions*. The unique areas formed by the hypervariable regions are present in too low an amount in the individual to generate self-tolerance. Thus, the immune system may not distinguish the unique portion of the antibody as self and may produce antibodies to that region of the antibody. The area of the antibody capable of generating an immune response is called an *idiotope*, and antibody responses to idiotopes result in a network of idiotypic–anti-idiotypic interactions that may help regulate the humoral immune response.[5]

There are two types of light chains, κ and λ, each encoded on different chromosomes. Each antibody molecule has either two κ or two λ chains, never one of each. The functional differences, if any, between κ and λ are not known. There are five types of heavy chains, α, δ, ε, γ, and μ, corresponding to the antibody classes IgA, IgD, IgE, IgG, and IgM, respectively. The different heavy chain classes have significantly different functions, as discussed in Antibody Classes. The IgA and IgG classes contain closely related subclasses, consisting of IgA1 and IgA2, and IgG1, IgG2, IgG3, and IgG4 (Table 36-1).

Enzymatic digestion of IgG molecules by papain results in three cleavage products, two identical Fab fragments consisting of a light chain bound to the V-C_H1 region of the heavy chain and an Fc portion consisting of two C_H2-C_H3 heavy chains bound to each other. *Fab* was so named for its property of antigen binding, and *Fc* was so named for its property of crystallizing. When IgG is digested by pepsin, the C-terminal region is digested into small fragments. The remaining product consists of the Fab region along with the hinge region. Fab fragments containing the hinge region are termed Fab′. When the two Fab′ fragments in an antibody molecule remain associated, the fragment is called $F(ab')_2$.

ANTIBODY CLASSES (See Table 36-1)

Immunoglobulin M

IgM is the first Ig molecule to be expressed during B-cell development. Its secretory form is a pentamer consisting of five IgM molecules joined at their C-termini by tail pieces and stabilized by a molecule called a *joining (J) chain*. The engagement of membrane-bound IgM by antigen results in the activation of naive B cells. Secreted IgM recognizes antigen, usually through low-affinity interactions, and it can activate complement. IgM is the major effector of the primary antibody response. Although IgM interactions are typically low affinity, IgM can be very effective in responding to a polyvalent antigen (such as a polysaccharide with repeating epitopes) because its pentameric structure allows for multiple low-affinity interactions, resulting in a high-avidity interaction. (*Avidity* refers to the overall strength of attachment, whereas *affinity* refers to the strength of attachment at a single antigen-binding site.)

Immunoglobulin D

The IgD molecule exists primarily in a membrane-bound form and is the second antibody class to be expressed during B-cell development. Its function is not completely understood, but in its membrane-bound form it can serve as an antigen receptor for naive B cells.[6]

Immunoglobulin A

IgA is the most abundant Ig in the body, being present in large quantity at mucosal sites. It is responsible for mucosal immunity and is secreted in breast milk, thus contributing to neonatal immunity. In its secreted form, it exists as a monomer, dimer, or trimer, with the multimers being formed by interactions between tail pieces and stabilized by the J chain. For transport across epithelial surfaces, IgA dimers attach to a type of FcR called the *polymeric Ig receptor*.[7] Once the transport process is complete, the IgA dimers remain attached to the extracellular portion of the receptor, called the *secretory component*, which protects the IgA from proteolysis. Cells of the immune system that have receptors for IgA include neutrophils, eosinophils, and monocytes.

Immunoglobulin G

IgG is the most abundant Ig in the circulation. Its secreted form is a monomer. IgG plays an important role in secondary antibody responses, and its interactions with antigen tend to be high-affinity, particularly as the immune response ma-

TABLE 36-1
Immunoglobulin Classes and Their Functions

A	Subtypes	Secreted Form	Approximate Molecular Weight of Secreted Form (kD)	Serum Concentration (mg/mL)	Serum Half-Life (Days)	Functions
IgM	None	Pentamer	970	1.5	5	Primary antibody response; antigen receptor on naive B cells; complement activation
IgD	None	Monomer[a]	180[a]	Trace	3	Antigen receptor on naive B cells
IgA	IgA1	Monomer, polymer (usually dimer)	160 (monomer), 390 (secretory IgA)	3	6	Mucosal immunity; neonatal immunity
	IgA2	Monomer, polymer (usually dimer)	160 (monomer), 390 (secretory IgA)	0.5	6	
IgG	IgG1	Monomer	150	9	23	Neonatal immunity; opsonization; complement activation (except IgG4); phagocytosis; antibody-dependent cell-mediated cytotoxicity; feedback inhibition of B cells
	IgG2	Monomer	150	3	23	
	IgG3	Monomer	170	1	7	
	IgG4	Monomer	150	0.5	23	
IgE	None	Monomer	190	0.05	2	Immediate hypersensitivity; defense against parasites

Ig = immunoglobulin.
[a]IgD is not a secreted molecule, but trace amounts can be found in serum.

tures. A number of cells have FcRs for IgG, including monocytes, neutrophils, eosinophils, natural killer (NK) cells, and B cells. IgG opsonizes (coats) antigen, allowing phagocytosis of the antigen, and activates complement. An exception is IgG4, which does not activate complement. IgG is important in neonatal immunity, as it is the only Ig class to cross the placenta, and it is secreted in breast milk. The interaction of IgG with the MHC class I-related receptor FcRn is involved in the delivery of IgG across the placenta as well as in prolonging its level in the circulation.[8] The serum half-life of IgG is 23 days, considerably longer than that of the other Ig classes.

Immunoglobulin E

IgE is found in very small amounts in the circulation. High-affinity receptors for the Fc portion of IgE are present on mast cells, basophils, and eosinophils, and low-affinity receptors are present on B cells and Langerhans cells. In mast cells, basophils, and eosinophils, IgE engagement with antigen activates the cells. IgE mediates immediate hypersensitivity, but its principal protective role may be to combat parasites.

MECHANISMS FOR THE GENERATION OF ANTIBODY DIVERSITY

The information encoded by an individual's DNA is limited by the need for the DNA to fit into a package the size of a cell. This space is far too small for sufficient DNA to encode billions of different lymphocyte receptors if the genes were encoded separately. Lymphocytes have adapted to this limitation by special mechanisms that increase by orders of magnitude the number of different possible antigen receptors.[9] Each clone of B cells produces identical antigen receptors (i.e., antibodies) with unique specificity. It is estimated that an individual has approximately 10^9 different B-cell clones, resulting in 10^9 distinct antibodies. A major mechanism for generating this enormous diversity is gene rearrangement, whereby segments of DNA within a lymphocyte undergo somatic recombinations.[10] Light chain genes contain three regions, V (variable), J (joining), and C (constant), and heavy chain genes contain four regions, V, D (diversity), J, and C. Within each region are many gene segments from which to select for the final antibody product, which is comprised of one gene segment from each region. The initial event in antibody formation is the joining of one D and one J segment from a heavy chain gene, with subsequent deletion of the DNA between the two segments. Next, a V segment is selected to join to the DJ segment, and any remaining D segments are deleted. The VDJ complex has attached 3′ to it any remaining J segments plus the C region. The unused J segments are removed during RNA processing. A similar process occurs in light chain loci; because there are no D segments in light chain loci, a VJ rather than a VDJ complex is formed.

The ability to select one segment each from the many segments available in the V, D, and J regions leads to a vast increase in the repertoire of possible antibodies. Additional diversity is generated by the juxtaposition of a rearranged light chain to a rearranged heavy chain and by the addition, deletion, or transposition of nucleotides at the junctions between V and D, D and J, and V and J segments, a phenomenon called *junctional diversity*.

B-CELL MATURATION

Bone marrow and fetal liver stem cells that give rise to B cells are initially pluripotent.[2,11] The stem cells may proceed to develop in the lymphocytic pathway, where they can give rise to B, T, or NK cells. The earliest cell committed to the B-cell lineage is called a *pro-B cell*. At the pro-B cell stage, the cell expresses recombination, activating gene and terminal deoxyribonucleotidyl transferase proteins, which will be needed subsequently for somatic recombination and nucleoside transfers involved in junctional diversity, respectively. At the pro-B-cell stage, limited somatic recombination has taken place, and Ig is not yet expressed.

The next stage of B-cell maturation is represented by the *pre-B cell* and is marked by the synthesis of a cytoplas-

B-CELL MATURATION AT A GLANCE

- The pro-B cell expresses enzymes needed for gene rearrangement and junctional diversity, but neither heavy nor light chains are expressed.
- The pre-B cell expresses μ heavy chains in the cytoplasm. On the cell surface, the heavy chains associate with surrogate light chains to form pre-B cell receptors.
- The immature B cell produces light chains and can therefore express antibody molecules on the cell surface. If antigen exposure occurs at this stage, negative selection may take place.
- The mature B cell expresses both immunoglobulin M and immunoglobulin D and is competent to respond to antigen.

mic μ heavy chain. Because light chains are not yet expressed at this stage, surface Ig is not present. Some of the μ heavy chains associate with invariant molecules called *surrogate light chains* to form complexes called *pre-B cell receptors*. These receptors are then expressed on the pre-B cell surface and provide important signals for the proliferation and maturation of the developing B cell.

The formation of light chains marks the next stage in B-cell maturation, the immature B cell. When light chains join with the μ heavy chains, an IgM molecule results and can be expressed on the cell surface. The cytoplasmic tails of IgM molecules are too short to transduce signals. Signal transduction is rather a function of two other molecules, called Ig α and Ig β, associated with IgM in a B-cell receptor complex on the cell surface. Although the presence of a B-cell receptor complex confers the ability to recognize specific antigens, at this stage such recognition does not result in proliferation or differentiation. Rather, the cells may undergo negative selection when antigen is encountered. Immature B cells recognizing self-antigen may be deleted through apoptosis[12] or may undergo receptor editing, a process by which a new, nonself specificity is acquired.[13]

Acquisition of the ability to express IgD as well as IgM is the hallmark of the next stage, the mature B cell. The cell is naive because it has not been activated by antigen, but it is competent to respond to antigen. Mature B cells exit the bone marrow and migrate to blood and lymphoid tissues, where they constitute the majority of B cells in those locations.

The encounter of antigen by mature naive B cells leads to B-cell activation, proliferation, and differentiation. A subset of B cells become memory B cells, which are then activated if the antigen is encountered subsequently.[14] Another subset of B cells differentiates into cells that make progressively less membrane-bound Ig and more secreted Ig. These cells can undergo class switching from IgM and IgD to IgA, IgE, or IgG.[15] The terminally differentiated B cells committed to the production of secreted Ig are plasma cells and have abundant rough endoplasmic reticulum, consistent with the function of the cells as antibody factories.

ANTIGENS BOUND BY B CELLS

B cells recognize a variety of macromolecules, including proteins, lipids, and nucleic acids. The portion of the macromolecule recognized by the antibody is called an *epitope* or *determinant*. B cells recognize both linear epitopes (epitopes formed by several adjacent amino acids) and, quite commonly, conformational epitopes (epitopes present as a result of folding of the macromolecule).[16] In contrast to B cells, T-cell responses are almost entirely restricted to linear epitopes of peptides.

Macromolecules, particularly large proteins, may contain several different epitopes, and a humoral response to a macromolecule typically is comprised of multiple different antibodies. Although each different antibody is specific for a given epitopic configuration, similarities in epitopes may exist such that an antibody to a given epitope on a given macromolecule also may be able to bind a different epitope on a different macromolecule. This phenomenon is called *cross-reactivity*, and may be important in the genesis of autoimmune antibody responses.

Macromolecules that have multiple identical epitopes are classified as being polyvalent or multivalent. Antibodies to these macromolecules or aggregates of macromolecules may form complexes called *immune complexes* with the antigen. At a particular concentration of antibody and antigen, called the zone of equivalence, a large network of linked antigens and antibodies forms. At lower or higher concentrations of antibody or antigen, the complexes are much smaller. Immune complexes, formed in the circulation or in tissue, may be responsible for disease through the initiation of an inflammatory response.

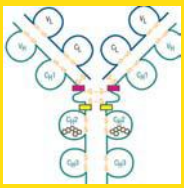
B-CELL ACTIVATION AND ANTIBODY FUNCTION

On engagement of the mature B-cell receptor by antigen, clustering of receptors initiates signaling transduced by Ig α and Ig β. The resulting signaling cascade eventuates in the expression of genes involved in B-cell activation. B-cell activation is facilitated by second signals, one of which is provided by the complement protein C3d.[17] Complement fragment C3d is formed as a result of complement activation through any of the complement activation pathways (see Complement System later in this chapter). The B-cell surface contains a co-receptor complex consisting of complement receptor 2 (CR2), CD19, and CD81. Simultaneous binding of antigen by antibody on the B-cell surface and of C3d by CR2 leads to markedly increased B-cell activation.

The subsequent response to an antigen often involves a complex interaction between B cells and T cells, leading to a fine-tuning of the immune response.[18] B cells are capable of functioning as antigen-presenting cells. In a response to a protein antigen, B cells take up the antigen, process it, and present peptide–class II MHC complexes to $CD4^+$ T cells. T cells recognizing the peptide–class II MHC complexes receive a primary signal from the complex and a secondary signal from co-stimulatory interactions, notably binding of B7-1 and B7-2 on B cells to CD28 on T cells.[19] These T cells are activated, and their activation, in turn, provides signals to the B cells through the actions of cell surface molecules (in particular, CD40 on B cells and CD40 ligand on T cells) and cytokines [e.g., interleukin 2 (IL-2), IL-4, IL-5, and IL-6].[2] The overall effects on B cells are activation, proliferation, and differentiation.

Class switching from IgM to IgA, IgE, or IgG occurs as a result of T cell–B cell interactions.[15,20] The determination of the antibody class selected is based on the location and cytokine milieu in which the interaction occurs. For example, B-cell responses to antigens encountered on mucosal surfaces characteristically result in class switching to IgA,

B-CELL ACTIVATION AND ANTIBODY FUNCTION AT A GLANCE



- When the B-cell receptor (surface antibody) binds antigen, a second signal provided by C3d engagement with complement receptor 2 significantly augments B-cell activation.
- B-cell responses to protein antigens typically involve T-cell help, with resultant antibody class switching and affinity maturation.
- Effector functions of antibodies include neutralization of antigen, complement activation, cell activation, phagocytosis, and antibody-dependent, cell-mediated cytotoxicity. Most of these are mediated through the binding of immunoglobulin (Ig) to Fc receptors containing an immunoreceptor tyrosine-based activation motif.
- Negative signaling to B cells is provided by binding of IgG to a B-cell Fc receptor that contains an immunoreceptor tyrosine-based inhibition motif. The availability of excess IgG to bind this receptor is an indication that antigen is being successfully eliminated and the immune response is no longer required.

and transforming growth factor-β is an important contributing cytokine.

T-cell interaction with B cells also results in affinity maturation, whereby the affinity of antibodies for the antigen progressively increases. During affinity maturation, somatic hypermutations in antibody genes result in antibodies with both greater and lesser affinity for the antigen.[21,22] Those antibodies with greater affinity confer a survival advantage on the B cells that produce them. Progressively, the population of B cells evolves in favor of those producing higher-affinity antibodies for the antigen. Both class switching and affinity maturation require the expression of an enzyme called *activation-induced cytosine deaminase*.[23]

As noted in the section Antigens Bound by B Cells, T-cell responses are limited almost entirely to peptides. Thus, B-cell responses to non-protein antigens may not result in T-cell help through the mechanisms described earlier.[24] One type of T-cell–independent B-cell response produces so-called *natural antibodies*—IgM antibodies that are largely anticarbohydrate antibodies produced without apparent antigen exposure.[25] These natural antibodies are characterized by a limited repertoire and are produced by B1 peritoneal cells either spontaneously or in response to bacteria that colonize the gut.

Antigen occupation of antibody-binding sites leads to functional results, called *effector functions*. With the exception of direct neutralization of antigen by antibody binding, effector functions are typically mediated through the binding of Ig to FcRs.[26,27] FcRs generally are divided into those that trigger cell activation and those that do not. Those that can trigger activation contain one or more motifs called *immunoreceptor tyrosine-based activation motifs*. Of those that do not trigger activation, some can inhibit cell activation and contain a motif called *immunoreceptor tyrosine-based inhibition motif*. FcRs that neither activate nor inhibit cell activation are involved in the transport of Ig through epithelia and the prolongation of the half-life of IgG.

The effector functions of antibodies serve to eliminate the antigen that initiated the immune response and also to downregulate the immune response when activation is not required. Effector functions of antibodies include neutralization of antigen, complement activation, cell activation (of monocytes, neutrophils, eosinophils, and B cells), phagocytosis (by monocytes and neutrophils), and antibody-dependent cell-mediated cytotoxicity (mediated by NK cells and eosinophils). In addition, engagement of IgG by antigen provides a negative signal to B cells, mediated through the binding of the antigen-antibody complex to an immunoreceptor tyrosine-based inhibition motif-containing Fcγ receptor, FcγIIB, on the B cell.[28]

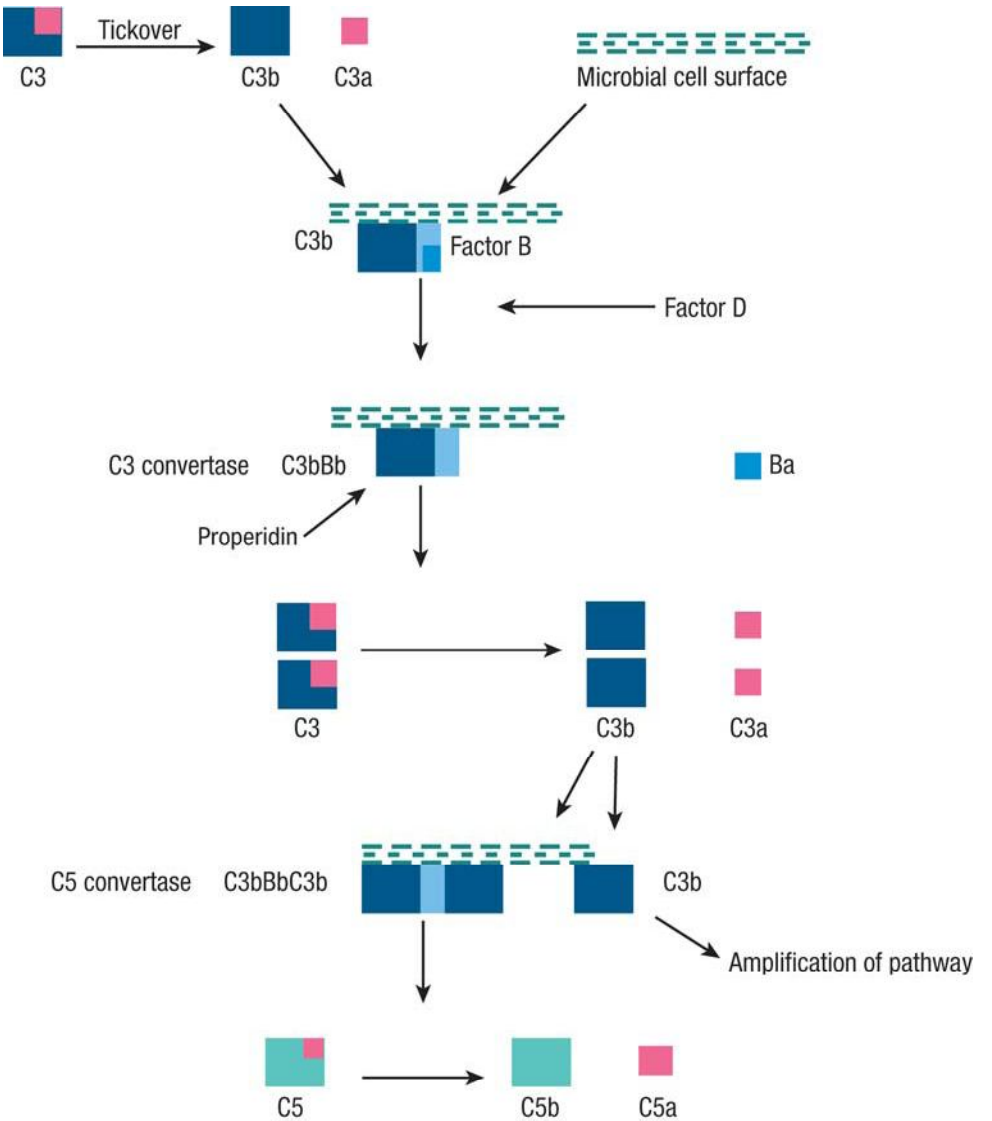
B CELLS AND ANTIBODIES IN DISEASE

Disorders of B cells or antibodies cause or contribute to many diseases of dermatologic relevance.[29–34] Immunodeficiency diseases may result from abnormalities of B-cell development or activation or from abnormalities in effector function pathways. B-cell lymphomas may result from failure to regulate proliferation, differentiation, or programmed cell death. Antibodies may initiate an inflammatory response that results in injury, as in IgE-mediated allergic reactions or immune-complex diseases. In some cases, the antigen may not be obviously harmful, but the response to the antigen is. In other cases, the antigen may be pathogenic, but the character or magnitude of the immune response is inappropriate or inadequately controlled. The regulatory systems that protect an organism from attack by its own immune system occasionally fail. In some cases, autoimmunity may be initiated as a result of an immune response to a pathogen. The pathogen may act as a non-specific activator of the immune system, or may activate the immune response specifically (e.g., by containing an epitope or epitopes that are cross-reactive with an autoepitope). These responses may be particularly difficult to control because the major stimulus for the immune response, the antigen, is a normal component of "self" and cannot be eliminated. Thus, through many mechanisms, the normal protective B-cell response, which developed as an elegant means to discriminate very finely among various potential pathogens, can be subverted to result in harm to the organism.

COMPLEMENT SYSTEM

The complement system was discovered through its ability to contribute to, or "complement," bacterial cell lysis by antibodies.[35,36] At physiologic temperatures, serum containing antibacterial antibodies lysed bacteria effectively, whereas serum heated to 56°C (133°F) lost its ability to lyse bacteria. Because antibodies are quite stable at 56°C (133°F), it was postulated that the loss of lytic ability was due to the degradation of heat-labile non-antibody molecules.

Although the complement system was first identified through its role in humoral immunity, it evolved rather early as a component of innate immunity (see Chap. 10) and has multiple functions in immune defense. The complement system is constituted in part by a set of plasma proteins that are normally inactive or minimally active.[2] The initial steps of activation involve the cleavage of an inactive protein into a smaller and a larger fragment. The larger fragment, then, is itself able to cleave other proteins in the cascade. Because an activated molecule in one step is capable of generating



◀ **FIGURE 36-2** The alternative pathway of complement activation. Shown are the steps from the initial attachment of C3b to a microbial cell surface through the cleavage of C5 into C5a and C5b. The final steps of complement activation are shown in Fig. 36-4. See Alternative Pathway for details.

many activated molecules in the following step, the sequential cleavage and activation of complement proteins result in amplification of the cascade.

PATHWAYS OF COMPLEMENT ACTIVATION

The early stages of the activation of complement ultimately result in cleavage of the complement protein C3. This is followed by the cleavage of C5 and initiation of the final steps of complement activation. There are three distinct pathways that lead to the cleavage of C3, the classical, the alternative, and the lectin pathways. Although the classical pathway was the first to be described, the alternative pathway is evolutionarily older.[37]

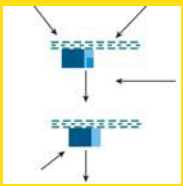
Alternative Pathway (Fig. 36-2)

The first step in the activation of the alternative pathway is the binding of C3b to a cell surface such as a bacterial cell surface. Intact C3 is an inactive molecule, but there is a low-level spontaneous cleavage of C3, called *tickover*, which results in the continuous availability of the C3b fragment. C3b can bind stably to a cell surface through an interaction between a thioester group of C3b and a hydroxyl group of the cell surface. In intact C3, the thioester domain is covered by hydrophobic residues that prevent hydrolysis of the thioester bond. The anaphylatoxin (ANA) domain of C3 stabilizes this inactive conformation. Once the ANA domain is cleaved to release C3a, the thioester group is exposed, and conformational change results in its ability to bond to the cell surface.[38,39] If this chemical bonding does not occur, the thioester group is hydrolyzed and C3b is inactivated.

Once stable attachment of C3b to the cell surface takes place, a plasma protein called *Factor B* binds to C3b. Factor B is in turn cleaved by Factor D, generating Bb and Ba. The complex of C3b and Bb, stabilized by the plasma protein properidin, is the alternative pathway C3 convertase (i.e., it cleaves C3 into C3a and C3b). The addition of further C3b to the complex results in C3bBbC3b, which constitutes the alternative pathway C5 convertase. The late steps of complement activation, after the cleavage of C5, are common to the three pathways and are described in Final Steps of Complement Activation.

Thus, the low level of C3b in the plasma acts as a sentinel for microbes. Once C3b is bound to the cell surface, subsequent molecular interactions result in a substantial amplification of the alternative pathway and cleavage of C5. The requirement for binding of C3b to a structural element serves to limit the effect of complement activation to the area where complement activation is needed. The alternative pathway of complement activation does not require finely specific recognition of antigen and so is considered a component of innate

COMPLEMENT SYSTEM AND ACTIVATION PATHWAYS AT A GLANCE



- The complement system functions to kill microbes via lysis or phagocytosis, to clear immune complexes and apoptotic debris from the circulation, to promote inflammation, and to stimulate humoral immunity.
- The three pathways of complement activation are the alternative, classical, and lectin pathways.
- The early steps in complement activation are triggered enzyme cascades in which cleavage of an inactive protein into fragments results in cleavage of subsequent proteins in the cascade.
- The alternative and lectin pathways are primarily pathways of innate immunity; the classical pathway is a pathway characteristically initiated by humoral immunity.
- The complement pathways converge at the cleavage of C3 and subsequent cleavage of C5. The final steps of activation consist of the addition of C6–8 to C5b, and polymerization of C9 to form the membrane attack complex.

immunity. It follows that if specific recognition is not required, C3b can bind to human cells as well as microbes. However, activation on human cells is generally prevented by the intervention of regulatory proteins present on the surface of human cells, protecting these cells from inappropriate and harmful attack by the complement system.[40]

Classical Pathway (Fig. 36-3)

The initial step in the activation of the classical pathway is characteristically the binding of the portion of the C1 complex called *C1q* to IgG or IgM antibodies.[36] The C1q molecule consists of six identical arms attached to a central trunk. The globular ends of the arms attach to the complement-binding regions of the heavy chains of certain Ig classes. In order for C1q to be activated, it must bind simultaneously to at least two Ig heavy chains. This means, in effect, that the Ig must have bound antigen. In the case of IgG, binding of multiple epitopes by antibodies results in close proximity of the antibodies and thus the proper configuration for C1q activation. (As mentioned in Immunoglobulin G, IgG4 is an exception, in that it does not bind C1q or activate complement.) Because IgM exists as a pentamer, theoretically IgM without bound antigen could activate complement. However, when IgM is not bound by antigen, the C1q binding site is not accessible. When antigen is bound, a conformational change results in exposure of the C1q binding site.

The complement component C1 is a complex of C1q, C1r, and C1s. Binding of two or more of the globular heads of C1q results in activation of C1r. Activated C1r is a protease that cleaves and activates C1s, and activated C1s, in turn, cleaves C4 into C4a and C4b. (The numbering of the complement proteins differs from their positions in the activation sequence, as components were discovered before the elucidation of their positions in the pathway.) C4b, like C3b, contains a thioester group that can form stable bonds with hydroxyl groups on a particular structure. Bound C4b is then bound by C2, which is cleaved into C2a and C2b. The C4bC2a complex is the classical pathway C3 convertase. (Note: Typically, suffix "a" denotes the smaller and "b" the larger complement fragment. The nomenclature of C2, with C2a being the larger fragment and C2b the smaller, is contradictory to that of the rest of the complement system.)

The cleavage of C3 results in C3a and C3b. The C3b fragment may then go on to activate complement by the alternative pathway, or act in concert with C4bC2a to form C4bC2aC3b, the classical pathway C5 convertase.

The major characteristics of the classical pathway are much the same as those of the alternative pathway. Activation of the pathway requires attachment of a complement protein to a structure such as a cell surface or immune complex, so that the effects of complement activation are spatially limited. Initial activation steps result in the formation of a C3 convertase that cleaves C3. Cleavage of C3 leads to the formation of a C5 convertase that cleaves C5 into C5a and C5b. A major difference is the initiation of the classical pathway by specific recognition of antigen by antibodies, in contrast to the rather non-specific binding that occurs to initiate the alternative pathway.

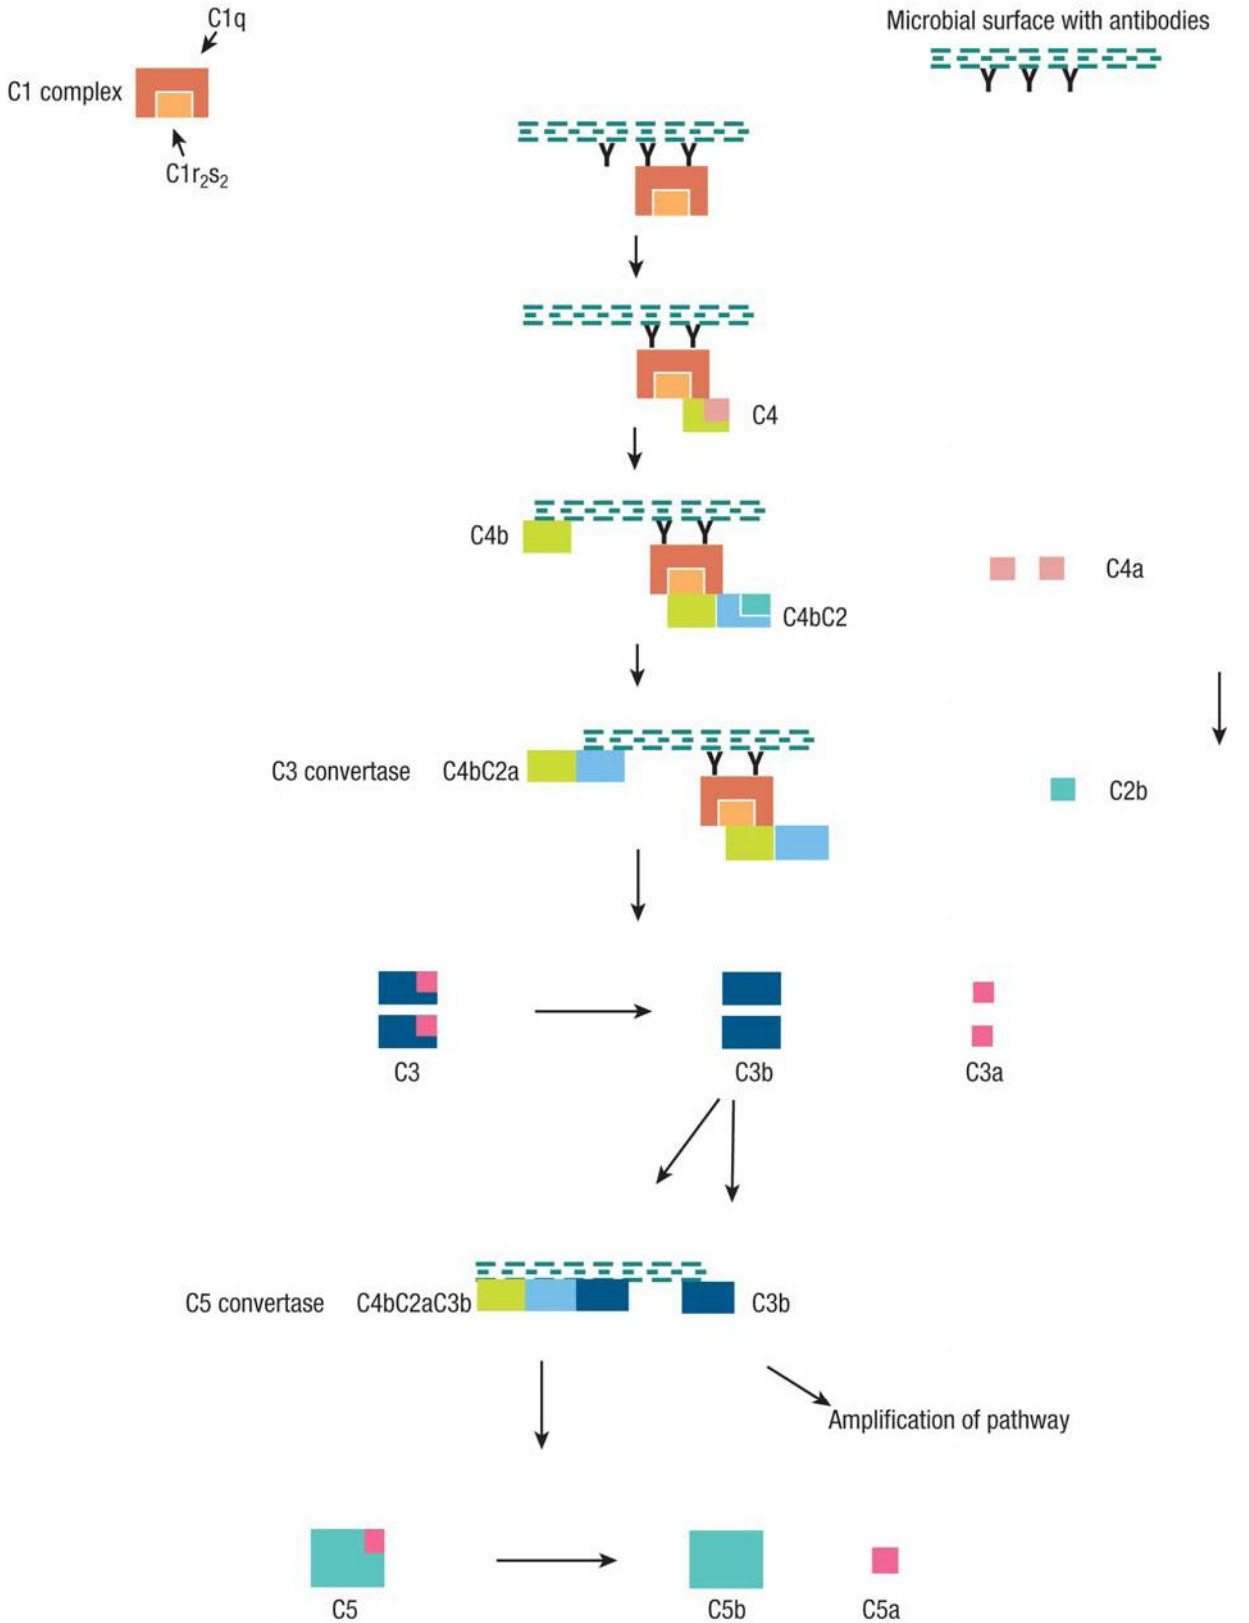
Lectin Pathway

The lectin pathway is very similar to the classical pathway, with the exception of the initiating steps. The first step is the binding of a plasma lectin, mannose-binding protein (MBP), to polysaccharides on microbial cell surfaces.[41] MBP, a member of the collectin (collagenous lectin) family, is structurally similar to C1q and can associate with C1r and C1s. MBP attachment to a microbe can begin the cascade through the activation of C1r and C1s. MBP also interacts with MBP-associated serine proteases, which are analogous to C1r and C1s. Binding of MBP to microbial cell surfaces results in cleavage of MBP-associated serine protease and thence cleavage of C4.[42] In either case, the effect is the formation of C4b and its stable binding to a cell surface. As is the case for the alternative pathway, the lectin pathway is a component of innate immunity.

Final Steps of Complement Activation (Fig. 36-4)

The alternative, classical, and lectin pathways converge at the cleavage of C5. The C5b fragment remains surface-bound. The next steps do not involve enzymatic cleavage, but rather the sequential binding of C6, C7, and C8 to C5b. The C5b-8 complex stably bound to a cell membrane becomes an active membrane attack complex (MAC) through the addition of C9. C9 polymerizes around the complex and forms pores in cell membranes. These pores may result in cell death through osmotic rupture, particularly in non-nucleated erythrocytes.

Nucleated cells are more resistant to lysis, but may still exhibit effects attributable to MAC binding.[43] It is quite possible that the non-lytic changes induced by MAC are of more functional and pathologic significance overall than is MAC-induced cell lysis.[44] These non-lytic effects may differ depending on cell type and milieu, and similar effects may lead to different outcomes. For example, MAC insertion into phagocyte cell membranes can lead to the production of inflammatory mediators such as reactive oxygen species and prostaglandins, resulting in phagocyte activation.[45] Glomerular epithelial cells may also exhibit inflammatory mediator production, but, in that setting, the inflammatory media-

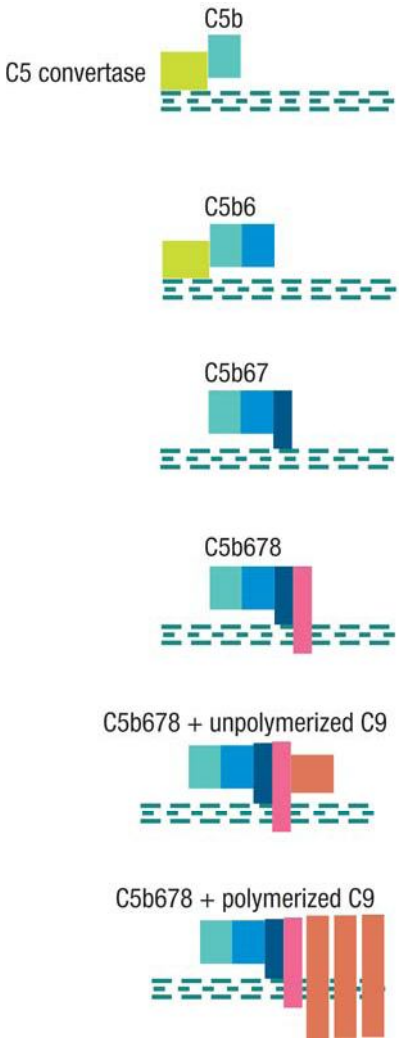


▲ **FIGURE 36-3** The classical pathway of complement activation. Shown are the steps from the initial binding of C1q to antibody-antigen complex through the cleavage of C5 into C5a and C5b. The final steps of complement activation are shown in Fig. 36-4. See Classical Pathway for details.

tors may lead to tissue injury.[46] MAC has also been reported to cause proliferation of certain cells, and MAC has been reported to have both apoptotic and anti-apoptotic properties.[43]

Additional Initiators of Complement Activation

In addition to the characteristic initiators of the three pathways, certain additional structures can trigger complement activation.[47] These include, among others, the following: in the alternative pathway, IgA immune complexes and endotoxin; in the classical pathway, C-reactive protein, ap-



▲ **FIGURE 36-4** Formation of the membrane attack complex. The alternative, classical, and lectin pathways converge at the formation of C5b and its sequential attachment to C6, C7, C8, and C9. The polymerization of C9 results in tubular structures on the cell membrane.

optotic bodies, and serum amyloid P; and in the lectin pathway, serum ficolin.[41,48]

FUNCTIONS OF COMPLEMENT PROTEINS

As mentioned earlier, the earliest function of the complement system to be discovered was the lysis of bacteria. Killing of microbes through direct lysis is mediated by the MAC, C5b-9. Microbes may also be destroyed through coating, or opsonization, by complement and phagocytosis of the opsonized particles by phagocytic cells. The processes of opsonization and phagocytosis are also mechanisms for another important function of complement—the clearance of immune complexes and apoptotic debris from the circulation.

An ancillary function of complement activation is the induction of inflammation. Inflammation, characterized by vascular changes and ingress and activation of leukocytes and inflammatory proteins, serves to augment the localized immune response in tissue. Three mediators of inflammation initiated by complement activation are the complement fragments C3a, C4a, and C5a. These are called *anaphylatoxins* because of their ability to induce degranulation of mast cells.[49] The most potent of these ANAs is C5a. Receptors for C5a are expressed on endothelial cells, mast cells, eosinophils, basophils, monocytes, neutrophils, smooth muscle cells, and epithelial cells. Binding of C5a to endothelial cells results in increased vascular permeability and expression of P-selectin, both of which promote leukocyte accumulation in tissue. Binding to neutrophils results in increased neutrophil motility, adhesion to endothelial cells, and production of reactive oxygen species. The overall result is the accumulation of cells at local sites in tissue where they can phagocytose and efficiently kill microbes.

The activation of complement also results in stimulation of the humoral immune system through the generation of C3d. B cells whose cell surface antibodies recognize complement-bound antigen are upregulated by the concurrent binding of C3d to CR2 on the B-cell surface. Opsonization by complement also facilitates antigen presentation to B cells by follicular dendritic cells.

COMPLEMENT RECEPTORS

There are several proteins that interact with complement and serve to mediate or regulate its functions. One set of these proteins is the complement receptors.

The type 1 complement receptor, CR1 (CD35), is a member of a family of proteins called *regulators of complement activation* (RCA), which share a common structure consisting of multiple short consensus repeats, also known as *complement control protein repeats*.[40] CR1 binds C3b or C4b and is expressed on peripheral blood cells, including monocytes, B and T lymphocytes, neutrophils, eosinophils, and erythrocytes, on follicular dendritic cells, and on keratinocytes.[50] On phagocytic cells, binding of CR1 to C3b or C4b results in phagocytosis of particles opsonized by complement fragments, as well as activation of microbicidal mechanisms in the phagocytic cells. On erythrocytes, binding of CR1 to C3b- or C4b-coated immune complexes results in transport of the complexes to the spleen and liver, where they are cleared from the circulation by phagocytes. Thus, CR1 serves as an important mediator of complement function. It also can serve as a downregulator of complement activation, as it is involved in the dissociation of C3 convertase complexes.

The type 2 complement receptor, CR2 (CD21), is also a member of the RCA family.[47] CR2 binds C3 fragments iC3b, C3dg, and C3d, as well as Epstein-Barr virus, interferon-α, and the immunoregulatory protein CD23. CR2 is expressed on subsets of B and T lymphocytes, basophils, mast cells, follicular dendritic cells, and some epithelial cells. On B cells, CR2 serves as a co-receptor for B-cell activation. When CR2 is bound by C3d, the level of B-cell activation is increased by orders of magnitude.[51] On dendritic cells, CR2 engagement results in a trapping of immune complexes in germinal centers. CR2 also appears to play a role in antigen presentation to T cells.

The type 3 complement receptor, CR3 (CD11b/CD18, Mac-1), is an integrin cell surface molecule expressed on monocytes, neutrophils, NK cells, and mast cells.[52] It functions to promote phagocytosis of microbes through binding to iC3b and through direct binding to microbes. It interacts with intercellular adhesion molecule 1 expressed endogenously on endothelial cells to stabilize the adhesion of leukocytes to endothelium, facilitating the recruitment of leukocytes from the circulation into tissue. It also may play a role in neutrophil apoptosis.

The type 4 complement receptor, CR4 (CD11c/CD18), is also an integrin cell surface molecule. It is expressed on monocytes, neutrophils, NK cells, and dendritic cells, and probably functions similarly to CR3.

REGULATION OF COMPLEMENT ACTIVATION

Molecules involved in the regulation of complement activation serve to downregulate the immune response once an immune response is no longer needed and to limit the immune response to the sites required, specifically protecting self from complement attack.

The C1 inhibitor (C1 INH) is a protease inhibitor that inhibits certain plasma serine proteases, including C1, kallikrein, and factor XII.[36] C1 exists as a complex of C1q and a tetramer of two C1r and two C1s fragments. When C1q

COMPLEMENT RECEPTORS AND REGULATORY PROTEINS

AT A GLANCE

- Some of the important effects of complement are mediated through binding of complement proteins to complement receptors. CR1 functions in phagocytosis, immune complex clearance, and down-regulation. CR2 is important in stimulation of humoral immunity. CR3 and -4 promote phagocytosis.
- Regulation of complement activation is provided by certain serum and cell surface proteins. Many of the regulatory cell surface proteins are expressed on human cells but not microbes, thus protecting human cells from complement damage.
- Some of the regulatory proteins downregulate complement activation by displacing components of the early steps of the cascade. These include C1 inhibitor, factor H, C4 binding inhibitor, decay accelerating factor, membrane co-factor protein, and CR1.

binds antibody, C1 INH can act to limit complement activation by binding to the C1rC1s tetramer, dissociating it from C1q and preventing downstream activation of the pathway.

Another major point of interaction of regulatory proteins is with bound C3b or C4b.[40] As mentioned earlier, the thioester group of unbound C3b or C4b is rapidly hydrolyzed, rendering these molecules inactive. For surface-bound C3b or C4b, inactivation occurs through the displacement of components of the alternative or classical pathway C3 convertase from C3b or C4b or through proteolysis of C3b or C4b. In the alternative pathway, inactivation of the C3 convertase complex, C3bBb, can take place through the displacement of Bb from C3b by the plasma protein factor H or the cell surface proteins decay accelerating factor (DAF, CD55), membrane co-factor protein (MCP, CD46), and CR1. These three cell surface proteins, all members of the RCA family, are expressed on human cells but not microbes, thereby allowing complement activation to proceed on microbes while protecting human cells from injury. Factor H preferentially binds cell surfaces with high levels of sialic acid, and the relative abundance of sialic acid on human cells but not microbes further focuses the downregulation of complement activation on human cells. In the classical and lectin pathways, the C3 convertase is C4bC2b. DAF, MCP, and CR1 can displace C2b from C4b, as can the plasma protein C4-binding protein (C4BP). Thus, the cell surface proteins DAF, MCP, and CR1 can dissociate the C3 convertases of both the alternative and the classical/lectin pathways, whereas the plasma proteins factor H and C4BP are specific for alternative or classical/lectin, respectively. Proteolysis of C3b or C4b is mediated by factor I, a plasma protein that requires co-factors for its activity. MCP, CR1, factor H, and C4BP can all serve as co-factors for factor I.

Regulation of complement at the late steps is mediated in part by CD59, a cell surface protein expressed on human cells but not microbes. It binds the C5b-8 complex and inhibits addition of C9, blocking formation of the MAC. Plasma S protein binds the C5b-7 complex and blocks its insertion into the cell membrane and also inhibits C9 polymerization.[53] Intact MACs may be removed from cells through shedding on membrane vesicles or by internalization and degradation.[43]

Carboxypeptidase N can remove the terminal arginine of C3a, C4a, and C5a and has been referred to as *ANA inactivator*.[54] Carboxypeptidase R has also been shown to remove the terminal arginine of C3a and C5a.[55]

COMPLEMENT AND DISEASE

Genetic Abnormalities of the Complement System

Deficiencies of complement cascade proteins, complement receptors, or complement regulatory proteins can lead to a variety of diseases.[56] Genetic deficiencies of complement have been associated primarily with increased risk for infection or autoimmunity. As examples, deficiencies of many complement components, particularly the early complement components C1–C4, have been associated with early-onset systemic lupus erythematosus (SLE), C3 deficiency has been associated with life-threatening pyogenic infections, and C5–C9 deficiencies have been associated with neisserial infections (reviewed in Chap. 144). Genetic deficiency of mannose-binding lectin is relatively common, with significantly low levels occurring in about 10 percent of Caucasians, and is associated with increased risk for infection and autoimmunity, including SLE.[57,58]

Altered expression of CR3 (CD11b/CD18) and CR4 (CD11c/CD18) occurs in leukocyte adhesion deficiency-1, a congenital disorder resulting from mutations in the gene encoding CD18. Mutation in CD18 also affects expression of CD11a/CD18 (leukocyte function–associated antigen-1). Patients with leukocyte adhesion deficiency-1 exhibit significant abnormalities of leukocyte adhesion and have recurrent infections (see Chap. 144).

Deficiency of the complement regulatory protein C1 INH causes angioneurotic edema as a result both of poorly regulated classical pathway activation and of excess bradykinin due to the actions of

COMPLEMENT AND DISEASE

AT A GLANCE

- Genetic deficiencies of complement components have been associated primarily with susceptibility to infection or autoimmunity. Genetic deficiencies of regulatory complement proteins may result in inappropriately prolonged complement activation, such as occurs with C1 inhibitor deficiency.
- Complement is associated with systemic lupus erythematosus through several possible mechanisms. These include increased risk of autoimmunity conferred by certain complement deficiencies, tissue damage resulting from autoantibody-induced complement activation, ineffective clearance of autoimmunity-promoting apoptotic debris, and failure to eliminate self-reactive B cells.
- Complement activation has been implicated in the pathogenesis of atherosclerosis, diabetic microvascular disease, and rejection of xenotransplants.
- Certain infectious agents have evolved mechanisms for evasion of destruction by complement, and some use complement receptors or regulatory proteins to gain entry into the cell.

kallikrein and factor XII. Angioedema may also occur if one has markedly reduced levels of the ANA inactivator, carboxypeptidase N[59] (see Chap. 37).

Deficiency of a protein required for the proper expression of DAF and CD59 on the cell surface is associated with paroxysmal nocturnal hemoglobinuria, a disease characterized by complement-mediated erythrocyte lysis.[60] Hemolytic-uremic syndrome has been associated with mutations in MCP, factor H, and factor I.[61] Factor H deficiency has also been associated with membranoproliferative glomerulonephritis.

Complement, Systemic Lupus Erythematosus, and Autoantibodies

Complement has been closely associated with SLE (see also Chap. 156), albeit in seemingly paradoxical ways.[62,63] Genetic deficiencies of complement components are associated with SLE, but some of the tissue injury seen in SLE appears to be mediated in part by complement activation. Thus, complement seems to be simultaneously protective and deleterious. These observations underscore the protean roles of complement in the immune system. Complement activation has the potential for causing tissue injury, but complement components may be important in clearance of immune complexes and apoptotic debris. Apoptotic bodies that are not cleared effectively may be able to trigger autoimmunity through presentation of normally sequestered autoantigens to the immune system. It has also been suggested that complement participates in eliminating self-reactive immature B cells, a further mechanism for a protective effect of complement in SLE.[63]

Altered expression of both CR1 and CR2 has been observed in patients with SLE.[64] In murine models of lupus, knockout mice lacking expression of CR1 and CR2 (located on the same gene in mice and produced through alternative splicing) have accelerated autoimmunity if the mice otherwise have the optimal genetic background. These findings indicate that the interaction of CR2 and C3d, important in B-cell response to antigen, is another factor that determines susceptibility to SLE.

Autoantibodies to complement components can result in or exacerbate disease.[65] Autoantibodies to C1q are relatively common in SLE and have been associated with more severe renal disease, possibly through an adverse affect on the clearance of immune complexes or apoptotic bodies.[66] C3 nephritic factor is an autoantibody to the C3 convertase, C3bBb, which acts to stabilize the complex. Its clinical significance is its association with membranoproliferative glomerulonephritis type II and partial lipodystrophy.

Complement and Vascular Disease

Complement activation has been implicated in the pathogenesis of atherosclerosis, as well as myocardial reperfusion injury after myocardial ischemia.[67,68] In the microvascular proliferative disease associated with diabetes, glycation, and thereby inactivation of CD59, may result in cellular proliferation due to nonlytic proliferative effects of MAC.[69] Complement activation has also been implicated in hyperacute rejection of xenotransplants due to the presence of natural antibodies to components of the endothelial cells of the transplanted organ, with resultant complement activation, endothelial cell injury, and intravascular coagulation. Pigs genetically engineered to overexpress MCP, DAF, or CD59 have been developed to circumvent this problem.[40]

Evasion or Subversion of Complement by Microbes

The observation that individuals with deficiencies of components of the late stages of complement activation are at increased risk for only a limited set of infections illustrates that infectious agents have evolved means of evading destruction by complement. Gram-positive bacteria have thick cell walls that are difficult to penetrate by MAC.[36] Group A streptococcus M protein binds factor H, which downregulates complement activation. A protein of vaccinia virus acts as a cofactor for factor I, leading to proteolysis of C3b and C4b. In human immunodeficiency virus (HIV) infection, the inclusion of downregulatory molecules of the complement system into the viral or host cell membrane allows HIV to evade complement-mediated destruction.[70] DAF can be subsumed into the HIV virus membrane upon budding from infected human cells, and factor H can bind to HIV surface glycoproteins on infected human cells.

The complement system has been subverted by certain infectious agents for entry into the cell. Epstein-Barr virus penetrates B cells via binding to CR2 on the B-cell surface.[36] Measles virus binds to cells via MCP. Mycobacteria make C4-like molecules that bind C2a and then cleave C3. The deposition of C3b on the mycobacterial cell membrane leads to its uptake into macrophages, where it exists as an intracellular parasite.

CHAPTER 37

Urticaria and Angioedema

Allen P. Kaplan

Urticaria is defined as a skin lesion consisting of a wheal-and-flare reaction in which localized intracutaneous edema (wheal) is surrounded by an area of redness (erythema) that is typically pruritic. Individual hives can last from as briefly as 30 minutes to as long as 36 hours. They can be as small as a millimeter or 6 to 8 inches in diameter (giant urticaria). They blanch with pressure as the dilated blood vessels are compressed, which also accounts for the central pallor of the wheal. The dilated blood vessels and increased permeability that characterize urticaria are present in the superficial dermis and involve the venular plexus in that location. Angioedema can be caused by the same pathogenic mechanisms as urticaria, but the pathology is in the deep dermis and subcutaneous tissue and swelling is the major manifestation. The overlying skin may be erythematous or normal. There is less pruritus (fewer type C nerve endings at the deeper cutaneous levels), but pain or burning may be present.

EPIDEMIOLOGY

Urticaria and angioedema are common. Age, race, sex, occupation, geographic location, and season of the year can be implicated in urticaria and angioedema only insofar as they may contribute to exposure to an eliciting agent. Of a group of college students, 15 percent to 20 percent reported having experienced urticaria, whereas 1 percent to 3 percent of the patients referred to hospital dermatology clinics in the United Kingdom noted urticaria and angioedema. In the National Ambulatory Medical Care Survey data for 1990 to 1997 in the United States, women accounted for 69 percent of patient visits. There was a bimodal age distribution among patients, with peaks at birth to 9 years and at 30 to 40 years.[1]

Urticaria/angioedema is considered to be acute if the condition lasts less than 6 weeks. Most acute episodes are due to adverse reactions to medications or foods or, in children, to viral illnesses. Episodes of urticaria/angioedema persisting beyond 6 weeks are considered chronic and are divided into two major subgroups, chronic autoimmune urticaria (45 percent) and chronic idiopathic urticaria (55 percent), which have a combined incidence in the general population of 0.5 percent.[2] Physically induced urticaria/angioedema is not included in the definition. Various types of physical urticaria/angioedema may last for years, but the individual lesions last fewer than 2 hours (except in delayed pressure urticaria) and are intermittent. Whereas 85 percent of children experience urticaria in the absence of angioedema, 40 percent of adult patients with urticaria also experience angioedema.

Approximately 50 percent of patients with chronic urticaria (with or without angioedema) are free of lesions within 1 year, 65 percent within 3 years, and 85 percent within 5 years; fewer than 5 percent have lesions that last for more than 10 years. Angioedema alters the natural history, and only 25 percent of patients who also have angioedema experience resolution of lesions within 1 year. There are no data regarding the remission rate in patients with only angioedema. The hereditary group of disorders is considered to be lifelong once the diagnosis becomes clinically manifest.

PATHOGENESIS

Mast Cell and Histamine Release

The mast cell is the major effector cell in most forms of urticaria and angioedema, although other cell types undoubtedly contribute. Cutaneous mast cells adhere to fibronectin and laminin through the very late activation (VLA) β_1 integrins VLA-3, VLA-4, and VLA-5 and to vitronectin through the $\alpha_v\beta_3$ integrin. Cutaneous mast cells, but not those from other sites, release histamine in response to compound 48/80, C5a, morphine, and codeine. The neuropeptides substance P (SP), vasoactive intestinal peptide (VIP), and somatostatin (but not neurotensin, neurokinins A and B, bradykinin, or calcitonin gene-related peptide), activate mast cells for histamine secretion. Dermal microdialysis studies of the application of SP on skin indicate that it induces histamine release only at 10^{-6} *M*, which suggests that after physiologic nociceptor activation, SP does not contribute significantly to histamine release.[3] Not all potential biologic products are generated when cutaneous mast cells are stimulated. For example, SP releases histamine from cutaneous mast cells above 10^{-6} *M* but does not induce prostaglandin D_2 (PGD_2). Vascular permeability in skin is produced predominantly by H_1 histamine receptors (85 percent); H_2 histamine receptors account for the remaining 15 percent.

The current hypothesis regarding cellular infiltration that follows mast cell degranulation suggests that the release of mast cell products (histamine, leukotrienes, cytokines, chemokines) leads to alterations in vasopermeability, upregulation of adhesion molecules on endothelial cells, and rolling and attachment of blood leukocytes, followed by chemotaxis and transendothelial cell migration.

Various forms of physical urticaria/angioedema have provided experimental models for the study of urticaria/

URTICARIA AND ANGIOEDEMA AT A GLANCE

- Occurs acutely at some time in 20 percent of the population; incidence of chronic urticaria/angioedema is approximately 0.5 percent.
- Acute urticaria/angioedema is caused by drugs, foods, occasionally infection in association with immunoglobulin E–dependent mechanisms (allergy), or metabolic factors.
- Chronic urticaria/angioedema is an autoimmune disorder in 45 percent of patients.
- In the absence of urticaria, angioedema can be due to overproduction or impaired breakdown of bradykinin.
- Treatment of acute urticaria/angioedema relies on antihistamines and short courses of corticosteroids, and identification and elimination of endogenous and exogenous causes.
- Treatment of C1 inhibitor deficiency includes androgenic agents, antifibrinolytic agents, and C1 inhibitor (C1 INH) concentrates. Fresh frozen plasma and C1 INH concentrate can abort acute episodes.
- Treatment of physical urticaria/angioedema includes high-dose antihistamine prophylaxis, except for delayed-pressure urticaria.
- Treatment of chronic idiopathic or autoimmune urticaria/angioedema includes antihistamines (non-sedating and sedating preparations), low-dose daily or alternate day corticosteroids, or cyclosporine.

angioedema by allowing the observation of the elicited clinical response, examination of lesional and normal skin biopsy specimens, assay of chemical mediators released into the blood or tissues, and characterization of peripheral leukocyte responses.[6,7] The intracutaneous injection of specific antigen in sensitized individuals has provided an experimental model for analysis of the role of immunoglobulin E (IgE) and its interaction with the mast cell. In many subjects, the challenged cutaneous sites demonstrate a biphasic response, with a transient, pruritic, erythematous wheal-and-flare reaction followed by a tender, deep, erythematous, poorly demarcated area of swelling that persists for up to 24 hours. This is the late-phase response with recruitment of variable numbers of neutrophils, prominent eosinophils, monocytes, small numbers of basophils, and $CD4^+$ T lymphocytes of the T helper 2 (Th2) subclass.[8]

Autoimmunity and Chronic Urticaria

The first suggestion that patients with chronic urticaria and angioedema might have an autoimmune diathesis was the observation that there is an increased incidence of antithyroid antibodies in such patients relative to the incidence in the population at large.[9] These include antimicrosomal (peroxidase) and antithyroglobulin antibodies, as seen in patients with Hashimoto thyroiditis.[10] Patients may have clinical hypothyroidism, but a small number might be hyperthyroid if inflammation is at an early stage when thyroid hormone is released into the circulation. This atypical presentation should be distinguished from the occasional case of Graves disease. Nevertheless, most patients are euthyroid. The incidence of antithyroid antibodies in patients with chronic urticaria, as reported in the literature, varies between 15 percent and 24 percent,[11,12] but the most recent data are closer to the latter figure[12] and demonstrate segregation of antithyroid antibodies with chronic autoimmune urticaria rather than chronic idiopathic urticaria. The association is, however, not absolute. The incidence in the autoimmune subgroup was 27 percent and the incidence in the chronic idiopathic urticaria subgroup was 11 percent, whereas the incidence in the population at large is 7 percent to 8 percent. Gruber et al. (1988)[13] considered the possibility that patients might have circulating anti-IgE antibodies that are functional and did indeed find these in 5 percent to 10 percent of patients. Grattan et al.[14,15] sought antibodies reactive with skin mast cells by performing an autologous skin test and found a 30 percent incidence of positive reactions in patients with chronic urticaria. There were only rare positive reactions in healthy control subjects or patients with other forms of urticaria. Subsequently, this level of positivity was shown by Hide et al.[16] to be due to an IgG antibody reactive with the α subunit of the IgE receptor; in addition, a 5 percent to 10 percent incidence of functional anti-IgE antibodies was confirmed.[17]

Functional Assays of the Anti–Immunoglobulin E Receptors

Assays for anti-IgE receptor antibody have included in vivo methods and in vitro assays. The autologous skin test,[14,18] provided one of the first clues that a subset of patients with chronic urticaria have an autoimmune disorder. Basophils are frequently used as an in vitro surrogate for mast cells, and secretion of histamine as a result of incubation with patient sera or purified IgG was readily demonstrated[19–21] but was not observed if the source of basophils was a "nonreleaser"—that is, basophils with an abnormality in the signal transduction molecules lyn or syc, which are unresponsive to signals through the IgE receptor but are normally responsive to other secretagogues, such as the cytokine monocyte chemoattractant protein-1.[22] The incidence of a positive assay result was generally higher than that observed with the autologous skin test; reported values varied between 35 percent and 50 percent.[19,21,23] Absorption of sera with cloned α subunit decreased the percentage of histamine release as the amount of added α subunit was increased,[22] which confirmed reactivity with this receptor subunit. The assay could be made more sensitive by preincubating basophils with interleukin 3 (IL-3),[24] although the percentage of positive reactions was not significantly affected. Release of leukotriene C4 and IL-3 along with histamine was also demonstrable.[25,26] Although more cumbersome, activation of cutaneous mast cells could also be performed in vitro by using either thin skin slices[27] or partially purified mast cells derived from foreskin samples.[28]

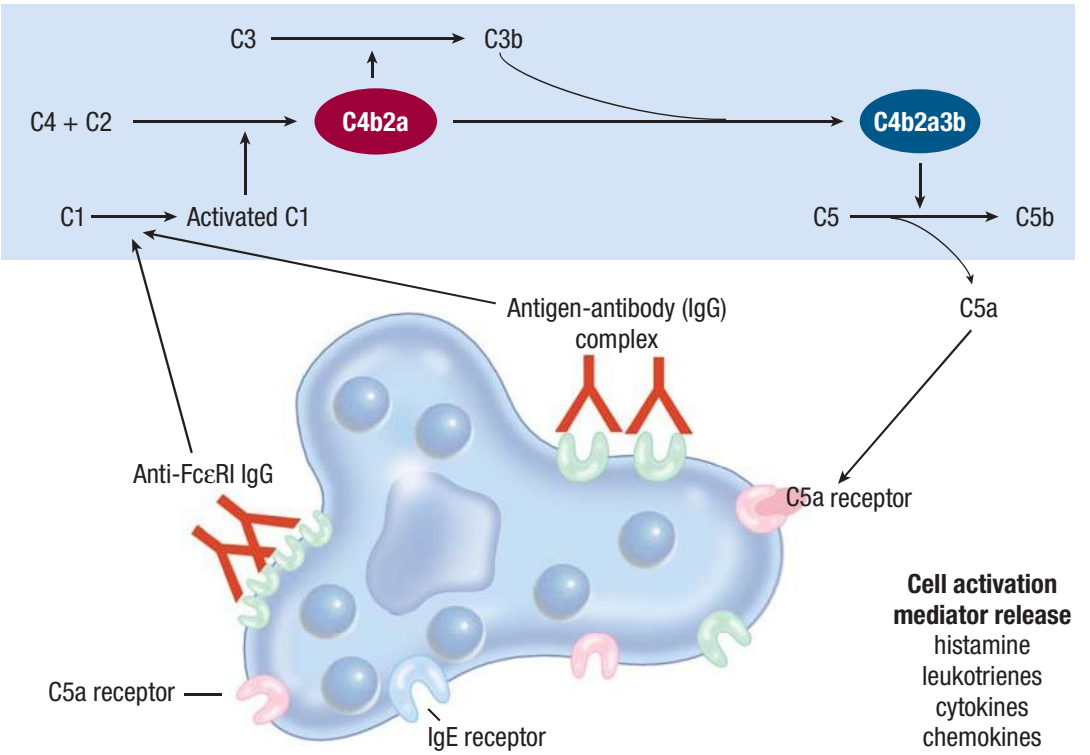
Binding Assays for Antireceptor Antibody

Attempts to quantitate IgG antibody to the α subunit have, in general, been unsuccessful. Initial attempts to demonstrate the presence of antibody by means of immunoblotting[23,29] have not proved useful, because positive reactions can be seen in other autoimmune disorders[29] or occasionally in sera[23] from subjects with no history of urticaria. In addition, studies of the relationship of a positive immunoblot result with histamine release did not yield a significant correlation[22]; sera with a positive blot result but negative histamine release were frequently seen. However, sera with positive histamine release and a negative blot result did have demonstrable IgG anti-α because absorption of such sera with the α subunit inhibited histamine release. Thus lack of sensitivity of the immunoblot explained part of the discrepancy, but the cause of the false-positive blot results was not apparent.

Subclass analysis of the pathogenic IgG has been helpful in further delineating the relationship (or lack thereof) between binding assays and functional methods. An early report suggested that much of the antireceptor antibody exists within the IgG1 and IgG3 subclasses, but these data were based on immunoblot analysis.[29] Thus, we used affinity chromatography to purify IgG subclasses from the sera of patients with chronic urticaria to determine which have functional antireceptor antibody. When we isolated IgG2 antibody from nine patients with chronic urticaria, none of them released histamine from human basophils, irrespective of whether a positive IgG2 anti-α antibody immunoblot result was seen. Much of the histamine release does appear to be due to IgG1 and IgG3, and rarely to IgG4.[30]

Role of Complement

The notion that complement might contribute to the histamine release observed with sera from patients with chronic urticaria was suggested by studies in which complement depletion or inactivation appeared to diminish histamine release.[20,29] A series of reports[22,28,34] documented not only a role for complement but also more specifically activation of the classical pathway and generation of C5a. First, we demonstrated that the addition of purified patient IgG to normal serum (as a source of complement) but not sera deficient in C2 or C5 augmented cutaneous mast cell histamine release.[28] This was confirmed with basophils.[22,34] We could also reconstitute C5-deficient serum with purified C5 to recover the augmentation of histamine release provided by serum. Then we



▲ **FIGURE 37-1** Schematic diagram of the activation of cutaneous mast cells by immunoglobulin G (IgG) antireceptor antibody, followed by activation of complement, release of C5a, and augmentation of mast cell release.

demonstrated inhibition of the complement contribution to histamine release by using an antibody to the C5a receptor.[34] It is not clear why the presence of a functional anti-IgE receptor would cause symptoms limited to the skin, but among the differences between pulmonary and cutaneous mast cells is the absence of C5a receptors on lung mast cells. On the other hand, it is also not clear why the IgG2 anti-IgE receptor antibody, which is often demonstrable by means of immunoblotting, does not activate basophils or cutaneous mast cells, because IgG2 anti-FcεRIα should cross-link α subunits, as might any IgG subclass antibody directed to the α subunit. The difference might have to do with antibody affinity or differing α subunit epitopes with which these antibodies react. The geometry of binding is also a factor, because the Fc regions of two adjacent IgG molecules must each be able to bind to one of the globular heads of C1Q to initiate complement activation (Fig. 37-1). It is theoretically possible to have binding of IgG to the IgE receptor in the absence of cross-linking (e.g., the receptors are too far apart) and still observe histamine release if the two Fc regions are sufficiently close together to activate C1. If receptors are sparse, the antibody can bind without activating either the cells or complement, whereas receptor saturation with IgE might preclude binding. These considerations may account for the marked heterogeneity in patient manifestations and severity.

Cellular Infiltrate

Mast cell degranulation initiates the inflammatory process in autoimmune chronic urticaria and is assumed also to do so in idiopathic chronic urticaria. Evidence for increased numbers of mast cells in chronic urticaria has been presented,[35,36] but there are also publications indicating no significant differences from normal[37]; these studies did not discriminate the autoimmune from the idiopathic groups. However, no alternative mechanisms for mast cell degranulation in the idiopathic groups have been suggested to date. Yet the histology of the lesions in the two groups differs in only minor ways. Common to all biopsy specimens is a perivascular infiltrate that surrounds small venules within the superficial and deep venular plexus, with a prominence of $CD4^+$ T lymphocytes and monocytes and virtually no B cells.[35,38] Granulocytes are quite variable but are plentiful if the lesion undergoes biopsy early in its development. Neutrophils and eosinophils are both present,[39,40] although the degree of eosinophil accumulation varies greatly.[38] Even when eosinophils are not evident, major basic protein can be identified within lesions (in at least two-thirds of patients), which most likely represents evidence of prior eosinophil degranulation.[41] The presence of basophils has also been demonstrated by using an antibody (BB1) that is specific for this cell type.[40] Thus the infiltrate resembles that of an allergic late-phase reaction, as suggested previously.[42] Endothelial cell activation is suggested by the presence of intercellular adhesion molecule 1 and E-selectin in biopsy specimens of urticarial lesions.[43] Sources of chemokines include the mast cell and the activated endothelial cell; the latter cells are stimulated not only by cytokines or monokines, such as IL-4, IL-1, and tumor necrosis factor-α (TNF-α) but also by the vasoactive factors—for example, histamine and leukotrienes released from activated mast cells.[44]

Basophil Releasability

The basophils of patients with chronic urticaria have been shown to be hyporesponsive to anti-IgE, an observation made by Kern and Lichtenstein[47] long before there were any clues to the pathogenesis of this disorder. These findings were confirmed[48] and appeared to be associated with basopenia[49] and to segregate to the autoimmune subgroup. One obvious interpretation is that there is in vivo desensitization of

basophils in the presence of circulating anti-IgE receptor. However, we have found a paradoxical result when the isolated basophils of patients with chronic urticaria were activated and compared with the basophils of healthy control subjects. Although the basophils of the patients with urticaria were clearly less responsive to anti-IgE, they demonstrated augmented histamine release when incubated with serum, and it did not matter whether the serum was taken from normal individuals, from other patients with chronic urticaria, or was their own (autologous).[50]

Bradykinin: Role in Angioedema

Kinins are low-molecular-weight peptides that participate in inflammatory processes by virtue of their ability to activate endothelial cells and, as a consequence, lead to vasodilatation, increased vascular permeability, production of nitric oxide, and mobilization of arachidonic acid. Kinins also stimulate sensory nerve endings, causing a burning dysesthesia. Thus the classical parameters of inflammation (i.e., redness, heat, swelling, and pain) can all result from kinin formation. Bradykinin is the best characterized of this group of vasoactive substances.

There are two general pathways by which bradykinin is generated. The simpler of the two has only two components: an enzyme tissue kallikrein[52] and a plasma substrate, low-molecular-weight kininogen.[53,54] Tissue kallikrein is secreted by many cells throughout the body; however, certain tissues produce particularly large quantities. These include glandular tissues (salivary and sweat glands and pancreatic exocrine gland) and the lung, kidney, intestine, and brain.

The second pathway for bradykinin formation is far more complex and is part of the initiating mechanism by which the intrinsic coagulation pathway is activated (see eFig 37-1.1 in online edition).[55] Factor XII is the initiating protein that binds to certain negatively charged macromolecular surfaces and autoactivates (autodigests) to form factor XIIa.[56,57] This is synonomous with Hageman factor as designated in the figure. There are two plasma substrates of factor XIIa—namely, prekallikrein[58] and factor XI[59,60]—and each of these circulates as a complex with high-molecular-weight kininogen (HK).[61,62] These complexes also attach to initiating surfaces, and the major attachment sites are on two of the domains of HK, which thereby places both prekallikrein and factor XI in optimal conformation for cleavage to kallikrein (plasma kallikrein) and factor XIa, respectively. It is important to note that plasma kallikrein and tissue kallikrein are separate gene products and have little amino acid sequence homology, although they have related functions (i.e., cleavage of kininogens). Tissue kallikrein prefers low-molecular-weight kininogen but is capable of cleaving HK, whereas plasma kallikrein cleaves HK exclusively. The two kininogens have an identical amino acid sequence starting at the N-terminus and continuing to 12 amino acids beyond the bradykinin moiety[54] but differ in C-terminal domains because of alternative splicing at the transcription level.[63,64]

CLINICAL FINDINGS

Circumscribed, raised, erythematous, usually pruritic, evanescent areas of edema that involve the superficial portion of the dermis are known as *urticaria* (Fig. 37-2); when the edematous process extends into the deep dermis and/or subcutaneous and submucosal layers, it is known as *angioedema*. Urticaria and angioedema may occur in any location together or individually. Angioedema commonly affects the face or a portion of an extremity, may be painful but not pruritic, and may last several days. Involvement of the lips, cheeks, and periorbital areas is common, but angioedema also may affect the tongue, pharynx, or larynx. The individual lesions of urticaria arise suddenly, rarely persist longer than 24 to 48 hours, and may continue to recur for indefinite periods. They are highly pruritic.

▲ **FIGURE 37-2** Urticaria and angioedema. This patient has urticaria occurring on the face, neck, and upper trunk with angioedema about the eyes.

Immunologic: Immunoglobulin E– and Immunoglobulin E Receptor–Dependent Urticaria/Angioedema

ATOPIC DIATHESIS Episodes of acute urticaria/angioedema that occur in individuals with a personal or family history of asthma, rhinitis, or eczema are presumed to be IgE dependent. In clinical practice, however, urticaria/angioedema infrequently accompanies an exacerbation of asthma, rhinitis, or eczema. The prevalence of chronic urticaria/angioedema is not increased in atopic individuals.

SPECIFIC ANTIGEN SENSITIVITY Common examples of specific antigens that provoke urticaria/angioedema are foods such as shellfish, nuts, milk, eggs, and chocolate; drugs and therapeutic agents, notably penicillin; aeroallergens; and Hymenoptera venom (see Fig. 37-2). Urticaria in patients with helminthic infestations has been attributed to IgE-dependent processes; however, proof of this relationship is often lacking. Specific allergens and non-specific stimuli may activate local reactions termed *recall urticaria* at sites previously injected with allergen immunotherapy.

Physical Urticaria/Angioedema[6,7]

DERMOGRAPHISM Dermographism is the most common form of physical urticaria and is the one most likely to be confused with chronic urticaria. A lesion appears as a linear wheal with a flare at a site at which the skin is briskly stroked with a firm object (Fig. 37-3). A transient wheal appears rapidly and usually fades within 30 minutes; however, the patient's normal skin is typically pruritic, so that an itch-scratch sequence may appear. The prevalence of

▲ **FIGURE 37-3** Topical dermatographic response to scratching the skin.

dermographism in the general population was reported as 1.5 percent and 4.2 percent, respectively, in two studies, and its prevalence in patients with chronic urticaria is 22 percent. It is not associated with atopy. The peak prevalence occurs in the second and third decades. In one study, the duration of dermographism was found to be longer than 5 years in 22 percent of individuals and longer than 10 years in 10 percent.

Elevations in blood histamine levels have been documented in some patients after experimental scratching, and increased levels of histamine,[74] tryptase, SP, and VIP, but not calcitonin gene–related peptide, have been detected in experimental suction-blister aspirates. The dermographic response has been passively transferred to the skin of normal subjects with serum or IgE.[75]

In delayed dermographism lesions develop 3 to 6 hours after stimulation, either with or without an immediate reaction, and last 24 to 48 hours. The eruption is composed of linear red indurated wheals. This condition may be associated with delayed pressure urticaria, and these two may, in fact, represent the same entity. Cold-dependent dermographism is a condition characterized by marked augmentation of the dermatographic response when the skin is chilled.[76]

PRESSURE URTICARIA Delayed pressure urticaria appears as erythematous, deep, local swellings, often painful, that arise from 3 to 6 hours after sustained pressure has been applied to the skin.[77,78] Spontaneous episodes are elicited on areas of contact after sitting on a hard chair, under shoulder straps and belts, on the feet after running, and on the hands after manual labor. The peak prevalence occurs in the third decade. Delayed pressure urticaria may occasionally be associated with fever, chills, arthralgias, and myalgias, as well as with an elevated erythrocyte sedimentation rate and leukocytosis. In one study, it accompanied chronic urticaria in 37 percent of patients. This is far more commonly seen than pressure urticaria with no spontaneously occurring hives. An IgE-mediated mechanism has not been demonstrated; however, histamine and IL-6 have been detected in lesional experimental suction-blister aspirates and in fluid from skin chambers, respectively.[4,79,80]

VIBRATORY ANGIOEDEMA Vibratory angioedema may occur as an acquired idiopathic disorder, in association with cholinergic urticaria, or after several years of occupational exposure to vibration.[81] It has been described in families with an autosomal dominant pattern of inheritance.[82] The heritable form often is accompanied by facial flushing. An increase in the level of plasma histamine was detected during an experimental attack in patients with the hereditary form and in patients with acquired disease.[81,82] A typical symptom is hives across the back when toweling off after a shower (in the absence of dermatographism).

COLD URTICARIA There are both acquired and inherited forms of cold urticaria/angioedema; however, the familial form is rare. Idiopathic or primary acquired cold urticaria may be associated with headache, hypotension, syncope, wheezing, shortness of breath, palpitations, nausea, vomiting, and diarrhea. Attacks occur within minutes after exposures that include changes in ambient temperature and direct contact with cold objects. The elicitation of a wheal after the application of ice has been called a diagnostic cold contact test (Fig. 37-4). If the entire body is cooled, as in swimming, hypotension and syncope, which are potentially lethal events (causing drowning), may occur. In rare instances, acquired cold urticaria has been associated with circulating cryoglobulins, cryofibrinogens, cold agglutinins, and cold hemolysins, especially in children with infectious mononucleosis.[83–85]

Passive transfer of cold urticaria by intracutaneous injection of serum or IgE to the skin of normal recipients has been documented.[86,87] Histamine, chemotactic factors for eosinophils and neutrophils, PGD_2, cysteinyl leukotrienes, platelet-activating factor, and TNF-α have been released into the circulation after experimental challenge.[88–94] Histamine, SP, and VIP, but not calcitonin gene–related peptide, have been detected in experimental suction-blister aspirates. Histamine has been released in vitro from chilled skin biopsy specimens that have been re-warmed.[95] Neutrophils harvested from the blood of an experimentally cold-challenged arm manifested an impaired chemotactic response suggesting in vivo desensitization. Whereas complement has no role in primary acquired cold urticaria, cold challenge of patients with cold urticaria who have circulating immune complexes (such as cryoglobulins) can provoke a cutaneous necrotizing venulitis with complement activation.[96–99]

▲ **FIGURE 37-4** Positive ice cube test results in a patient with cold urticaria. The peaked left corner of the urticarial lesion is the track of ice water running down the arm.

Rare forms of acquired cold urticaria that have been described mainly in case reports include systemic cold urticaria,[76] localized cold urticaria,[100] cold-induced cholinergic urticaria, cold-dependent dermographism,[76] and localized cold reflex urticaria.[101,102] Two forms of dominantly inherited cold urticaria have been described. Familial cold urticaria has been termed *familial cold autoinflammatory syndrome* and is considered a type of periodic fever.[103] It is a disorder showing an autosomal dominant pattern of inheritance with a genetic linkage to chromosome band 1q44. The responsible gene has been identified as CIASI, which codes for a protein involved in regulation of inflammation and apoptosis.[104] The eruption occurs as erythematous macules and infrequent wheals and is associated with burning or pruritus. Fever, headaches, conjunctivitis, arthralgias, and a neutrophilic leukocytosis are features of attacks. The delay between cold exposure and onset of symptoms is 2.5 hours, and the average duration of an episode is 12 hours. Renal disease with amyloidosis occurs infrequently. Skin biopsy specimens show mast cell degranulation and an infiltrate of neutrophils. Results of the cold contact test and passive transfer with serum have been negative. Serum levels of IL-6 and granulocyte colony-stimulating factor were elevated in one patient. Other studies suggest a pathogenic role for IL-1. Delayed cold urticaria occurs as erythematous, edematous, deep swellings that appears 9 to 18 hours after cold challenge. Lesional biopsy specimens show edema with minimal numbers of mononuclear cells; mast cells are not degranulated; and neither complement proteins nor immunoglobulins are detected. Cold immersion does not release histamine, and the condition cannot be passively transferred.

CHOLINERGIC URTICARIA Cholinergic urticaria develops after an increase in core

▲ **FIGURE 37-5** Lesions of cholinergic urticaria observed in a patient after 15 minutes of exercise in a warm room.

body temperature, such as during a warm bath, prolonged exercise, or episodes of fever.[105] The highest prevalence is observed in individuals aged 23 to 28 years. The eruption appears as distinctive, pruritic, small, 1- to 2-mm wheals that are surrounded by areas of erythema (Fig. 37-5). Occasionally, the lesions may become confluent, or angioedema may develop. Systemic features include dizziness, headache, syncope, flushing, wheezing, shortness of breath, nausea, vomiting, and diarrhea. An increased prevalence of atopy has been reported. The intracutaneous injection of cholinergic agents, such as methacholine chloride, produces a wheal with satellite lesions in approximately one-third of patients.[106,107] Alterations in pulmonary function have been documented during experimental exercise challenge[108] or after the inhalation of acetylcholine, but most patients are asymptomatic.

A major sub-population of patients with cholinergic urticaria have a positive skin test result and in vitro histamine release in response to autologous sweat.[109] It is not clear whether or not this is IgE mediated, and any antigen present in sweat is unidentified. This is the same sub-population with a positive methacholine skin test result with satellite lesions and a non-follicular distribution of the wheals. The remaining patients had negative results on autologous sweat skin tests and no in vitro histamine release. Results of the methacholine skin test are negative for satellite lesions and the hives tend to be follicular in distribution.

Familial cases have been reported only in men in four families.[110] This observation suggests an autosomal dominant or sex-linked pattern of inheritance. One of these individuals had co-existing dermographism and aquagenic urticaria.

After exercise challenge, histamine and factors chemotactic for eosinophils and neutrophils are released into the circulation.[88,108] Tryptase has been detected in lesional suction-blister aspirates. The urticarial response has been passively transferred on one occasion; however, most other attempts to do so have been unsuccessful.

Cold urticaria and cholinergic urticaria are not uncommonly seen together,[111,112] and cold-induced cholinergic urticaria represents an unusual variant in which typical "cholinergic"-appearing lesions occur with exercise, but only if the person is chilled, for example, with exercise outside on a winter's day. The ice cube test and methacholine skin test both yield negative results.[113]

LOCAL HEAT URTICARIA Local heat urticaria is a rare form of urticaria in which wheals develop within minutes after exposure to locally applied heat. An increased incidence of atopy has been reported. Passive transfer has been negative. Histamine, neutrophil chemotactic activity, and PGD_2 have been detected in the circulation after experimental challenge.[114] A familial delayed form of local heat urticaria in which the urticaria occurred in 1 to 2 hours after challenge and lasted up to 10 hours has been described.

SOLAR URTICARIA Solar urticaria occurs as pruritus, erythema, wheals, and occasionally angioedema that develop within minutes after exposure to sun or artificial light sources. Headache, syncope, dizziness, wheezing, and nausea are systemic features. Most commonly, solar urticaria appears during the third decade.[115] In one study, 48 percent of patients had a history of atopy. Although solar urticaria may be associated with systemic lupus erythematosus and polymorphous light eruption, it is usually idiopathic. The development of skin lesions under experimental conditions in response to specific wavelengths has allowed classification into six sub-types; however, individuals may respond to more than one portion of the light spectrum. In type I, elicited by wavelengths of 285 to 320 nm, and in type IV, elicited by wavelengths of 400 to 500 nm, the responses have been passively transferred with serum, which suggests a role for IgE antibody. In type I, the wavelengths responsible are blocked by window glass.[116,117] Type VI, which is identical to erythropoietic protoporphyria, is due to ferrochelatase (heme synthase) deficiency (see Chap. 132).[118] There is evidence that an antigen on skin may become evident once the skin is irradiated with the appropriate wavelength of light, followed by complement activation and release of C5a.[119–121]

Histamine and chemotactic factors for eosinophils and neutrophils have been identified in blood after exposure of the affected individuals to ultraviolet A, ultraviolet B, and visible light.[122,123] In some individuals, uncharacterized serum factors with molecular weights ranging from 25 to 1000 kd, which elicit cutaneous wheal-and-erythema reactions after intracutaneous injection, have been implicated in the development of lesions.

EXERCISE-INDUCED ANAPHYLAXIS Exercise-induced anaphylaxis is a clinical symptom complex consisting of pruritus, urticaria, angioedema respiratory distress, and syncope that is distinct from cholinergic urticaria.[124–127] In most patients, the wheals are not punctate and resemble the hives seen in acute or chronic urticaria. The symptom complex is not readily reproduced by exercise challenges as is cholinergic urticaria. There is a high prevalence of an atopic diathesis. Some cases are food dependent—that is, exercise will lead to an anaphylaxis-like episode only if food was ingested within 5 hours of the exercise. The food dependency is subdivided into two groups; in the first the nature of the food eaten is not relevant, whereas in the second a specific food to which there is IgE-mediated hypersensitivity must be eaten for hives to appear.[128–131] Yet in these cases, eating the food without exercise does not result in urticaria. The food-dependent group is easier to treat because avoidance of food (or a specific food) for 5 to 6 hours before exercise prevents episodes. Cases not related to food require therapy for acute episodes and attempts to prevent episodes with high-dose antihistaminics or avoidance of exercise. Results of a questionnaire study of individuals who had had exercise-induced anaphylaxis for more than a decade[132] disclosed that the frequency of attacks had decreased in 47 percent and had stabilized in 46 percent. Forty-one percent had been free of attacks for 1 year. Rare familial forms have been described. In exercise-induced anaphylaxis, baseline pulmonary function test results are normal. Biopsy specimens show mast cell degranulation, and histamine and tryptase are released into the circulation when symptoms appear.

ADRENERGIC URTICARIA Adrenergic urticaria occurs as wheals surrounded by a white halo that develop during emotional stress. The lesions can be elicited by the intracutaneous injection of norepinephrine.

AQUAGENIC URTICARIA AND AQUAGENIC PRURITUS Contact of the skin with water of any temperature may result in pruritus alone or, more rarely, urticaria. The eruption consists of small wheals that are reminiscent of cholinergic urticaria. Aquagenic urticaria has been reported in more than one member in five families.[133] Aquagenic pruritus without urticaria is usually idiopathic but also occurs in elderly persons with dry skin and in patients with polycythemia vera, Hodgkin disease, myelodysplastic syndrome, and hypereosinophilic syndrome. Patients with aquagenic pruritus should be evaluated for the emergence of a hematologic disorder. After experimental challenge, blood histamine levels were elevated in subjects with aquagenic pruritus and with aquagenic urticaria. Mast cell degranulation was present in lesional tissues. Passive transfer was negative.

Contact Urticaria

Urticaria may occur after direct contact with a variety of substances. It may be IgE mediated or nonimmunologic. The transient eruption appears within minutes, and when it is IgE mediated, it may be associated with systemic manifestations. Passive transfer has been documented in some instances. Proteins from latex products are a prominent cause of IgE-mediated contact urticaria.[134] Latex proteins also may become airborne allergens, as demonstrated by allergen-loaded airborne glove powder used in inhalation challenge tests. These patients may manifest cross-reactivity to fruits, such as banana, avocado, and kiwi.[135] Associated manifestations include rhinitis, conjunctivitis, dyspnea, and shock. The risk group is dominated by biomedical workers and individuals with frequent contact with latex, such as children with spina bifida. Agents such as stinging nettles, arthropod hairs, and chemicals may induce release of histamine directly from mast cells.

Papular Urticaria

Papular urticaria occurs as episodic, symmetrically distributed, pruritic, 3- to 10-mm urticarial papules that result from a hypersensitivity reaction to the bites of insects such as mosquitoes, fleas, and bedbugs. This condition occurs mainly in children. The lesions tend to appear in groups on exposed areas such as the extensor aspects of the extremities.[136]

Urticaria/Angioedema Mediated by Bradykinin, the Complement System, or Other Effector Mechanisms

KININS AND C1 INHIBITOR DEFICIENCY C1 inhibitor (C1 INH) is the sole plasma inhibitor of factor XIIa and factor XIIf,[137,138] and it is one of the major inhibitors of kallikrein[139] as well as factor XIa.[140] Thus, in the absence of C1 INH, stimuli that activate the kinin-forming pathway will do so in a markedly augmented fashion; the amount of active enzyme and the duration of action of the enzymes are prolonged. C1 INH deficiency can be familial, in which there is a mutant C1 INH gene, or it can be acquired. Both the hereditary and acquired disorders have two sub-types. For the hereditary disorder, type 1 hereditary angioedema (HAE) (85 percent) is an autosomal dominant disorder with a mutant gene (often with duplication, deletions, or frameshifts) that leads to markedly suppressed C1 INH protein levels as a result of abnormal secretion or intracellular degradation.[141] Type 2 HAE (15 percent) is also a dominantly inherited disorder, typically with a point (missense) mutation that leads to synthesis of a dysfunctional protein.[142] The C1 INH protein level may be normal or even elevated, and a functional assay is needed to assess activity. The acquired disorder also has two forms, although they may overlap in some patients. One group is associated with B-cell lymphoma[143–145] or connective tissue disease,[146] in which there is consumption of C1 INH. Examples are systemic lupus erythematosus and cryoglobulinemia, in which complement activation is prominent, and B-cell lymphomas, in which immune complexes are formed by anti-idiotypic antibodies to monoclonal immunoglobulin expressed by the transformed B lymphocytes.[147] The second form is an autoimmune disorder with a circulating IgG antibody to C1 INH itself.[148–150] Acquired types have depressed C1q levels, whereas hereditary types do not, and depressed C4 levels characterize all forms of C1 INH deficiency. The acquired autoimmune subgroup shows a circulating 95-kd cleavage product of C1 INH because the antibody depresses C1 INH function yet allows cleavage by enzymes with which it usually interacts.[150–152] Research data indicate the presence of acquired type II C1 INH deficiency in patients usually considered to have acquired type 1 C1 INH deficiency; hence, an overlap syndrome occurs.

It is now clear that depletion of C4 and C2 during episodes of swelling[153,154] is a marker of complement activation but does not lead to release of a vasoactive peptide responsible for the swelling. Bradykinin is, in fact, the mediator of the swelling,[155–157] and the evidence in support of this conclusion is summarized below. Patients with HAE are hyper-responsive to cutaneous injection of kallikrein.[158] They have elevated bradykinin levels and low prekallikrein and HK levels during attacks of swelling.[159–161] The augmentation in complement activation seen at those times may be due to activation of C1r and C1s by factor XIIf.[162] The presence of kallikrein-like activity in induced blisters of patients with HAE also supports this notion,[163] as does the progressive generation of bradykinin on incubation of HAE plasma in plastic (non–contact-activated) tubes[155,156] as well as the presence of activated factor XII and cleaved HK levels seen during attacks.[164] One unique family has been described in which there is a point mutation in the C1 INH (A1a 443→Val) leading to an inability to inhibit complement but normal inhibition of factor XIIa and kallikrein.[165,166] No family member with this type 2 mutation has had angioedema,[165] although complement activation is present. In some studies plasma bradykinin levels have been shown to be elevated during attacks of swelling in both hereditary and acquired C1 INH deficiency,[160] and local bradykinin generation has been documented at the sites of swelling.[167] It is not known whether bradykinin generation is predominantly seen in the fluid phase, occurs along cell (endothelial) surfaces, or both. Fig. 37-6 depicts a patient with facial swelling due to HAE. Fig. 37-7 is a diagram depicting the steps in the bradykinin-forming cascade that are inhibitable by C1 INH.

An estrogen-dependent form of HAE has been recognized. One of the first reports involved a single family with seven affected individuals in three generations, which suggests a hereditary (autosomal dominant) pattern.[168] Clinical features include angioedema without urticaria, laryngeal edema, and abdominal pain with vomiting. Attacks occur during pregnancy and with the administration of exogenous estrogens.

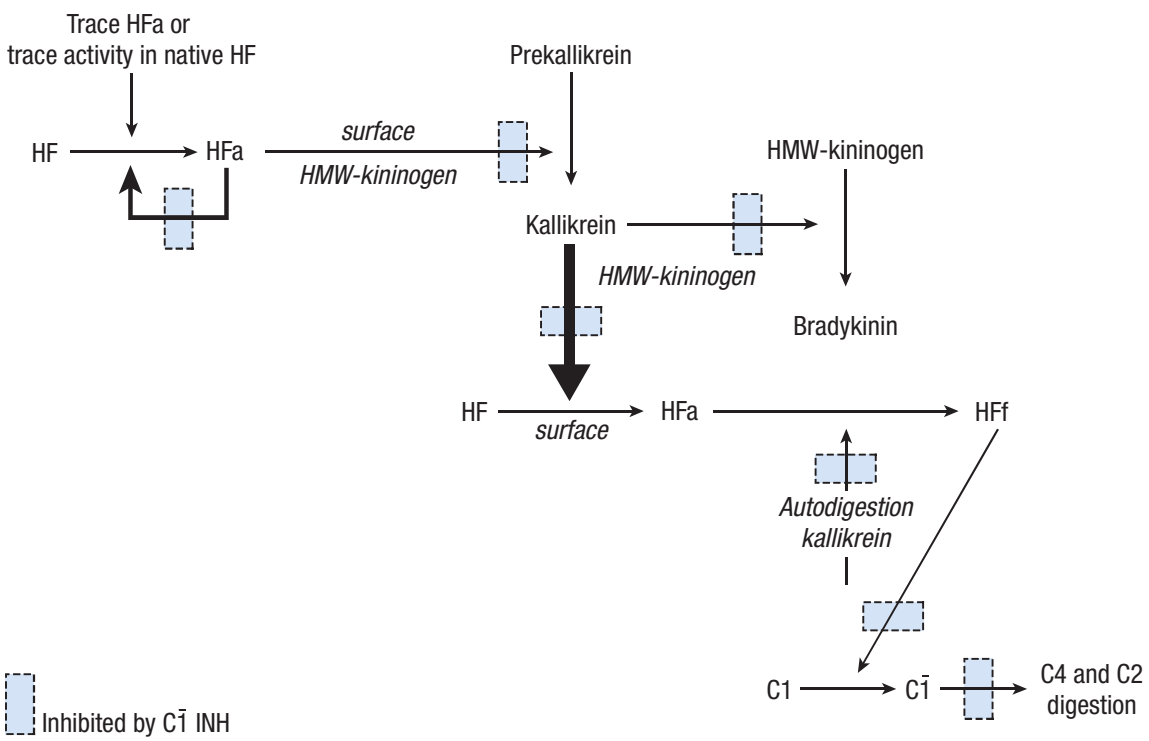
▲ **FIGURE 37-6** Hereditary angioedema. Extensive involvement (**A**) is to be contrasted with the patient's normal facies (**B**).

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS Angioedema has been associated with the administration of angiotensin-converting enzyme (ACE) inhibitors.[169] The frequency of angioedema occurring after ACE inhibitor therapy is 0.1 percent to 0.7 percent. Angioedema develops during the first week of therapy in up to 72 percent of affected individuals and usually involves the head and neck, including the mouth, tongue, pharynx, and larynx. Urticaria occurs only rarely. Cough and angioedema of the gastrointestinal tract are associated features. It has been suggested that therapy with ACE inhibitors is contraindicated in patients with a prior history of idiopathic angioedema, HAE, and acquired C1 INH deficiency.[170] It appears that this swelling is also a consequence of elevated levels of bradykinin[160]; however, the accumulation of bradykinin is due to a defect in degradation rather than excessive production. ACE, being identical to kininase II, is the major enzyme responsible for bradykinin degradation (see eFig. 37-1.1 in on-line edition), and although it is present in plasma, the vascular endothelium of the lung appears to be its major site of action.[171] The action of ACE always leads to the formation of degradation products with no activity, whereas kininase I alone yields the des-arg products, which are capable of stimulating B1 receptors.

The excessive accumulation of bradykinin implies that production is ongoing, for example, that some event leads to activation of the plasma cascade, or that release of tissue kallikrein is present so that faulty inactivation of bradykinin leads to swelling. Continuous turnover of the cascade is implied by data demonstrating activation along the surface of cells and cellular expression or secretion of a prekallikrein activator other than factor XIIa.[172,173]

Urticarial Vasculitis

Chronic urticaria and angioedema may be manifestations of cutaneous necrotizing venulitis, which is known as *urticarial venulitis* (see Chap. 164).[174,175] Associated features include fever, malaise, arthralgia, abdominal pain, and less commonly conjunctivitis, uveitis, diffuse glomerulonephritis, obstructive and restrictive pulmonary disease, and benign intracranial hypertension.



▲ **FIGURE 37-7** Pathways for the formation of bradykinin, with indication of all steps inhibitable by C1 inhibitor (INH) as well as complement activation by means of Hageman factor fragment (factor XIIf) (HFf). HF = Hageman factor (factor XII); HFa = activated Hageman factor (factor XIIa); HMW = high-molecular-weight.

Serum Sickness

Serum sickness, which was defined originally as an adverse reaction that resulted from the administration of heterologous serum to humans, may similarly occur after the administration of drugs. Serum sickness occurs 7 to 21 days after the administration of the offending agent and is manifested by fever, urticaria, lymphadenopathy, myalgia, arthralgia, and arthritis. Symptoms are usually self-limited and last 4 to 5 days. More than 70 percent of patients with serum sickness experience urticaria, which may be pruritic or painful. The initial manifestation of urticaria may appear at the site of injection.

Reactions to the Administration of Blood Products

Urticaria/angioedema may develop after the administration of blood products. It usually is the result of immune complex formation and complement activation that leads directly to vascular and smooth muscle alterations and indirectly via anaphylatoxins to mast cell mediator release. Aggregated IgG may also be responsible for human reactions to immunoglobulins as evidenced by the fact that the administration of IgG from which aggregates have been removed is not associated with urticaria or anaphylaxis.

An uncommon mechanism for the development of urticaria after the administration of blood products is the transfusion of IgE of donor origin directed toward an antigen to which the recipient is subsequently exposed. Another mechanism may be the transfusion of a soluble antigen present in the donor preparation into a previously sensitized recipient.

Infections

Episodes of acute urticaria can be associated with upper respiratory tract viral infections, most commonly in children.[185] The acute urticaria resolves within 3 weeks. Hepatitis B virus infection has been associated with episodes of urticaria lasting up to 1 week that are accompanied by fever and arthralgias as part of the prodrome. The mechanism is analogous to that seen in serum sickness–like reactions with viral-antibody immune complexes.

Urticaria/Angioedema after Direct Mast Cell Degranulation

Various therapeutic and diagnostic agents have been associated with urticaria/angioedema. Up to 8 percent of patients receiving radiographic contrast media experience such reactions, which occur most commonly after intravenous administration. Decreased serum alternative pathway complement protein levels and increased serum histamine levels have been detected in patients receiving radiocontrast media. Opiate analgesics, polymyxin B, curare, and D-tubocurarine induce release of histamine from mast cells and basophils.

Urticaria/Angioedema Related to Abnormalities of Arachidonic Acid Metabolism

Intolerance to aspirin manifested as urticaria/angioedema occurs in otherwise normal individuals or in patients with allergic rhinitis and/or bronchial asthma. Urticaria/angioedema in response to aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) occurred in approximately 10 percent to 20 percent of individuals referred to a hospital dermatology clinic in the United Kingdom. Patients intolerant of aspirin also may react to indomethacin and to other NSAIDs.

Reactions to aspirin are shared with other NSAIDs because they reflect inhibition of prostaglandin endoperoxide synthase 1 (PGHS-1, cyclooxygenase 1)[186] as well as inhibition of the inducible PGHS-2 (cyclooxygenase 2). Sodium salicylate and choline salicylate generally are well tolerated because of their weak activity against PGHS-1. PGHS-2 inhibitors are generally well tolerated in those with NSAID-induced urticaria.[187,188] Reactions to NSAIDs increase the levels of cysteinyl leukotrienes,[189] which may relate to the appearance of urticaria, although their role in NSAID-induced asthma is better characterized. Prick skin tests are of no diagnostic value, passive transfer reaction results are negative, and neither IgG nor IgE antibodies have been associated with clinical disease. The clinical manifestations elicited by aspirin challenge of aspirin-intolerant patients are blocked when such patients are protected with a cysteinyl leukotriene receptor blocker or biosynthetic inhibitor; this finding confirms a pathobiologic role for the cysteinyl leukotrienes.

Chronic Idiopathic Urticaria and Idiopathic Angioedema

Because the clinical entity of chronic idiopathic urticaria and idiopathic angioedema is frequently encountered and in fact represents the most common form of chronic urticaria, has a capricious course, and is recognized easily, it is frequently associated with concomitant events. Such attributions must be interpreted with caution. Although infections, food allergies, adverse reactions to food additives, metabolic and hormonal abnormalities, malignant conditions, and emotional factors have been claimed as causes, proof of their etiologic relationship often is lacking. The latest consideration is chronic urticaria as a consequence of infection with *Helicobacter pylori*. Articles both supporting[190–192] and denying[193–196] such a relationship are numerous, and a definite answer is not available. However the *H. pylori* infection rate in the population at large is far greater than the incidence of chronic urticaria, and in the opinion of this author, the association is spurious. The controversy has been put in perspective by M. Greaves.[197] Idiopathic angioedema is diagnosed when angioedema is recurrent, when urticaria is absent, and when no exogenous agent or underlying abnormality is identifiable. An extensive review of angioedema has been published.[170]

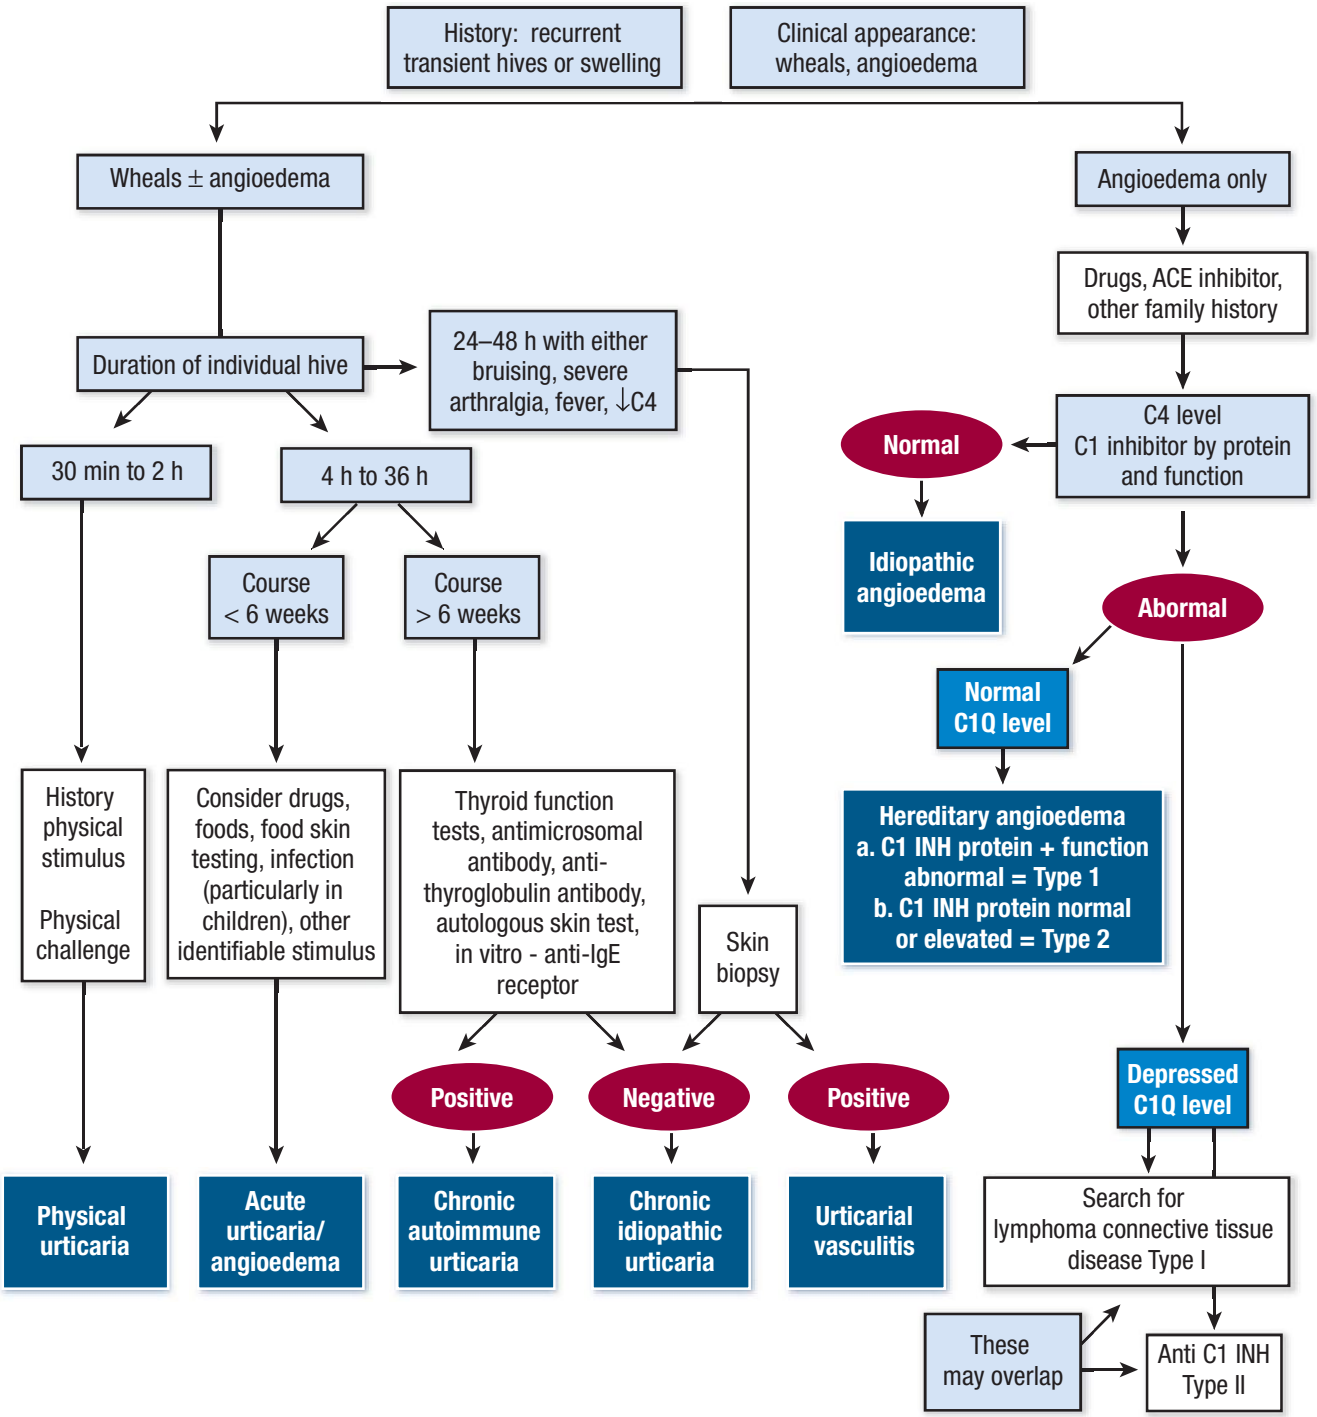
Cyclic episodic angioedema has been associated with fever, weight gain, absence of internal organ damage, a benign course, and peripheral blood eosinophilia.[198] Biopsy specimens of tissues show eosinophils, eosinophil granule proteins, and CD4 lymphocytes exhibiting HLA-OR. Blood levels of IL-1, soluble IL-2 receptor, and IL-5 are elevated.

Miscellaneous

Muckle-Wells syndrome consists of urticaria, amyloidosis, and nerve deafness and is due to the same gene defect as that seen in familial cold urticaria.[104] Schnitzler syndrome is a chronic urticaria associated with IgM monoclonal protein and osteosclerosis, and antibody to IL-1α has been shown to be present.[199]

APPROACH TO THE PATIENT

The evaluation of patients with urticaria/angioedema (Fig. 37-8) begins with a comprehensive history taking, with particular emphasis on the recognized causes, and a physical examination. Some varieties of urticaria may be identified by their characteristic appearance, such as the small wheals with a large erythematous flare of cholinergic urticaria, the linear wheals in dermographism, and the localization of lesions



▲ **FIGURE 37-8** Approach to the patient with urticaria/angioedema. ACE = angiotensin-converting enzyme; IgE, immunoglobulin E; INH = inhibitor; ↓ = decreased.

to exposed areas in light- or cold-induced urticaria. If suggested by the history, the physical examination in all patients with urticaria should include tests for physical urticaria, such as a brisk stroke to elicit dermographism, the use of a weight to elicit delayed pressure urticaria, and application of a cold or warm stimulus to identify cold-induced urticaria and localized heat urticaria, respectively. Exercise, such as running in place, may elicit cholinergic urticaria and, in some instances, exercise-induced anaphylaxis. Phototests to elicit solar urticaria usually are performed in referral centers, as are challenges for exercise-induced anaphylaxis.

When urticaria has been present for days or weeks at a time (but less than 6 weeks) or occurs recurrently for similar intervals, the main considerations are allergic reactions (IgE mediated) to food or drugs. A careful history regarding possibilities is essential. Skin testing can corroborate IgE-mediated hypersensitivity to foods or can provide suspects when the history is unrevealing. Double-blind placebo-controlled food challenge can demonstrate clinical relevance in cases in which the role of a food is uncertain. Non–IgE-mediated causes of urticaria include adverse reactions to NSAIDs and opiates. Any of these can be associated with concomitant angioedema or, less commonly, present as angioedema in the absence of urticaria. Children may have acute urticaria in association with viral illnesses; it is unclear whether infection with bacteria

Box 37-1

Differential Diagnosis of Urticaria/Angioedema

ACUTE (< 6 WK)
- Drug reaction
  - Immunoglobulin E (IgE) mediated
  - Metabolic—idiosyncratic
  - Cellular immunity
- Food reactions
  - IgE mediated
  - Non–IgE mediated (e.g., scombroid poisoning)
- Intravenous administration
  - Blood products
  - Contrast agents
  - Intravenous γ globulin
- Infection
  - Viral in children
  - Infectious mononucleosis or hepatitis B prodrome
  - ? Bacterial in children

PHYSICAL
- Individual lesions last < 2 h
  - Cold urticaria
  - Cholinergic urticaria
  - Dermatographism
  - Local heat urticaria
  - Aquagenic urticaria
  - Cold-induced cholinergic urticaria
  - Cold-dependent dermatographism
- Lesions last > 2 h
  - Delayed pressure urticaria
  - Vibratory angioedema
  - Familial cold-induced syndromes, usually with fever

CHRONIC (> 6 WK)
- Autoimmune, often with antithyroid antibodies
- Idiopathic
- Urticarial vasculitis
  - Idiopathic—skin only
  - Associated with other connective tissue disease
- Familial febrile syndromes with urticaria-like rash
- Schnitzler syndrome

such as *Streptococcus* can induce urticaria as well, but neither form occurs in adults with the exception of urticaria in association with infectious mononucleosis (Epstein-Barr virus) or as a prodrome to hepatitis B infection. In each of these circumstances, individual lesions last anywhere from 4 hours to 24 hours and fade without associated purpura. If hives last less than 2 hours, the cause is usually a physical urticaria, the most common being dermatographism, cholinergic urticaria, and cold urticaria. The main exception is delayed pressure urticaria, in which lesions typically last 12 to 36 hours and first appear 3 to 6 hours after the initiating stimuli. Once urticaria continues for longer than 6 weeks (particularly if present for many months or years) chronic urticaria is present. Chronic urticaria is now divided into chronic idiopathic urticaria for which a cause has not yet been found and chronic autoimmune urticaria. Angioedema accompanies chronic urticaria in 40 percent of cases and is more problematic in the autoimmune subgroup. Swelling in association with chronic urticaria can affect hands, feet, eyes, cheeks, lips, tongue, and pharynx, but not the larynx. When angioedema is present in the absence of an identifiable antigen or exogenous stimulus, the main entities to consider are C1 INH deficiency (hereditary or acquired) and idiopathic angioedema. Approximately 0.5 percent of patients have an urticarial vasculitis with palpable purpura or other stigmata of a possible vasculitis, such as fever, elevated sedimentation rate, petechiae or purpura, elevated white blood cell count, or lesions of unusual duration (36 to 72 hours). The differential diagnosis of acute, chronic, and physical urticaria/angioedema is summarized in Box 37-1.

LABORATORY FINDINGS

In most patients with chronic urticaria/angioedema, no underlying disorders or causes can be discerned. Diagnostic studies should be based on findings elicited by the history and physical examination. Evaluation of chronic urticaria/angioedema should include thyroid function tests and assays for antimicrosomal and antithyroglobulin antibodies, and the autologous skin test can be done, even in an office setting.[200] Routine screening laboratory tests are of little value. The histamine release assays for anti-IgE receptor or anti-IgE antibodies remain a research tool. Serum hypocomplementemia is not present in chronic idiopathic urticaria or chronic autoimmune urticaria, and mean levels of serum IgE in these patients are not different from those in the general population, in which the incidence of atopy is 20 percent.

Cryoproteins should be sought in patients with acquired cold urticaria. An anti-nuclear antibody test should be performed in patients with solar urticaria. Assessment of serum complement proteins may be helpful in identifying patients with urticarial venulitis or serum sickness (C4, C3, C1q binding assay for circulatory immune complexes) as well as those with hereditary and acquired forms of C1 INH deficiency (C4, C1 INH by protein and function, C1q level).

Skin biopsy of chronic urticarial lesions should be undertaken to identify urticarial venulitis or to assess rashes for which the urticarial nature is not clear.

There is little role for routine prick skin testing or the radioallergosorbent test in the diagnosis of specific IgE-mediated antigen sensitivity in chronic urticaria/angioedema. Inhalant materials are uncommon causes of urticaria/angioedema, and food skin tests may be difficult to interpret. The tests for drugs are limited to penicillin but cannot be performed in patients with dermographism. The radioallergosorbent test should be reserved for those in whom skin testing is contraindicated, unavailable, or unrevealing despite a history provoking high suspicion of such a disorder.

A finding of the release of histamine from peripheral basophilic leukocytes has supported the diagnosis of anaphylactic sensitivity to a variety of antigens, which include pollens and insect venom.

Histopathology

Edema involving the superficial portion of the dermis is characteristic of urticaria, whereas angioedema involves the deeper dermis and subcutaneous tissue. Both disorders are associated with dilation of the venules.

In chronic urticaria, the dermal infiltrating inflammatory cells may be sparse or dense and include more CD4 than CD8 T lymphocytes, neutrophils, eosinophils, and basophils[45,201] without B lymphocytes or natural killer cells. NKT cells have not been assessed. Increased expression of TNF-α and IL-3 on endothelial cells and perivascular cells was detected in the upper dermis of patients with acute urticaria, chronic idiopathic urticaria, and delayed pressure urticaria and in one patient with cold urticaria.[202] TNF-α also was detected on epidermal keratinocytes in lesional and non-lesional biopsy specimens. In chronic idiopathic urticaria,

CD11b and CD18 cells were detected about the blood vessels in the superficial and deep dermis. Direct immunofluorescence tests for immunoglobulins and complement proteins were negative.

Major basic protein and eosinophil cationic protein, which are derived from the eosinophil granule, are present around blood vessels and are dispersed in the dermis in lesions of acute urticaria, chronic idiopathic urticaria, delayed pressure urticaria, cholinergic urticaria, and solar urticaria. In chronic idiopathic urticaria, free eosinophil granules in the dermis were increased in wheals of longer than 24 hours' duration compared with wheals lasting fewer than 24 hours. The secreted form of eosinophil cationic protein and eosinophil-derived neurotoxin were detected on cells in greater amounts in biopsy specimens from patients with chronic urticaria without autoantibodies than in those with autoantibodies. P-selectin, E-selectin, intercellular adhesion molecule 1, and vascular cellular adhesion molecule 1 have been demonstrated on the vascular endothelium of patients with chronic idiopathic urticaria and dermographism. Major histocompatability complex class II antigen also is upregulated on the endothelial cells of patients with chronic urticaria, and the peripheral blood lymphocytes have increased CD40 ligand expression and higher Bcl-2 expression; these observations suggest an augmentation of autoimmune phenomena.[203]

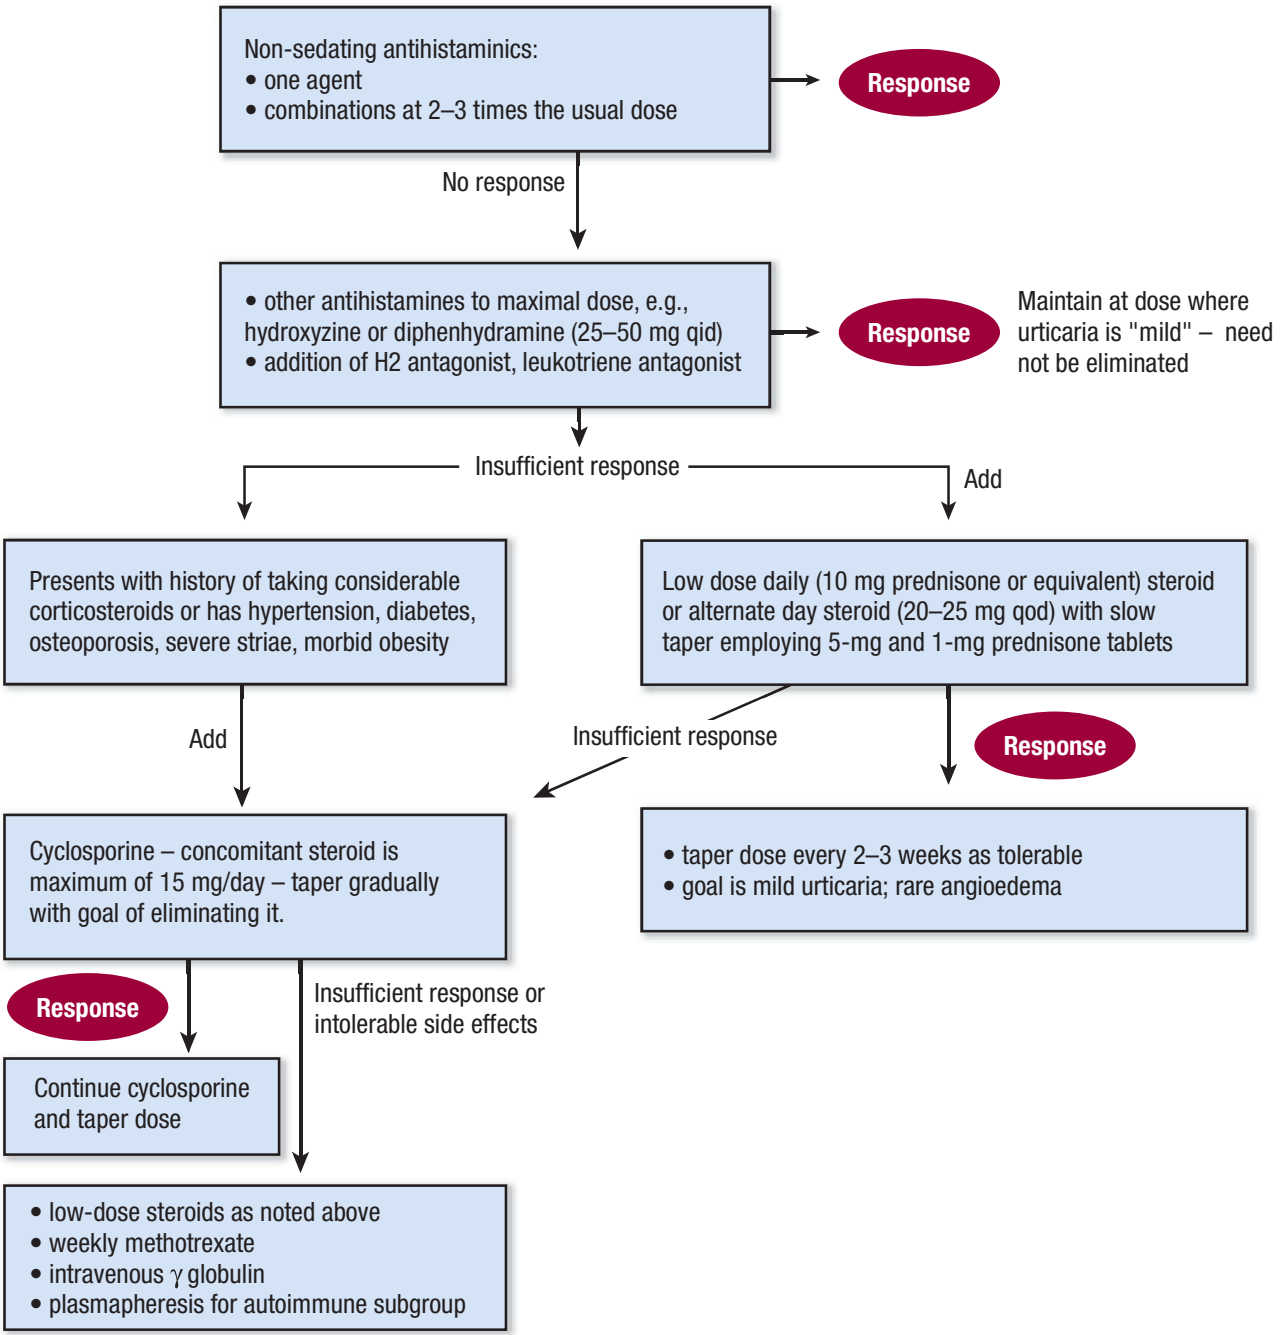
In papular urticaria, the epidermis is thick, with intercellular edema and lymphocytes. In the dermis, there is edema with an infiltrate containing T lymphocytes, macrophages, eosinophils, and neutrophils without B lymphocytes or the deposition of immunoglobulins, fibrin, or C3.

TREATMENT

Therapy for acute urticaria uses antihistamines as described in Fig. 37-9; however, the rash can be severe and generalized, and angioedema may be present as well. Thus, if relief provided by nonsedating antihistamines appears insufficient, one can use hydroxyzine or diphenhydramine at 25 to 50 mg qid. A course of corticosteroid can be used, for example, 60 to 80 mg/day for 3 days followed by a taper by 5 to 10 mg/day. Epinephrine can relieve severe symptoms of urticaria or angioedema (generalized urticaria, severe pruritus, accelerating angioedema) and is indicated if laryngeal edema is present. Edema of the posterior tongue and/or pharyngeal edema can be confused with it.

The ideal treatment for urticaria/angioedema is identification and removal of its cause. Many patients with acute urticaria and angioedema probably are not treated by physicians because the cause in identified by the individual or the course is limited. Treatment of chronic urticaria focuses on measures that provide symptomatic relief. The physician should provide not only medications but also support and reassurance. In a questionnaire study, patients with chronic idiopathic urticaria considered the worst aspects to be pruritus and the unpredictable nature of the attacks. The presence of facial angioedema can be particularly disconcerting, and tongue and/or pharyngeal edema is often considered life threatening. This is not the case and is confused with the potential for laryngeal edema seen with anaphylaxis or anaphylaxis-like reactions, C1 INH deficiency, or reactivity to ACE inhibitors. Affected individuals reported sleep disturbances, diminished energy, social isolation, and altered emotional reactions as well as difficulties in relation to work, home activities, social life, and sex life.[204,205] Another study showed a correlation between the severity of chronic idiopathic urticaria and depression. In a questionnaire study, individuals with delayed pressure urticaria and cholinergic urticaria had the most quality-of-life impairment.[206] Those with cholinergic urticaria suffered in relation to their sporting activities and sexual relationships. Although urticaria/angioedema may be a source of frustration to both physicians and patients, most individuals can achieve acceptable symptomatic control of their disease without identification of the cause. In some individuals it is important to avoid aspirin and other NSAIDs. Antipruritic lotions, cool compresses, and ice packs may provide temporary relief. H_1-type antihistaminic drugs are the mainstays in the management of urticaria/angioedema. The older H_1-type antihistaminics are known as *classic*, *traditional*, or *first-generation* H_1-type antihistamines. Newer low-sedating or second- and third-generation H_1-type antihistamines with reduced sedative and anticholinergic side effects have become the initial therapeutic agents of choice. The drug should be taken on a regular basis and not as needed. If the initial drug chosen is ineffective, an agent from a different pharmacologic class should be used, and non-sedating antihistaminics can be combined. When this is ineffective, doses of hydroxyzine or diphenhydramine in the range of 25 to 50 mg qid may be needed. The same is true for the treatment of dermatographism when it is particularly severe. It should be noted that if the molar release of histamine in the skin exceeds that of the delivered antihistamine (as can be seen with dermatographism), the histamine will keep the receptors to which it is bound in the active conformation, and therapeutic efficacy with the antihistamine will be achieved only when its molar concentration is much greater than that of histamine. Diphenhydramine is an alternative to hydroxyzine or cetirizine for dermatographism but not for cholinergic urticaria.[207,208] Cold urticaria can be treated with most antihistaminics, but cyproheptadine (Periactin) at 4 to 8 mg tid or qid seems to be particularly effective.[209–212] Local heat urticaria is treated with antihistaminics; no regimen is particularly favored. Although anecdotal reports suggest that delayed pressure urticaria will respond to NSAIDs, dapsone, cetirizine, or sulfasalazine, most require corticosteroids (used as in chronic urticaria) to control symptoms, and cyclosporine can be a particularly effective alternative. Familial cold autoinflammatory sydrome (urticaria) responds to parenteral IL-1 receptor antagonist (anakinra)

Treatment choices for chronic urticaria (idiopathic or autoimmune) have been reviewed[213] and are summarized in Fig. 37-9. It is important to use first-generation antihistamines at a maximal dose if non-sedating antihistamines have not been helpful before resorting to corticosteroids or cyclosporine. H_2-receptor antagonists may yield some additional histamine receptor blockade, although their contribution is usually modest. The efficacy of leukotriene antagonists is controversial, with equal numbers of articles pro and con. If steroids are used, this author recommends not exceeding 25 mg qod or 10 mg daily. With either approach, attempts to slowly taper the dose should be made every 2 to 3 weeks. One-mg prednisone tablets can be very helpful when the daily dose is less than 10 mg. Double-blind, placebo-controlled studies of cyclosporine indicate that it is a good alternative to corticosteroid[214,215] and can be safer when used appropriately. Measurement of blood pressure, blood urea nitrogen level, and creatinine level, and a urinalysis should be performed every 6 to 8 weeks. The starting adult dosage is 100 mg bid; it can be slowly advanced to 100 mg tid, but no higher. The response rate is 75 percent in



▲ **FIGURE 37-9** Treatment of chronic idiopathic or autoimmune urticaria/angioedema. Note that the following agents are expected to be effective rarely, if ever: hydroxychloroquine, cholchicine, dapsone, sulfasalazine, mycophenolate mofetil. Hydroxychloroquine is, however, the drug of choice for the hypocomplementemic urticarial vasculitis syndrome. Urticarial vasculitis may respond to dapsone or colchicine.

the autoimmune groups and 50 percent in the idiopathic group. No comparable studies have been performed (or clinical effects obtained) with dapsone, hydroxychloroquine, colchicine, sulfasalazine, or methotrexate, and only small numbers of cases have been treated successfully with intravenous γ globulin or phasmapheresis.[216,217]

Urticarial vasculitis is treated with antihistamines and, if severe, low-dose corticosteroid. Here dapsone or hydroxychloroquine may be steroid sparing. When urticarial vasculitis is part of a systemic disease, the treatment will focus on what is needed for the underlying disorder. The drug of choice for the hypocomplementemic urticarial vasculitis syndrome (with circulating immune complexes due to IgG anti-C1q)[179] is hydroxychloroquine.[218]

Angioedema caused by ACE inhibitors can be an acute emergency with laryngeal edema or tongue or pharyngeal edema that is so extensive the patient cannot manage secretions, and intubation is necessary. Supportive therapy, epinephrine, and time are needed; there is no response to antihistamines or corticosteroids. Other antihypertensive agents can be substituted, including those that block angiotensin II receptors.

Acute attacks of HAE are treated with epinephrine, intubation, or tracheostomy when severe laryngeal edema is encountered, and fresh frozen plasma or C1 inhibition concentrate is given to abort episodes. Prophylaxis uses androgens such as danazol (200-mg tab-

lets)[219,220] or stanozolol (2-mg tablets),[221,222] or antifibrinolytics[223–225] such as ε-aminocaproic acid or tranexamic acid (not available in the United States). The androgens are more commonly used—one watches for hirsutism, irregular menses, or abnormal liver chemistry test results as potential side effects. Increased dosages may be used when the patient undergoes elective surgical procedures (e.g., three tablets per day for 2 or 3 days before the procedure, the day of the procedure, and 1 day after). A C1 INH concentrate (or cloned material) is not available in the United States but is routinely used to treat acute episodes in Europe and Australia. Inhibitors of kallikrein (for acute episodes) are in clinical trials. Acquired C1 INH deficiency can be treated with low-dose androgens in addition to therapy of the underlying condition. Plasmapheresis and/or cytotoxic agents may be needed in type II acquired C1 INH deficiency.

ACKNOWLEDGMENT

I wish to thank Dr. Nicholas Soter, who reviewed this manuscript, made many helpful suggestions, and donated two of the photographs.

CHAPTER 38

Erythema Multiforme

Jean-Claude Roujeau

Erythema multiforme (EM) is an acute self-limited, usually mild, and often relapsing mucocutaneous syndrome. The disease is usually related to an acute infection, most often a recurrent herpes simplex virus (HSV) infection. EM is defined only by its clinical characteristics: target-shaped plaques predominant on the face and extremities.

The absence of specific pathology, specific cause, and biologic markers contribute to a confusing nosology. The definition of EM in this chapter is based on the classification proposed by Bastuji-Garin et al.[1] The principle of this classification is to consider Stevens-Johnson syndrome (SJS) as a minor form of toxic epidermal necrolysis (TEN) and to separate these two diseases from EM (see Chap. 39). The validity of this classification has been challenged by some studies, especially for cases in children and cases related to *Mycoplasma pneumoniae*. It has been confirmed by several others studies, however, especially the prospective international Severe Cutaneous Adverse Reactions study.[2] That study demonstrated that, compared with SJS patients, EM patients were younger, more often male, had a 10-fold higher rate of recurrence, and less frequently had a body temperature higher than 38.5°C (101.3°F) and involvement of two or more mucous membranes.

The original name proposed by von Hebra was *erythema exudativum multiforme*. The term *erythema multiforme* has now been universally accepted (Table 38-1).

EPIDEMIOLOGY

EM is considered relatively common, but its incidence is unknown. Evaluations have been limited to cases severe enough to require hospitalization. Such cases are definitely rare, with figures in the range of 1 to 6 per million per year. Minor forms of EM are certainly more frequent, but the diagnosis of EM is nonetheless too often made.

TABLE 38-1
Erythema Multiforme Sub-Types

- Erythema multiforme minor: Skin lesions without involvement of mucous membranes
- Erythema multiforme major: Skin lesions with involvement of mucous membranes
- Herpes-associated erythema multiforme
- Mucosal erythema multiforme (Fuchs syndrome, ectodermosis pluriorificialis): mucous membrane lesions without cutaneous involvement

ERYTHEMA MULTIFORME AT A GLANCE

- Rare cutaneous and/or mucocutaneous eruption characterized by target lesions.
- Benign course but frequent recurrences.
- Most cases related to herpes simplex virus (HSV) infection.
- Frequent recurrences can be prevented by long-term use of anti-HSV medications.

EM occurs in patients of all ages, but mostly in adolescents and young adults. There is a slight male preponderance (male-female sex ratio of approximately 3:2). EM is recurrent in at least 30 percent of patients.

There is no established underlying disease. Infection with human immuno-

deficiency virus and autoimmune disorders do not increase the risk of EM, and this contrasts with SJS. Cases may occur in clusters, which suggests a role for infectious agents. There is no indication that the incidence may vary with ethnicity or geographic location.

Predisposing genes have been reported, with 66 percent of EM patients having HLA-DQB1*0301 allele, compared with 31 percent of controls.[3] The association was even stronger in patients with herpes-associated EM. Because of the weakness of this association, familial cases remain very rare.

ETIOLOGY

Most cases of EM are related to infections. Herpes virus is definitely the most common cause, principally in recurrent cases. Proof of causality of herpes is firmly established from clinical experience, epidemiology,[2] detection of HSV DNA in the lesions of EM,[4,5] and prevention of EM by suppression of HSV recurrences.[6] Clinically, a link with herpes can be established in about one-half of cases. In addition 10 percent to 40 percent of cases without clinical suspicion of herpes were also demonstrated to be herpes related, because HSV DNA was detected in the EM lesions by polymerase chain reaction (PCR) testing. EM eruptions begin on average 7 days after a recurrence of herpes. The delay can be substantially shorter. Not all symptomatic herpes recurrences are followed by EM, and asymptomatic ones can induce EM. Therefore, this causality link can be overlooked by both patients and physicians. HSV-1 is usually the cause, but HSV-2 can also induce EM. The proportion probably reflects the prevalence of infection by HSV subtypes in the population.

M. pneumoniae is the second major cause of EM and may even be the major cause in pediatric cases.[7–9] In cases related to *M. pneumoniae* the clinical presentation is often less typical and more severe than in cases associated with HSV. The relationship to *M. pneumoniae* is often difficult to establish. Clinical and radiologic signs of atypical pneumonia can be mild, and *M. pneumoniae* is usually not directly detected. PCR testing of throat swabs is the most sensitive technique. Serologic results are considered diagnostic in the presence of immunoglobulin M antibodies or a more than twofold increase in immunoglobulin G antibodies to *M. pneumoniae*. *M. pneumoniae*–related EM can recur.

Many other infections have been reported to be causes of EM in individual cases or small series, but the evidence for causality of these other agents is only circumstantial. Published reports have implicated infection with orf virus, varicella-zoster virus, parvovirus B19, and hepatitis B and C viruses, as well as infectious mononucleosis and a variety of other bacterial or viral infections. Immunization has been also implicated as a cause in children.

Drugs are a rare cause of EM with mucous membrane lesions. It may be argued whether these eruptions are truly EM or mere imitators, for example, annular urticaria or maculopapular eruption with some lesions resembling targets.

Idiopathic cases are those in which neither HSV infection nor any other cause can be identified. Such cases are fairly common under routine circumstances. But HSV has been found in situ by PCR in up to 40 percent of "idiopathic" recurrent cases.[10] Some such cases respond to prophylactic antiviral treatment and are thus likely to have been triggered by asymptomatic HSV infection; others are resistant.

EM-like dermatitis may result from contact sensitization. These rashes should be viewed as imitators of EM, despite their clinical and histopathologic similarities.

PATHOGENESIS

Mechanisms have been investigated in depth in herpes-associated EM.[5] It is not known whether similar pathophysiologic mechanisms apply to EM due to other causes.

Complete infective HSV has never been isolated from lesions of herpes-associated EM. The presence of HSV DNA in EM lesions has been reported in numerous studies using the PCR assay. These studies demonstrated that keratinocytes did not contain complete viral DNA but only fragments, always including the viral polymerase (Pol) gene. HSV Pol DNA is located in basal keratinocytes and in lower spinous cell layers. The viral Pol protein is synthesized in epidermal cells. HSV-specific T cells, including cytotoxic cells, are recruited, and the virus-specific response is followed by a non-specific inflammatory amplification by autoreactive T cells. These cells and the cytokines they produce induce the delayed hypersensitivity-like appearance of the pathology of EM lesions.

HSV is present in the blood for a few days around an overt recurrence of herpes. If keratinocytes were infected in that way, one would expect disseminated herpes rather than EM. It has been shown that HSV DNA is transported to the epidermis by cells that engulf the virus and fragment the DNA. These cells are monocytes, macrophages, and especially $CD34^+$ Langerhans cell progenitors harboring the skin homing receptor cutaneous lymphocyte-associated antigen. Upregulation of adhesion molecules greatly increases binding of HSV-containing mononuclear cells to endothelial cells. HLA-class I and adhesion molecule upregulation in endothelial cells may account for the dermal inflammatory response. When reaching the epidermis the cells transmit the viral Pol gene to keratinocytes. The genes may persist for a few months, but the synthesis and expression of the Pol protein will last for only a few days. This may explain the transient character of clinical lesions.

Incomplete fragmentation of viral DNA, increased number of circulating $CD34^+$ cells, and/or increased immune response to Pol protein may explain why only a small proportion of persons with recurrent herpes develop EM.

CLINICAL FINDINGS

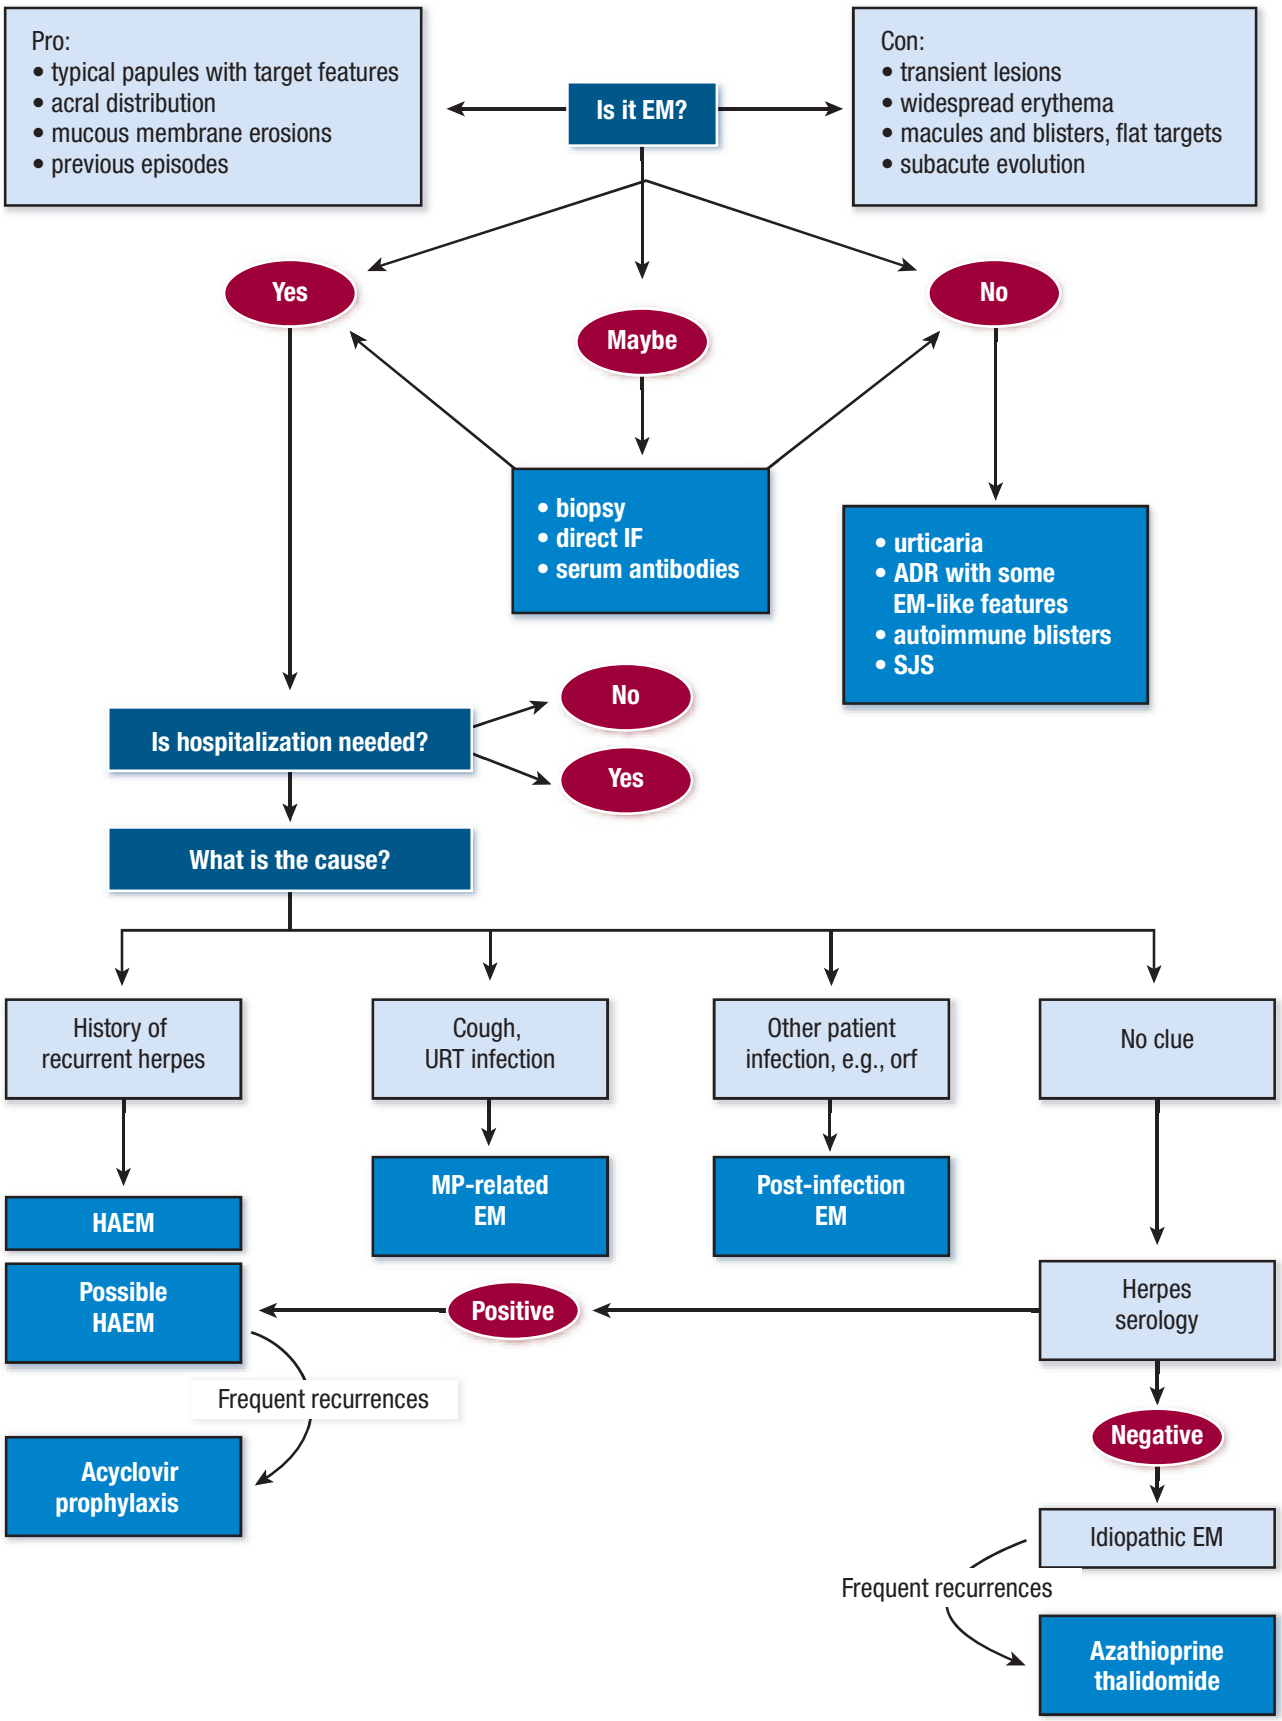
The first step is to suspect EM, based on clinical features. A skin biopsy and laboratory investigations are useful mainly if the diagnosis is not definite clinically. The second step is to determine whether hospitalization is needed when EM major (EMM) occurs with oral lesions that impair feeding, when a possible diagnosis of SJS is suspected, or when severe constitutional symptoms are present. The third step is to establish the cause of EM by identifying a history of recurrent herpes, performing chest radiography, or documenting *M. pneumoniae* infection (Fig. 38-1).

History

Prodromal symptoms are absent in most cases. If present, they are usually mild, suggesting an upper respiratory infection (e.g., cough, rhinitis, low-grade fever).

In EMM, fever higher than 38.5°C (101.3°F) is present in one-third of cases.[2]

A history of previous attack(s) is found in at least one-third of patients and thus helps with the diagnosis. The events of the preceding 3 weeks should be reviewed for clinical evidence of any



▲ **FIGURE 38-1** Approach to the patient with erythema multiforme (EM). ADR = adverse drug reaction; HAEM = herpes-associated erythema multiforme; IF = immunofluorescence; MP = *Mycoplasma pneumoniae*; SJS = Stevens-Johnson syndrome; URT = upper respiratory tract.

precipitating agent, with a special focus on recurrent herpes.

Cutaneous Lesions

The skin rash arises abruptly. In most patients, all lesions appear within 3 days, but in some, several crops follow each other during one episode of EM.

Often there are a limited number of lesions, but up to hundreds may form. Most occur in a symmetric, acral distribution on the extensor surfaces of the extremities (hands and feet, elbows, and knees), face, and neck and appear less frequently on thighs, buttocks, and trunk. Lesions often first appear acrally and then spread in a centripetal manner. Mechanical factors (Koebner phenomenon) and actinic factors (predilection of sun-exposed sites) appear to influence the distribution of lesions. Although patients occasionally report burning and itching, the eruption is usually asymptomatic.

The diversity in clinical pattern implied by the name *multiforme* is mainly due to the findings in each single lesion; most lesions are usually rather similar in a given patient at a given time. The typical lesion is a highly regular, circular, wheal-like erythematous papule or plaque that persists for 1 week or longer (Fig. 38-2). It measures from a few millimeters to approximately 3 cm and may expand slightly over 24 to 48 hours. Although the periphery remains erythematous and edematous, the center becomes violaceous and dark; inflammatory activity may regress or relapse in the center, which gives rise to concentric rings of color (see Fig. 38-2). Often, the center turns purpuric and/or necrotic or transforms into a tense vesicle or bulla. The result is the classic target or iris lesion.

▲ **FIGURE 38-2** Typical target lesions on the palm.

▲ **FIGURE 38-3** Erythema multiforme major. Involvement of the lips with a target pattern.

According to the proposed classification, typical target lesions consist of at least three concentric components: (1) a dusky central disk, or blister; (2) more peripherally, an infiltrated pale ring; and (3) an erythematous halo. Not all lesions of EM are typical; some display two rings only ("raised atypical targets"). However, all are papular, in contrast with macules, which are the typical lesions in SJS-TEN. In some patients with EM, most lesions are livid vesicles overlying a just slightly darker central portion, encircled by an erythematous margin (Fig. 38-3). Larger lesions may have a central bulla and a marginal ring of vesicles (herpes iris of Bateman) (Fig. 38-4).

Unusual presentations include cases in which recurrent EM in the same patient produces typical target lesions in one instance but plaques in a subsequent event. Mucous membranes can be severely involved in some episodes and spared in others (see Mucous Membrane Lesions).

▲ **FIGURE 38-4** Multiple concentric vesicular rings (herpes iris of Bateman). This pattern may be more frequent in *Mycoplasma pneumoniae*–related cases of erythema multiforme major.

In most cases, EM affects well under 10 percent of the body surface area. In 88 hospital cases of EMM prospectively included in the Severe Cutaneous Adverse Reactions study, the median involvement was 1 percent of the body surface area.[2] Very rare instances of extensive skin lesions with "giant" targets and prominent involvement of several mucous sites may be difficult to distinguish from SJS.

The duration of an individual lesion is shorter than 2 weeks, but residual pigmentation may remain for months. There is no scarring.

Mucous Membrane Lesions

Mucosal lesions are present in up to 70 percent of patients, most often limited to the oral cavity.

Predilection sites for mucosal lesions are the lips, on both cutaneous and mucosal sides; non-attached gingivae; and the ventral side of the tongue. The hard palate is usually spared, as are the attached gingivae. On the cutaneous part of the lips, identifiable target lesions may be discernible (see Fig. 38-3). On the mucosa proper there are erosions with fibrinous deposits, and occasionally intact vesicles and bullae can be seen (Fig. 38-5). The process may rarely extend to the throat, larynx, and even the trachea and bronchi.

Eye involvement begins with pain and bilateral conjunctivitis in which vesicles and erosions can occur (Fig. 38-6).

The nasal, urethral, and anal mucosae also may be inflamed and eroded.

Ectodermosis pluriorificialis is a rare occurrence characterized by severe involvement of two or three mucosal sites in the absence of skin lesions. Its often relapsing nature suggests that it is HSV related. Moreover, typical target lesions may arise on the skin with new attacks.

Relationship to Recurrent Herpes

In more than 70 percent of patients with recurrent EM, an episode of recurrent HSV infection precedes the rash; the association with herpes labialis predominates over that with genital herpes or herpes in other locations. EM usually follows recurrent herpes but may also occur after primary HSV infection. The average interval is 7 days (range, 2 to 17 days); the duration of the lag period appears to be specific for individual patients. In a

▲ **FIGURE 38-5** Erythema multiforme major (EMM). Mouth lesions of EMM usually manifest as erosions.

small number of patients, HSV recrudescence and EM may occur simultaneously. Not all episodes of EM are preceded by clinically evident HSV infection, and not all HSV episodes are followed by EM. Episodes of recurrent HSV infection may precede the development of HSV-related EM by many years.

Related Physical Findings

Fever and other constitutional symptoms are usually absent in EM minor, and the physical examination is normal. Fever higher than 38.5°C (101.3°F) is present in 32 percent of cases of EMM. Mouth erosions may be very painful and may impair alimentation. The patient may be unable to close the mouth and may constantly drool blood-stained saliva. Cervical lymphadenopathy is usually present in these patients. The pain of genital erosions may lead to reflex urinary retention. Cough, polypnea, and hypoxia may occur in *M. pneumoniae*–related cases.

▲ **FIGURE 38-6** Erythema multiforme major. Eye lesions. Conjunctivitis with erosions.

LABORATORY FINDINGS

Histopathologic Analysis

Early lesions of EM exhibit lymphocyte accumulation at the dermal-epidermal interface, with exocytosis into the epidermis, lymphocytes attached to scattered necrotic keratinocytes (satellite cell necrosis), spongiosis, vacuolar degeneration of the basal cell layer, and focal junctional and sub-epidermal cleft formation (Fig. 38-7). The papillary dermis may be edematous but principally contains a dense mononuclear cell infiltrate, which is more abundant in older lesions. The vessels are ectatic with swollen endothelial cells; there may be extravasated erythrocytes and eosinophils. Immunofluorescence findings are negative or non-specific. In advanced lesions sub-epidermal blister formation may occur, but necrosis rarely involves the entire epidermis (see eFig. 38-7.1 in on-line edition). In late lesions, melanophages may be prominent.

The histopathologic appearance of EM lesions is different from that of SJS-TEN lesions, in which dermal inflammation is moderate to absent and epidermal necrosis much more pronounced (see Chap. 39). Still, the histopathologic appearances are somewhat overlapping and do not allow the distinction of EM from SJS-TEN in all instances. The main reason for performing a biopsy is to rule out other diagnoses.

Other Laboratory Tests

There are no specific laboratory tests for EM. In more severe cases, an elevated erythrocyte sedimentation rate, moderate leukocytosis, increased levels of acute-phase proteins, and mildly elevated liver aminotransferase levels may occur. In the presence of respiratory symptoms a chest radiograph is needed, and documentation of *M. pneumoniae* infection by PCR assay of a throat swab and serologic testing (a pair at a 2- or 3-week interval) should be sought. Investigations to document causality are important in cases with frequent recurrences when prevention with long-term antiviral treatment is considered and when there is no clinical evidence of association with herpes. HSV can sometimes be isolated from the initial lesion of labial herpes. Amplification of HSV Pol gene from biopsy samples of EM lesions is not done routinely. A negative result on serologic testing for HSV may be helpful to exclude the possibility of herpes-associated EM. The positive predictive value of the presence of HLA-DQB1*0301 is too low to have any clinical value.

DIFFERENTIAL DIAGNOSIS (Box 38-1)

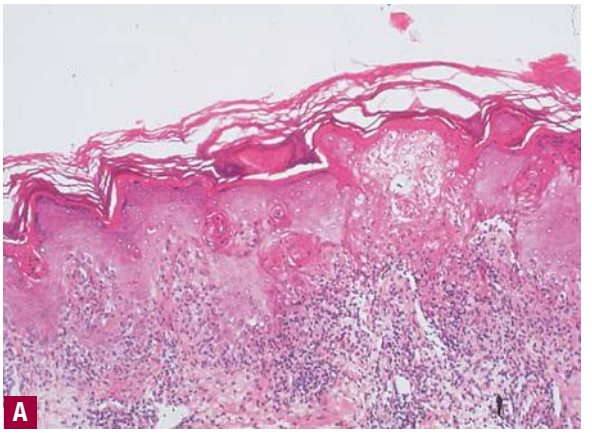
In a retrospective analysis of 66 pediatric cases discharged from hospital with a diagnosis of EM 24 (36 percent) were clearly not EM or SJS.[7] Diseases that had been frequently erroneously called EM were urticaria and maculopapular drug eruption.

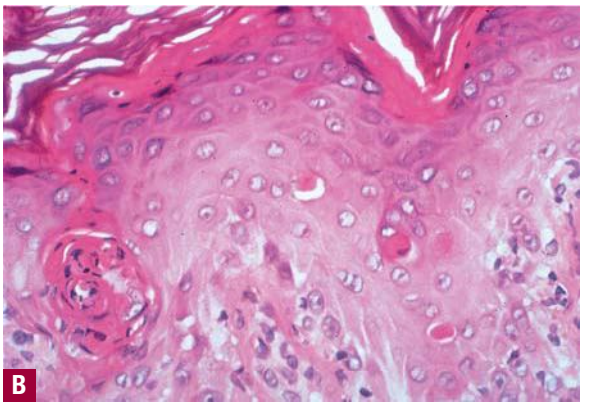
The designation of *Rowell syndrome*[11] is used for a variety of cutaneous lupus erythematosus with lesions resembling those of EM. Subacute evolution, a positive result on direct fluorescence testing, and the presence of anti-nuclear antibodies exclude EM.

Sweet syndrome can mimic EM minor; biopsy easily distinguishes the two. Paraneoplastic pemphigus and more rarely other autoimmune blistering diseases occasionally present with target-like lesions that can be confused with those of EM.

One of these has been reported as EMM with antidesmoplakin antibodies.[12] It resembles EMM in its acute and recurrent course, but the presence of acantholysis, deposits of immunoglobulin G around basal cells, and serum antibodies against desmoplakin distinguish it from EM.

Whether considered a variant of EMM or a separate disease, SJS should be recognized promptly for three reasons: (1) the possibility of life-threatening complications, (2) the risk of progression to TEN, and (3) the need for urgent withdrawal of suspected causative drug(s). Pain, constitutional symp-





▲ **FIGURE 38-7** Histopathologic features of erythema multiforme (early lesion). **A.** An intense lymphohistiocytic infiltrate fills the mid-dermis and obliterates many blood vessels. There is sub-epidermal cleft formation and circumscribed necrosis of the epidermis. **B.** High-power magnification of scattered keratinocyte necrosis.

toms, severe erosions of mucosae, rapid progression, and dusky or violaceous skin lesions are alerting features.

COURSE AND COMPLICATIONS

EM runs a mild course in most cases, and each individual attack subsides within 1 to 4 weeks. Recovery is complete, and there are usually no sequelae, except for transient hypopigmentation or hyperpigmentation in some cases.

In rare instances the ocular erosions of EMM may cause severe residual scarring of the eye. *M. pneumoniae*–related EMM may be associated with severe erosive bronchitis.

Recurrences are common and may characterize the majority of cases. In one report of a large series of patients with recurrent EM, the mean number of attacks was 6 per year (range, 2 to 36), and the mean total duration of disease was 9.5 years. In 33 percent, the condition persisted for more than 10 years.[13] Up to 50 recurrences have been described in a single patient. The severity of episodes in patients with recurrent EM is highly variable and unpredictable. The frequency of episodes and cumulative duration of disease are not correlated with the severity of attacks. The frequency and severity of recurrent EM tend to decrease spontaneously over time (after 2 years or longer), parallel with the improvement of recurring HSV infection.

A small fraction of patients experience a prolonged series of overlapping attacks of EM; this has been labeled *continuous EM* or *persistent EM*.[13]

TREATMENT

The aims of treatment are to reduce the duration of fever, eruption, and hospitalization. Based on retrospective series or small controlled trials, the use of systemic corticosteroids seems to shorten the duration of fever and eruption but may increase the length of hospitalization because of complications. However,

Box 38-1

Differential Diagnosis of Erythema Multiforme (EM)

	MUCOUS MEMBRANE LESIONS	CLINICAL PATTERN	PATHOLOGIC FINDINGS	LABORATORY TESTING	COURSE
Urticaria	No	Circinate, transient	Edema		More acute than EM
Maculopapular drug eruption	Rare (lips)	Widespread polymorphous target-like lesions, macules, papules, plaques	Most often non-specific		
Lupus (Rowell syndrome)	Possible (mouth)	Face and thorax Large target-like lesions, annular plaques	Interface dermatitis Positive result on DIF ("lupus band")	Anti-nuclear antibodies present	Subacute
Paraneoplastic pemphigus	Constant; always early and severe	EM-like lesion plus lichenoid papules Positive Nikolsky sign	Acantholysis Positive result on DIF	Antibodies present	Chronic
Pemphigoid	Rare	Circinate erythematous patches	Sub-epidermal blister	Antibodies present	Chronic
Antidesmoplakin "EM major"	Constant	EM-like lesions	Basal acantholysis Positive result on DIF	Antibodies present	Acute relapsing
Stevens-Johnson syndrome	Constant	Widespread small blisters Atypical targets Constitutional symptoms	Interface dermatitis Epidermal necrosis		Acute

DIF = direct immunofluorescence testing.

the methodology of most studies was poor, with small series often mixing the various forms of idiopathic and viral-associated EM and drug-induced SJS.

Several series indicate that administering anti-HSV drugs for the treatment of full-blown postherpetic EM is useless. When symptomatic, *M. pneumoniae* infection should be treated with antibiotics (macrolides in children, macrolides or quinolone in adults). There is no evidence indicating whether it improves the evolution of the associated EM. Therefore, when asymptomatic infection is suggested by serologic testing, treatment is not mandatory.

Liquid antacids, topical glucocorticoids, and local anesthetics relieve symptoms of painful mouth erosions.

PREVENTION

Continuous therapy with oral anti-HSV drugs (see Chap. 232) is effective to prevent recurrences of herpes-associated EM with or without clinical evidence that herpes is the precipitating factor.[6] Topical acyclovir therapy used in a prophylactic manner does not prevent recurrent herpetic EM.

In a series of 65 patients with recurrent EM, 11 were treated with azathioprine when all other treatments had failed. Azathioprine was beneficial in all 11 patients.[13]

Retrospective uncontrolled analyses of thalidomide therapy have indicated that it is moderately effective for the treatment of EM.[14] In one randomized controlled trial, levamisole appeared useful. Because agranulocytosis is a severe and not exceptional adverse effect, levamisole use is permitted in only a few countries. The benefit-risk ratio is probably too low to support its use in the treatment of EM.

CHAPTER 39

Epidermal Necrolysis (Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis)

L. Valeyrie-Allanore
Jean-Claude Roujeau

Toxic epidermal necrolysis (TEN) and Stevens-Johnson syndrome (SJS) are acute life-threatening mucocutaneous reactions characterized by extensive necrosis and detachment of the epidermis. Stevens and Johnson first reported two cases of disseminated cutaneous eruptions associated with an erosive stomatitis and severe ocular involvement.[1] In 1956, Lyell described patients with epidermal loss secondary to necrosis and first introduced the term *toxic epidermal necrolysis*.[2] Both SJS and TEN are characterized by skin and mucous membrane involvement. Erythematous macules, mainly localized on the trunk and proximal limbs, evolve progressively to confluent flaccid blisters leading to epidermal detachment. Because of the similarities in clinical and histopathologic findings, drug etiology, and mechanisms, these two conditions represent severity variants of an identical process that differs only in the percentage of body surface involved.[3–5] It is therefore better to use the designation *epidermal necrolysis* for both, as proposed by Ruiz-Maldonado (acute disseminated epidermal necrosis)[6] and Lyell (exanthematic necrolysis).[7]

EPIDEMIOLOGY

Epidermal necrolysis (EN) is rare. The overall incidence of SJS and TEN was estimated at 1 to 6 cases per million person-years and 0.4 to 1.2 cases per million person-years, respectively.[8,9] EN can occur at any age, with the risk increasing with age after the fourth decade, and more frequently affects women, showing a sex ratio of 0.6. Patients infected with human immunodeficiency virus and to a lesser degree patients with collagen vascular disease and cancer are at increased risk.[10–12] The overall mortality associated with EN is 20 percent to 25 percent, varying from 5 percent to 12 percent for SJS to more than 30 percent for TEN. Increasing age, significant co-morbidity, and greater ex-

EPIDERMAL NECROLYSIS AT A GLANCE

- Rare and life-threatening reaction, mainly drug-induced.
- Widespread apoptosis of keratinocytes provoked by the activation of a cell-mediated cytotoxic reaction.
- Confluent purpuric and erythematous macules evolving to flaccid blisters and epidermal detachment predominating on the trunk and upper limbs and associated with mucous membrane involvement.
- Pathologic analysis shows full-thickness necrosis of epidermis associated with mild mononuclear cell infiltrate.
- Early identification and withdrawal of suspect drugs are essential for good patient outcome.
- Treatment is mainly symptomatic.

tent of skin involvement correlate with poor prognosis.

A prognosis score (SCORTEN) has been constructed for EN,[13] and its usefulness has been confirmed by several teams.[14,15] The performance of the score is at its best on day 3 of hospitalization[16] (Table 39-1).

ETIOLOGY

The pathophysiology of EN is still unclear; however, it is now established that drugs are the most important etiologic factors.[17–19] More than 100 different drugs have been reported as possible causes.[17–20] The importance of one medication can be established in approximately 70 percent of cases.[21] Retrospective population-based studies or case series were not accurate enough to quantify the risk of medications.[22] A multinational case-control study analyzed the association of EN with specific drugs along other epidemiologic co-factors.[20] Fewer than a dozen "high-risk" medications were implicated in one-half of cases of EN in Europe (Table 39-2). These high-risk drugs are antibacterial sulfonamides, aromatic anticonvulsants, allopurinol, oxicam nonsteroidal anti-inflammatory drugs, lamotrigine, and nevirapine.[20–25] The risk seems confined to the first 8 weeks of treatment. Slow dose escalation decreases the rate of rash with lamotrigine and nevirapine,[26,27] but there is no evidence that it decreases the risk of EN.[24] Oxcarbazepine, a 10-keto derivative of carbamazepine, which was considered to carry a lower risk, seems to significantly cross-react with carbamazepine.[28] Many nonsteroidal anti-inflammatory drugs are suspected to be associated with EN,[12,29–30] but primarily oxicam derivatives and diclofenac.[31] A significant but much lower risk has also been reported for non-sulfonamide antibiotics such as aminopenicillins, quinolones, cephalosporins, and tetracyclines. The role of corticosteroids in the induction of EN is still unclear. In a case-control study, corticosteroids were found to be associated with a high relative risk, independent of underlying disease.

The role of infectious agents in the development of EN is much less prominent than for erythema multiforme. However, a few cases of EN associated with *Mycoplasma pneumoniae* infection, viral disease, and immunization have been reported.[32,33] These rare observations underscore the fact that medications are not the only cause of EN, but there is still little evidence that infections can explain more than a very small percentage of cases.

Cases of EN have been reported after bone marrow transplantation. Some are an extreme form of acute graft-versus-host disease (see Chap. 28); others could be drug induced. The relationship between EN and graft-versus-host disease is difficult to assess because skin lesions and skin histologic features are nearly indistinguishable.[34]

Finally, physical mechanisms such as radiotherapy in addition to treatment with anti-epileptic drugs such as phenytoin, phenobarbital, or carbamazepine can trigger EN on radiation sites.[35,36]

PATHOGENESIS

Even if the precise sequence of molecular and cellular events is incompletely understood, several studies provide important clues to the pathogenesis of EN. The immunologic pattern of early lesions suggests a cell-mediated cytotoxic reaction against keratinocytes leading to massive apoptosis.[37,38] Immunopathologic studies have demonstrated the presence of $CD8^+$ T killer lymphocytes in the epidermis and dermis in bullous adverse reactions, with some natural killer cell–like features, during the initial phase of EN, whereas monocytes are present more during the late phase.[39,40] These cytotoxic $CD8^+$ T cells express α-β T-cell receptors and are able to kill through perforin and granzyme B but not through Fas or Trail.[40]

TABLE 39-2
Medications and the Risk of Epidermal Necrolysis

HIGH RISK	LOWER RISK	DOUBTFUL RISK	NO EVIDENCE OF RISK
Allopurinol	Acetic acid NSAIDs (e.g., diclofenac)	Paracetamol (acetaminophen)	Aspirin
Sulfamethoxazole	Aminopenicillins	Pyrazolone analgesics	Sulfonylurea
Sulfadiazine	Cephalosporins	Corticosteroids	Thiazide diuretics
Sulfapyridine	Quinolones	Other NSAIDs (except aspirin)	Furosemide
Sulfadoxine	Cyclins	Sertraline	Aldactone
Sulfasalazine	Macrolides		Calcium channel blockers
Carbamazepine			β Blockers
Lamotrigine			Angiotensin-converting enzyme inhibitors
Phenobarbital			Angiotensin II receptor antagonists
Phenytoin			Statins
Phenylbutazone			Hormones
Nevirapine			Vitamins
Oxicam NSAIDs			
Thiacetazone			

NSAIDs = nonsteroidal anti-inflammatory drugs.

Approach to patient with EN

- early suspicion of diagnosis
- rapid confirmation (examination of frozen biopsy speciman may help)
- elimination of differential diagnoses (biopsy and direct immunofluorescence testing)
- evaluation of disease severity with special attention to respiratory function
- prompt referral to a specialized ward
- avoidance of a specific treatment of unproven value
- re-evaluation at discharge and a few weeks later
  - –appropriate documentation of the case
  - –determination of causality
  - –notification to regulatory agency
  - –evaluation and prevention of sequelae
  - –recommendations for future use of drugs

▲ **FIGURE 39-1** Approach to the patient with epidermal necrolysis.

It is now well established that this oligoclonal $CD8^+$ expansion corresponds to a drug-specific, major histocompatibility complex–restricted cytotoxicity against keratinocytes. Furthermore, regulatory $CD4^+CD25^+$ T cells have been demonstrated to be potentially important in the prevention of severe epidermal damage induced by reactive cytotoxic T lymphocytes.[41] Important cytokines such as interleukin 6, tumor necrosis factor-α (TNF-α), and Fas ligand (Fas-L) are also present in the lesional skin of EN patients. Viard et al. suggested that keratinocyte apoptosis in lesional skin was associated with increased expression of Fas on their membranes and was blocked by high concentrations of human immunoglobulins that interfere with the interaction of Fas and Fas-L.[42] TNF is probably also important. This molecule is present in lesional epidermis, in blister fluid, and in peripheral mononuclear cells and macrophages.[43,44]

Slow acetylation was found in patients with sulfonamide-induced TEN, which suggests an increased production of reactive metabolites.[45] However, the immunologic response is directed against the parent drug rather than reactive metabolites.[40]

Finally, genetic susceptibility could play an important role. A strong association was observed in Han Chinese between the human leukocyte antigen HLA-B1502 and SJS induced by carbamazepine and between HLA-B5801 and SJS induced by allopurinol.[46,47] However, the association between carbamazepine-induced EN and HLA-B1502 is not present in European patients who do not have Asian ancestry.[48]

CLINICAL FINDINGS

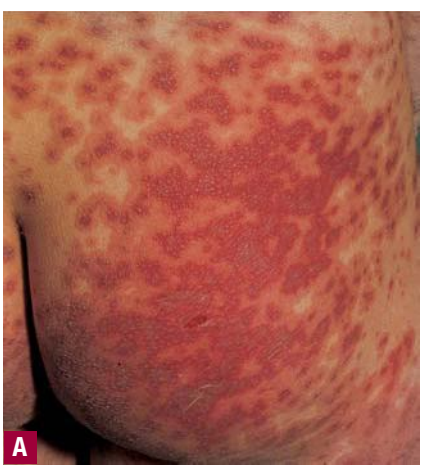
Even in cases requiring immediate referral to specialized wards, the dermatologist will have a specific role in the management of patients with EN (Fig. 39-1).

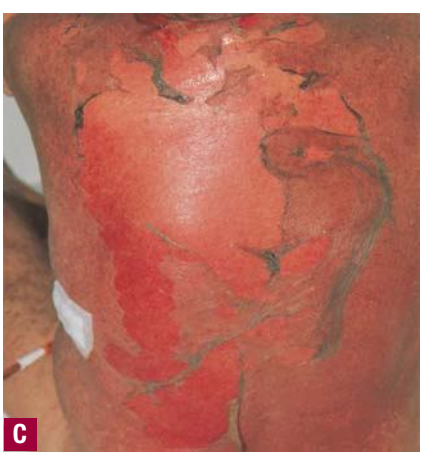
History

EN clinically begins within 8 weeks (usually 4 to 30 days) after the onset of drug exposure. Only in very rare cases with prior reaction and inadvertent rechallenge with the same drug does it appear more rapidly, within a few hours. Nonspecific symptoms such as fever, headache, rhinitis, and myalgias may precede the mucocutaneous lesions by 1 to 3 days. Pain on swallowing and burning or stinging of the eyes progressively develop, heralding mucous membrane involvement. About one-third of cases begin with non-specific symptoms, one-third with symptoms of mucous membrane involvement, and one-third with an exanthema. Whatever the initial symptoms are, their rapid progression, the addition of new signs, severe pain, and constitutional symptoms should alert one to the onset of a severe disease.

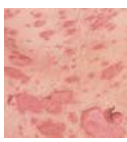
Cutaneous Lesions

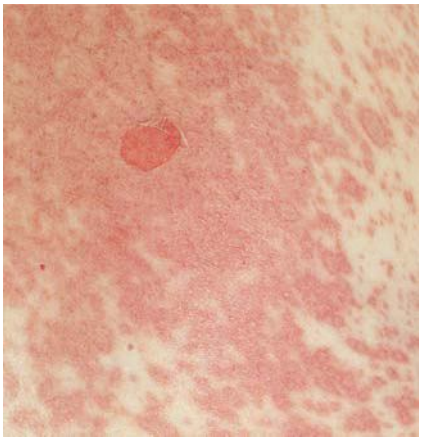
The eruption is initially symmetrically distributed on the face, the upper trunk, and the proximal extremities. The distal portions of the arms as well as the legs are relatively spared, but the rash can rapidly extend to the rest of the body within a few days and even within a few hours. The initial skin lesions are characterized by erythematous, dusky red, purpuric macules, irregularly shaped, which progressively coalesce. Atypical target lesions with dark centers are often observed (Fig. 39-2A). Confluence of





▲ **FIGURE 39-2** **A.** Early eruption. Erythematous dusky red macules (flat atypical target lesions) that progressively coalesce and show epidermal detachment. **B.** Advanced eruption. Blisters and epidermal detachment have led to large confluent erosions. **C.** Full-blown epidermal necrolysis characterized by large erosive areas reminiscent of scalding.





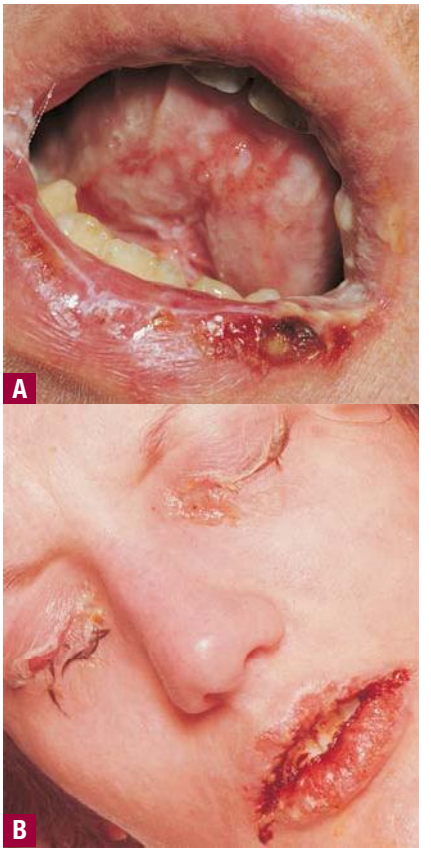
▲ **FIGURE 39-3** Early exanthematous phase with Nikolsky sign.

necrotic lesions leads to extensive and diffuse erythema. Nikolsky sign, or dislodgement of the epidermis by lateral pressure, is positive on erythematous zones (Fig. 39-3). At this stage, the lesions evolve to flaccid blisters, which spread with pressure and break easily (see Fig. 39-2B). The necrotic epidermis is easily detached at pressure points or by frictional trauma, revealing large areas of exposed, red, sometimes oozing dermis (see Fig. 39-2C). In other areas, epidermis may remain.

Patients are classified into one of three groups according to the total area in which the epidermis is detached or "detachable" (positive Nikolsky): SJS, less than 10 percent of body surface area (BSA); SJS/TEN overlap, between 10 percent and 30 percent; TEN, more than 30 percent of BSA. Correct evaluation of the extent of lesions is difficult, especially in zones with spotty lesions. It is helpful to remember that the surface of one hand (palm and fingers) represents a little less than 1 percent of the BSA.

Mucous Membrane Involvement

Mucous membrane involvement (nearly always on at least two sites) is observed in approximately 90 percent of cases and can precede or follow the skin eruption. It begins with erythema followed by painful erosions of the buccal, ocular, and genital mucosa. This usually leads to impaired alimentation, photophobia, conjunctival synechiae, and painful micturition. The oral cavity and the vermilion border of the lips are almost invariably affected and feature painful hemorrhagic erosions coated by grayish white pseudomembranes and crusts of the lips (Fig. 39-4A and B). Approximately 85 percent of patients have



▲ **FIGURE 39-4** **A.** Extensive erosions and necroses of the lower lip and oral mucosa. **B.** Massive erosions covered by crusts on the lips. Note also shedding of eyelashes.

conjunctival lesions, mainly manifested by hyperemia, erosions, chemosis, photophobia, and lacrimation. There may be shedding of eyelashes (see Fig. 39-4B). Severe forms may lead to corneal ulceration, anterior uveitis, and purulent conjunctivitis. Synechiae between eyelids and conjunctiva often occur. Shedding of nails occurs in severe forms.

Extra-Cutaneous Symptoms

EN is associated with high fever, pain, and weakness. Visceral involvement is also possible, particularly with pulmonary and digestive complications. Early pulmonary complications occur in approximately 25 percent of patients and are essentially manifested by dyspnea, bronchial hypersecretion, and hypoxemia but also by hemoptysis and expectoration of bronchial mucosal casts.[49,50] Bronchial involvement in EN is not correlated with the extent of skin lesions or with the related offending agent. In most cases chest radiographs are normal on admission but can rapidly reveal interstitial syndrome. In all reported cases, when acute respiratory failure developed rapidly after the onset of skin involvement, it was associated with poor prognosis. In the case of respiratory abnormalities, fiberoptic bronchoscopy appears to be a simple procedure to distinguish a specific epithelial detachment in the bronchi from an infectious pneumonitis, which has a much better prognosis.

Gastrointestinal tract involvement is less commonly observed, with epithelial necrosis of the esophagus, small bowel, or colon manifesting as profuse diarrhea with malabsorption, melena, and even colonic perforation.[51,52]

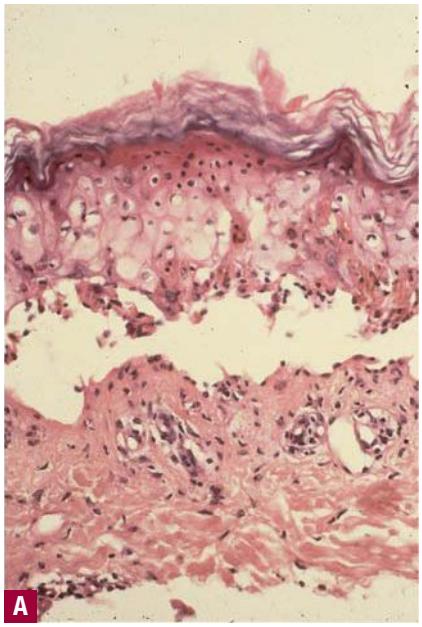
Renal involvement has been reported. Proteinuria, microalbuminuria, hematuria, and azotemia are not rare. Proximal tubule damage can result from necrosis of tubule cells by the same process that destroys epidermal cells. The involvement of glomerular structures is also possible.[53,54]

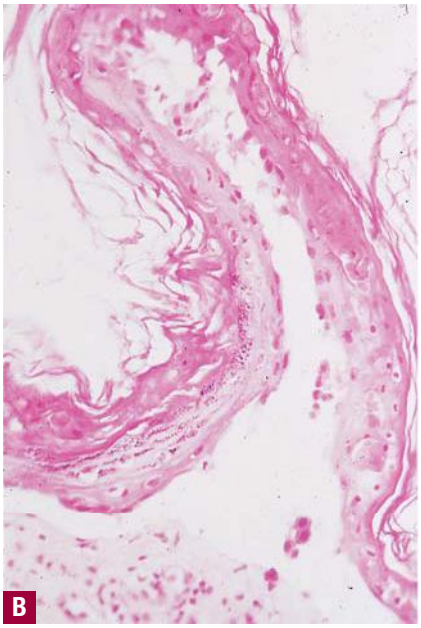
LABORATORY TESTS

Laboratory Values

Evaluation of respiratory rate and blood oxygenation are among the first steps to take in the emergency room. Any alteration should be checked through measurement of arterial blood gas levels. Serum bicarbonate levels below 20 m*M* indicate a poor prognosis. They usually result from respiratory alkalosis related to the specific involvement of bronchi and more rarely from metabolic acidosis.

Massive transdermal fluid loss is responsible for electrolyte imbalances, hypoalbuminemia, and hypoproteinemia, and mild and transient renal insufficiency and prerenal azotemia are common. Raised blood urea nitrogen level is one marker of severity. Anemia is usual, and mild leukocytosis as well as thrombocytopenia may occur. Neutropenia is often considered to be an unfavorable prognostic factor but is too rare to have a significant impact on SCORTEN. Transient peripheral $CD4^+$ lymphopenia is nearly always seen constant and is associated with decreased T-cell functions. Mild elevation in levels of hepatic enzymes and amylase (most probably of salivary origin) are frequent but without impact on prognosis. A hypercatabolic state is responsible for inhibition of insulin secretion or insulin resistance, which results in hyperglycemia and occasionally overt diabetes. A blood glucose level above 14 m*M* is one marker of severity. Other abnormalities in laboratory values may occur, indicating involvement of other organs and complications such as sepsis.





▲ **FIGURE 39-5** Histologic appearance of toxic epidermal necrolysis. **A.** Eosinophilic necrosis of the epidermis in the peak stage, with little inflammatory response in the dermis. Note cleavage in the junction zone. **B.** The completely necrotic epidermis has detached from the dermis and folded like a sheet.

Histopathology

Skin biopsy for routine histologic and immunofluorescence studies must be performed in every case of EN, even if the diagnosis is clinically obvious, because of a high probability of future legal actions and because it is the only way to exclude most differential diagnoses.

In the early stages, epidermal involvement is characterized by sparse apoptotic keratinocytes in the suprabasal layers, which rapidly evolves to a full-thickness EN and sub-epidermal detachment (Fig. 39-5). A moderately dense mononuclear cell infiltrate of the papillary dermis is observed, mainly represented by lymphocytes and macrophages. Among the T-cell population, $CD8^+$ lymphocytes with phenotypic features of cytotoxic cells are clearly represented, which suggests a cell-mediated immunologic reaction.[37,55] Eosinophils seems to be less common in patients with the most severe form of EN.[56,57] Results of direct immunofluorescence study are negative.

DIFFERENTIAL DIAGNOSIS (Box 39-1)

The absence of mucous membrane involvement or its restriction to a single site must always raise the suspicion of an alternative diagnosis: staphylococcal scalded skin syndrome in infants; purpura fulminans in children and young adults; acute generalized exanthematous pustulosis, thermal burns, phototoxicity, or pressure blisters in adults. Linear immunoglobulin A bullous disease and paraneoplastic pemphigus present with a less acute progression. Pathologic findings and a positive result on direct immunofluorescence testing are important for these diagnoses.

Early EN cases are often initially diagnosed as varicella. The rapid progression of skin lesions and the severity of mucous membrane involvement should raise the probability of EN.

In all aspects, including pathology, generalized bullous fixed drug eruption (GBFDE) resembles EN. It may have a similar drug-related mechanism. The distinction is worthwhile, however, because GBFDE has a much better prognosis, probably because of the mild involvement of mucous membranes and the absence of visceral complications. Prior attacks, rapid onset after drug intake, and very large, well-demarcated blisters are the hallmarks of GBFDE.

Thermal burns or scalding are occasionally an issue when a transient loss of consciousness occurs.

Destruction of epithelia by toxins, whether through contact (fumigants) or ingestion (colchicine poisoning, methotrexate overdose), may result in clinical features of EN. In these rare cases causality is generally obvious.

Overreporting of SJS is common. It usually arises from confusion between desquamation and detachment of epidermis and also between mucous membranes and periorificial skin. Because of such confusion, patients with a desquamative rash and scaly lips are occasionally diagnosed with and reported as having SJS.

Box 39-1

Differential Diagnosis of Epidermal Necrolysis (EN)

Most Likely

- ☐ Limited EN (Stevens-Johnson syndrome)
  - • Erythema multiforme major
  - • Varicella
- ☐ Widespread EN
  - • Acute generalized exanthematous pustulosis
  - • Generalized bullous fixed drug eruption

Consider

- ☐ Paraneoplastic pemphigus
- ☐ Linear immunoglobulin A bullous disease
- ☐ Pressure blisters after coma
- ☐ Phototoxic reaction
- ☐ Graft-versus-host disease

Always Rule Out

- ☐ Staphylococcal scalded skin syndrome
- ☐ Thermal burns
- ☐ Skin necrosis from disseminated intravascular coagulation or purpura fulminans
- ☐ Chemical toxicity (e.g., colchicine intoxication, methotrexate overdose)

COMPLICATIONS

During the acute phase, the most common complication of EN is sepsis. The epithelial loss predisposes these patients to bacterial or fungal infections, which are the main causes of mortality. Multisystem organ failure and pulmonary complications are observed in more than 30 percent and 15 percent of cases, respectively.[58] Late ophthalmic complications are seen in 20 percent to 75 percent of patients with EN.[59–61] The relationship between the initial severity of ocular involvement and the development of late complications seems now to be well established. Late ophthalmic complications are mainly due to functional alteration of the conjunctival epithelium with dryness and abnormal lacrimal film.[60] This leads to chronic inflammation, fibrosis, entropion, trichiasis, and symblepharon. Long-term irritation and deficiency of stem cells in the limbus may result in metaplasia of corneal epithelium with painful ulcerations and altered vision.

Hypopigmentation and/or hyperpigmentation are frequently observed, but rarely associated with hypertrophic or

atrophic scars. Nail changes, including change in pigmentation of the nail bed, ridging, dystrophic nails, and permanent anonychia, occur in more than 50 percent of cases.

Vulvar and vaginal complications of EN have been underestimated.[62] Dyspareunia is not rare and is related to vaginal dryness, itching, pain, and bleeding. Genital adhesions may lead to the requirement for surgical treatment. Esophageal, intestinal, bronchial, urethral, and anal strictures may also develop in rare cases.

Because these late complications and sequelae may develop insidiously, it is strongly suggested that all patients surviving EN have a clinical follow-up a few weeks after discharge, including examination by an ophthalmologist.

Symptoms suggesting post-traumatic stress disorder are not rare, and psychiatric consultation may be necessary.

PROGNOSIS AND CLINICAL COURSE

The epidermal detachment progresses for 5 to 7 days. Then, patients enter a plateau phase, which corresponds to progressive re-epithelialization. This can take a few days to several weeks, depending on the severity of the disease and the prior general condition of the patient. During this period, life-threatening complications such as sepsis or systemic organ failure may occur. The mortality rate is 5 percent to 12 percent for SJS and more than 30 percent for TEN. The prognosis is not affected by the type or dose of the responsible drug or the presence of human immunodeficiency virus infection (see Table 39-1).[13]

TREATMENT

EN is a life-threatening disease that requires optimal management: early recognition and withdrawal of the offending drug(s) and supportive care in an appropriate hospital setting.

Prompt withdrawal of offending agents is associated with an increased rate of survival in patients with EN induced by drugs with short elimination half-lives.[63] On the other hand, it is preferable to continue every important and non-suspected medication. That will avoid reluctance on the part of the patient's physicians to prescribe them in the future. In case of doubt, all non–life-sustaining drugs should be stopped, and particularly those administered within the previous 8 weeks.

Symptomatic Treatment

Only patients with limited skin involvement and a SCORTEN score of 0 or 1 can be treated in non-specialized wards. Others should be transferred to intensive care units or burn centers.

Supportive care consists of maintaining hemodynamic equilibrium and preventing life-threatening complications. The aims are basically the same as for extensive burns.

EN is associated with significant fluid loss from erosions, which results in hypovolemia and electrolyte imbalance. Fluid replacement must be started as soon as possible and adjusted daily. Volumes of infusions are usually less than for burns of similar extent, because interstitial edema is absent. Peripheral venous lines are preferred when possible, because the sites of insertion of central lines are often involved in detachment of epidermis and prone to infection.

The environmental temperature should be raised to 28°C to 30°C (82.4°F to 86°F). The use of an air-fluidized bed improves patient comfort.

Early nutritional support is preferentially provided by nasogastric tube to promote healing and to decrease the risk of bacterial translocation from the gastrointestinal tract.

To reduce the risk of infection, aseptic and careful handing is required. Skin, blood, and urine specimens should be cultured for bacteria and fungi at frequent intervals.

Prophylactic antibiotics are not indicated. Patients should receive antibiotics when clinical infection is suspected. Prophylactic anticoagulation is provided during hospitalization.

Extensive and aggressive débridement of necrotic epidermis is not recommended in EN because the superficial necrosis is not an obstacle to re-epithelialization, and might even accelerate the proliferation of stem cells due to the inflammatory cytokines.

There is no standard policy on wound dressings and the use of antiseptics. It is a matter of experience for each center. Skillfulness on the part of specialized nurses, careful manipulation, and an aggressive protocol of prevention and treatment of pain are essential.

Eyes should be examined daily by an ophthalmologist. Artificial tears, antibiotic or antiseptic eyedrops, and vitamin A are often used every 2 hours in the acute phase, and mechanical disruption of early synechiae is indicated. The mouth should be rinsed several times a day with antiseptic or antifungal solution.

Specific Treatment

Because of the importance of immunologic and cytotoxic mechanisms, a large number of immunosuppressive and/or anti-inflammatory therapies have been tried to halt the progression of the disease. None has clearly proved its efficacy. The low prevalence of the disease makes randomized clinical trials hard to perform.

CORTICOSTEROIDS The use of systemic corticosteroids is still controversial. Some studies found that such therapy could prevent the extension of the disease when given during the early phase.[64,65] Other studies concluded that steroids did not stop the progression of the disease and were even associated with increased mortality and adverse effects, particularly sepsis.[66,67] Furthermore, many cases have been reported in patients already treated with corticosteroids,[68,69] which may increase the risk of EN.[20] Thus, systemic corticosteroids cannot be recommended as the mainstay treatment of EN.

INTRAVENOUS IMMUNOGLOBULIN The proposal to use high-dose intravenous immunoglobulin was based on the demonstration that Fas-mediated cell death can be abrogated by the anti-Fas activity present in commercial batches of normal human immunoglobulins.[42] Benefits have been claimed by several studies and case reports[70,71] but refuted by several others.[72–74] Thus, intravenous immunoglobulin cannot be considered the standard of care, but if it is used, a minimal precaution is to avoid preparations that are potentially nephrotoxic.

CYCLOSPORIN A Cyclosporin is a powerful immunosuppressive agent associated with biologic effects that may theoretically be useful in treatment of EN: activation of T helper 2 cytokines, inhibition of $CD8^+$ cytotoxic mechanisms, and anti-apoptotic effect through inhibition of Fas-L, nuclear factor κ B, and TNF-α. Several case reports and series suggest the efficacy of cyclosporin A.[75,76] However, prospective studies are needed to confirm its benefits and the absence of significant adverse effects.

PLASMAPHERESIS OR HEMODIALYSIS The rationale for using plasmapheresis or hemodialysis is to prompt the removal of the offending medication, its metabolites, or inflammatory mediators such as cytokines. Small series reported their efficacy and safety in treating EN.[77–79] Considering the absence of evidence and the risks associated with intravascular catheters, however, these treatments cannot be recommended.

ANTI–TUMOR NECROSIS FACTOR AGENTS
Anti-TNF monoclonal antibodies have been successfully used to treat a few patients. Because a prior randomized controlled trial of thalidomide, an anti-TNF agent, had to be interrupted due to significantly increased mortality,[44] extreme caution is suggested in the use of anti-TNF agents to treat EN.

PREVENTION

The most important issue is to evaluate drug causality. In vitro tests or patch tests to medications occasionally can be useful in the exploration of drug allergy. When used in EN patients, their sensitivity was too low.[80,81]

Careful inquiry into all exposures to medications in the few weeks preceding the onset of the reaction leads to the identification of a probable culprit drug in approximately 70 percent of cases. The most useful clinical criteria are duration of treatment before onset (typically 4 to 30 days), absence of prior intake, and use of a drug known for being associated with a high risk.

The few published cases of recurrent SJS or TEN were always due to inadvertent re-administration of the same or a very closely related medication. Epidemiology and in vitro studies suggest that the list of possible cross-reactive medications is rather narrow, based on close chemical similarities. As an example, there is no evidence that patients who experienced SJS or TEN in reaction to an anti-infectious sulfonamide are at increased risk for reaction to sulfonamide-related diuretics or antidiabetic medications. Only anti-infectious sulfonamides should be contraindicated in this situation.

A list of the suspected medication(s) and molecules of the same biochemical structure must be given to the patient on a personal "allergy card." It is also very useful to provide a list of drugs of common use that cannot be suspected. Because of recent indications of genetic susceptibilities to the development of EN, prescription of the offending agent to family members should also be avoided.

Finally, prolonged ophthalmologic follow-up should be recommended for patients with eye symptoms. Very promising treatments have now been developed for the ocular sequelae of EN, including special scleral lenses and grafting of stem cells from contralateral limbus or mouth mucosa.[82–84]

Restriction of sun exposure may help resolve the pigmentation changes.

CHAPTER 40

Cutaneous Reactions to Drugs

Neil H. Shear
Sandra R. Knowles
Lori Shapiro

Complications of drug therapy are a major cause of patient morbidity and account for a significant number of patient deaths.[1] Drug eruptions range from common nuisance eruptions to rare or life-threatening drug-induced diseases. Drug reactions may be solely limited to the skin, or they may be part of a systemic reaction, such as drug hypersensitivity syndrome or toxic epidermal necrolysis (TEN) (see Chap. 39).

Drug eruptions are distinct disease entities and must be approached as any other cutaneous disease. A precise diagnosis of the reaction pattern can help narrow possible causes, because different drugs are more commonly associated with different types of reactions.

EPIDEMIOLOGY

In the Boston Collaborative Drug Surveillance Program, the prevalence of cutaneous adverse drug reactions (ADRs) in hospitalized patients was 2.2 percent. Antibiotics were responsible for 7 percent of detected reactions.[2] The Harvard Medical Practice Study showed that approximately 14 percent of ADRs in hospital patients are cutaneous or allergic in nature.[3]

ETIOLOGY

In the evaluation of patients with a history of an ADR, it is important to obtain a detailed medication history, including use of over-the-counter preparations and herbal and naturopathic remedies. New drugs started within the preceding 6 weeks are potential causative agents for most cutaneous eruptions (exceptions include drug-induced lupus and drug-induced cutaneous pseudolymphoma), as are drugs that have been used intermittently.

PATHOGENESIS OF DRUG ERUPTIONS

Constitutional factors influencing the risk of cutaneous eruption include pharmacogenetic variation in drug-metabolizing enzymes and human leukocyte antigen (HLA) associations. Acetylator phenotype alters the risk of developing drug-induced lupus due to hydralazine, procainamide, and isoniazid. HLA-DR4 is significantly more common in individuals with hydralazine-related drug-

CUTANEOUS ADVERSE DRUG ERUPTIONS

AT A GLANCE

- Drug-induced cutaneous eruptions are common.
- They range from common nuisance rashes to rare life-threatening diseases.
- The spectrum of clinical manifestations includes exanthematous, urticarial, pustular, bullous, and erythema multiforme–like eruptions.
- These reactions may mimic other cutaneous diseases such as acne, porphyria, lichen planus, and lupus.
- Fixed drug eruptions are usually solitary dusky macules that recur at the same site.
- Drug reactions may be limited solely to skin or may be part of a severe systemic reaction, such as drug hypersensitivity syndrome or toxic epidermal necrolysis.

induced lupus than in those with idiopathic systemic lupus erythematosus.[4] HLA factors may also influence the risk of reactions to nevirapine, abacavir, carbamazepine, and allopurinol.[5–8]

Many drugs associated with severe idiosyncratic drug reactions are metabolized by the body to form reactive, or toxic, drug products.[9] These reactive products comprise only a small proportion of a drug's metabolites and are usually rapidly detoxified. However, patients with drug hypersensitivity syndrome, TEN, and Stevens-Johnson syndrome (SJS) resulting from treatment with sulfonamide antibiotics and the aromatic anticonvulsants (e.g., carbamazepine, phenytoin, phenobarbital, primidone, and oxcarbazepine) show greater sensitivity in in vitro assessments to the oxidative, reactive metabolites of these drugs than do control subjects.[10,11]

Acquired factors also alter an individual's risk of drug eruption. Active viral infection and concurrent use of other medications have been shown to alter the frequency of drug-associated eruptions. Drug–drug interactions may also alter the risk of cutaneous eruption. Valproic acid increases the risk of severe cutaneous adverse reactions to lamotrigine, another anticonvulsant.[12] The basis of these interactions and reactions is unknown, but they may represent a mixture of factors, including alterations in drug metabolism, drug detoxification, antioxidant defenses, and immune reactivity.

The course and outcome of drug-induced disease are also influenced by host factors. Older age may delay the onset of drug eruptions and has been associated with a higher mortality rate in some severe reactions. A higher mortality rate is also observed in patients with severe reactions who have underlying malignancy.[13] Reactivation of latent viral infection with human herpesvirus 6 also appears common in drug hypersensitivity syndrome and may be partially responsible for some of the clinical features and/or course of the disease.[14] Viral infections may act as, or generate the production of, danger signals that lead to damaging immune responses to drugs, rather than immune tolerance.

The pathogenesis of most drug eruptions is not understood, although the clinical features of most drug reactions are consistent with immune-mediated disease. The immune system may target the native drug, its metabolic products, altered self, or a combination of these factors.

MORPHOLOGIC APPROACH TO DRUG ERUPTIONS

The morphology of cutaneous eruptions may be exanthematous, urticarial, blistering, or pustular. The extent of the reaction is variable. For example, once the morphology of the reaction has been documented, a specific diagnosis [e.g., fixed drug eruption (FDE) or acute generalized exanthematous pustulosis (AGEP)] can be made. The reaction may also present as a syndrome (e.g., serum sickness–like reaction or hypersensitivity syndrome reaction). Fever is associated with the more serious cutaneous ADRs.

Exanthematous Eruptions

Exanthematous eruptions, known also as *morbilliform* or *maculopapular*, are the most common form of drug eruptions, accounting for approximately 95 percent of skin reactions[2] (Fig. 40-1). Simple exanthems are erythematous changes in the skin without evidence of blistering or pustulation. The eruption typically starts on the trunk and spreads peripherally in a symmetric fashion. Pruritus is almost always present. These eruptions usually occur within 1 week of initiation of therapy and resolve within 7 to 14 days. Resolution occurs with a change in color from bright red to a brownish red, which may be followed by scaling or desquamation. The differential diagnosis in these patients includes a viral exanthem, collagen vascular disease, and bacterial and rickettsial infections.

▲ **FIGURE 40-1** Exanthematous drug eruption: Ampicillin. Symmetrically arranged, brightly erythematous macules and papules, which are discrete in some areas and confluent in others on the trunk and discrete on the extremities.

Exanthematous eruptions can be caused by many drugs, including the penicillins, sulfonamides, nonnucleoside reverse transcriptase inhibitors (e.g., nevirapine), and anti-epileptic medications.[2] Studies have shown that drug-specific T cells play a major role in exanthematous, bullous, and pustular drug reactions.[15] In patients who have concomitant infectious mononucleosis, the risk of developing an exanthematous eruption while being treated with an aminopenicillin (e.g., ampicillin) increases from 3 percent to 7 percent to 60 percent to 100 percent.[16] A similar drug-viral interaction has been observed in 50 percent of patients infected with human immunodeficiency virus (HIV) who are exposed to sulfonamide antibiotics.[17]

An exanthematous eruption in conjunction with fever and internal organ involvement (e.g., liver, kidney, central nervous system) signifies a more serious reaction, known as the *hypersensitivity syndrome reaction* (HSR) (Table 40-1). It occurs in approximately 1 in 3000 exposures to agents such as aromatic anticonvulsants, lamotrigine, sulfonamide antibiotics, dapsone, nitrofurantoin, nevirapine, minocycline, and allopurinol (Fig. 40-2). HSR occurs most frequently on first exposure to the drug, with initial

TABLE 40-1
Clinical Features of Selected Cutaneous Reactions to Drugs

Clinical Presentation	Drug Eruption	Fever	Internal Organ Involvement	Arthralgia	Lymphadenopathy	Implicated Drugs
Hypersensitivity syndrome reaction	Exanthem, exfoliative dermatitis, pustular eruptions, SJS/TEN	Present	Present	Absent	Present	Aromatic anticonvulsants (e.g., phenytoin, phenobarbital, carbamazepine), sulfonamide antibiotics, dapsone, minocycline, allopurinol, lamotrigine
Serum sickness–like reaction	Urticaria, exanthem	Present	Absent	Present	Present	Cefaclor, cefprozil, bupropion, minocycline, infliximab, rituximab
Drug-induced lupus	Usually absent	Present/absent	Present/absent	Present	Absent	Procainamide, hydralazine, isoniazid, minocycline, acebutolol
Drug-induced subacute cutaneous lupus erythematosus	Papulosquamous or annular cutaneous lesion (often photosensitive)	Absent	Absent	Absent	Absent	Thiazide diuretics, calcium channel blockers, ACE inhibitors
Acute generalized exanthematous pustulosis	Non-follicular pustules on an edematous erythematous base	Present	Absent	Absent	Absent	β Blockers, macrolide antibiotics, calcium channel blockers

ACE = angiotensin-converting enzyme; SJS = Stevens-Johnson syndrome; TEN = toxic epidermal necrolysis.

symptoms starting 1 to 6 weeks after exposure. Fever and malaise are often the presenting symptoms. Atypical lymphocytosis with subsequent eosinophilia may occur during the initial phases of the reaction in some patients. Although most patients have an exanthematous eruption, more serious cutaneous manifestations may be evident (Fig. 40-3). Internal organ involvement can be asymptomatic. Some patients may become hypothyroid approximately 2 months after the first symptoms appear.[18]

The formation of toxic metabolites by the aromatic anticonvulsants may play a pivotal role in the development of HSR.[11] In most individuals, the chemically reactive metabolites that are produced are detoxified by epoxide hydroxylases. If detoxification is defective, however, one of the metabolites may act as a hapten and initiate an immune response, stimulate apoptosis, or cause cell necrosis directly. Approximately 70 percent to 75 percent of patients who develop anticonvulsant HSR in response to one aromatic anticonvulsant show cross-reactivity to the other aromatic anticonvulsants. In addition, in vitro testing shows that there is a familial occurrence of HSR induced by anticonvulsants.[11] Thus, counseling of family members and disclosure of risk is essential.

Sulfonamide antibiotics are also metabolized to toxic metabolites, namely, hydroxylamines and nitroso compounds. In most people, the metabolite is detoxified. However, HSRs may occur in patients who are unable to detoxify this metabolite. Because siblings and other first-degree relatives are at an increased risk (perhaps as high as 1 in 4) of developing a similar adverse reaction, counseling of family members is essential.

Other aromatic amines, such as procainamide, dapsone, and acebutolol, are also metabolized to chemically reactive compounds. It is recommended that patients who develop symptoms compatible with a sulfonamide HSR avoid these aromatic amines, because the potential exists for cross-reactivity. However, cross-reactivity should not occur between sulfonamides and drugs that are not aromatic amines (e.g., sulfonylureas, thiazide diuretics, furosemide, and acetazolamide).[19]

Allopurinol is associated with the development of serious drug reactions, including HSR. In a patient who developed HSR with hepatitis, reactivation of human herpesvirus 6 occurred.[20] Allo-

▲ **FIGURE 40-2** Drug hypersensitivity syndrome: Phenytoin. Symmetric, bright red, exanthematous eruption, confluent in some sites; the patient had associated lymphadenopathy.

▲ **FIGURE 40-3** Hypersensitivity syndrome reaction, characterized by fever, a pustular eruption, and hepatitis, in a 23-year-old man after 18 days of treatment with minocycline.

purinol-induced adverse reactions, including HSR, SJS, and TEN, have been strongly associated with a genetic predisposition in Han Chinese; presence of the HLA-B*5801 allele was found to be an important genetic risk factor.[5]

Urticarial Eruptions

Urticaria is characterized by pruritic red wheals of various sizes. Individual lesions generally last for less than 24 hours, although new lesions can commonly develop. When deep dermal and subcutaneous tissues are also swollen, the reaction is known as *angioedema*. Angioedema is frequently unilateral and non-pruritic and lasts for 1 to 2 hours, although it may persist for 2 to 5 days.[21]

Urticaria and angioedema, when associated with drug use, are usually indicative of an immunoglobulin E (IgE)–mediated immediate hypersensitivity reaction. This mechanism is typified by immediate reactions to penicillin and other antibiotics (see Chap. 37). Signs and symptoms of IgE-mediated allergic reactions typically include pruritus, urticaria, cutaneous flushing, angioedema, nausea, vomiting, diarrhea, abdominal pain, nasal congestion, rhinorrhea, laryngeal edema, and bronchospasm or hypotension or both.

Serum sickness–like reactions (see Table 40-1) are defined by the presence of fever, rash (usually urticarial), and arthralgias 1 to 3 weeks after initiation of drug therapy. Lymphadenopathy and eosinophilia may also be present; however, in contrast to true serum sickness, immune complexes, hypocomplementemia, vasculitis, and renal lesions are absent.

Cefaclor is associated with an increased relative risk of serum sickness–like reactions. The overall incidence of cefaclor-induced serum sickness–like reactions has been estimated to be 0.024 percent to 0.2 percent per course of cefaclor prescribed. In genetically susceptible hosts, a reactive metabolite is generated during the metabolism of cefaclor that may bind with tissue proteins and elicit an inflammatory response manifesting as a serum sickness–like reaction.[24]

Other drugs that have been implicated in serum sickness–like reactions are cefprozil, bupropion, minocycline, and rituximab[25] as well as infliximab.[26] The incidence of serum sickness–like reactions caused by these drugs is unknown.

Pustular Eruptions

Acneiform eruptions are associated with the use of iodides, bromides, adrenocorticotropic hormone, glucocorticoids, isoniazid, androgens, lithium, actinomycin D, and phenytoin. Drug-induced acne may appear in atypical areas, such as on the arms and legs, and is most often monomorphous. Comedones are usually absent. The fact that acneiform eruptions do not affect prepubertal children indicates that previous hormonal priming is a necessary prerequisite. In cases in which the offending agent cannot be discontinued, topical tretinoin may be useful.[27]

AGEP is an acute febrile eruption that is often associated with leukocytosis[28] (Fig. 40-4 and Table 40-1). After initiation of the implicated drug, 1 to 3 weeks may elapse before skin lesions appear. The lesions often start on the face or main skin creases. Generalized desquamation occurs approximately 2 weeks later. The estimated incidence of AGEP is approximately 1 to 5 cases per million per year.[29] AGEP is most commonly associated with β-lactam and macrolide antibiotics and calcium channel blockers. Differential diagnosis includes pustular psoriasis, HSR with pustulation, sub-corneal pustular dermatosis (Sneddon-Wilkinson disease), pustular vasculitis, or TEN, especially in severe cases of AGEP. The typical histopathologic analysis of AGEP lesions shows spongiform sub-corneal and/or intraepidermal pustules, an often marked edema of the papillary dermis, and perivascular infiltrates with neutrophils and exocytosis of some eosinophils.[29] Discontinuance of therapy is usually the extent of treatment necessary in most patients, although some patients may require the use of corticosteroids. Positive results on patch tests and lymphocyte transformation tests suggest involvement of T cells in AGEP.[30]

Bullous Eruptions (Table 40-2)
